Limited data are available on the acute pharmacological therapy of ATs. Vagal maneuvers only rarely terminate AT, and the response to adenosine is variable. IV beta-blockers, diltiazem, or verapamil have modest efficacy (30% to 50%) in terminating the focal AT or slowing the ventricular rate. Class I or III antiarrhythmic drugs given orally or parenterally may be considered for refractory ATs. Adenosine does not slow or terminate microreentrant AT. In contrast, triggered activity ATs typically terminate abruptly in response to adenosine and do not spontaneously reinitiate. Automatic ATs are either slowed transiently by adenosine before gradual resumption of the AT rate or suppressed transiently before spontaneous reinitiation.⁹ Microreentrant ATs can terminate in response to carotid sinus massage and vagal maneuvers. Triggered activity ATs can also terminate in response to carotid sinus massage, vagal maneuvers, verapamil, beta-blockers, and sodium channel blockers. During automatic AT, carotid sinus massage can cause AV block and can slow the atrial rate; however, these interventions generally do not terminate the AT. Only beta-blockers have been useful in termination of paroxysmal (but not incessant) automatic AT. Termination of automatic AT is usually preceded by a cool-down phenomenon of the AT rate.^{1,9}

In general, most stable patients with SVT respond to pharmacological therapy, with conversion success rates of 80% to 98%. Electrical cardioversion is also recommended for patients with hemodynamically stable SVT when pharmacological therapy is ineffective or contraindicated. However, electrical cardioversion is inappropriate if the SVT is terminating and reinitiating spontaneously.¹

In patients with manifest preexcitation during normal sinus rhythm (NSR) presenting with AVRT (orthodromic or antidromic), vagal maneuvers are the first-line intervention for tachycardia termination. For persistent SVT, adenosine is recommended. Importantly, adenosine should be used with caution because it can induce AF with a rapid ventricular rate in the presence of an anterogradely conducting BT. This is unusual and should not be viewed as a contraindication to adenosine use, but one should be prepared for emergency cardioversion before administering adenosine to SVT patients. For refractory AVRT, IV diltiazem, verapamil, or beta-blockers may be considered to block conduction in the AVN, which represents the retrograde or anterograde limb in the AVRT circuit. AVN blocking drugs, however, are ineffective

in patients with an antidromic AVRT that utilizes two separate BTs for anterograde and retrograde conduction. Drug treatment directed at the BT (ibutilide, procainamide, flecainide) may be considered. When drug therapy fails or hemodynamic instability is present, electrical cardioversion should be considered.¹

Chronic Management

Most paroxysmal SVTs are generally benign and do not influence survival; therefore the primary indication for treatment is to alleviate symptoms and improve quality of life. The threshold for initiation of therapy and the decision to treat SVT with oral pharmacological therapy or catheter ablation depends on the frequency and duration of the arrhythmia, severity of symptoms, presence of concomitant structural heart disease, and patient preference (Fig. 20.4). The threshold for

treatment is also influenced by whether the patient is a competitive athlete, a woman considering pregnancy, or someone with a high-risk occupation (e.g., pilots, bus drivers).¹

Catheter Ablation

Given the high success rates and the low complication rate, catheter ablation is the treatment of choice in patients who desire to avoid or are unresponsive or intolerant to drug therapy.¹ Catheter ablation is also recommended for incessant SVT, even in asymptomatic patients, especially when tachycardia-induced cardiomyopathy has developed.

Pharmacological Therapy

For patients requiring therapy who are reluctant to undergo catheter ablation, drug therapy remains a viable alternative. Calcium channel blockers and beta-blockers may be considered in patients without ventricular preexcitation during NSR. Verapamil, propranolol, and digoxin likely have equivalent efficacy, and can improve symptoms in 60% to 80% of patients. However, verapamil, diltiazem, and beta-blockers are generally preferred to digoxin. The effective dose of digoxin is usually higher than that commonly used in clinical practice today. Given the risk of toxicity, digoxin should be reserved for patients who cannot take beta-blockers, diltiazem, or verapamil or a class IC agent (flecainide or propafenone) and must be used with caution in the presence of renal dysfunction.¹

In patients who do not respond, classes IC and III drugs may be considered. Flecainide and propafenone affect the AVN and BTs, reduce SVT frequency in 86% to 93% of patients, and may be considered in patients without ischemic or structural heart disease. Sotalol, dofetilide, and amiodarone are second-line agents. The probability of remaining free of SVT after 6 months of treatment is about 50% for dofetilide and 54% for propafenone, compared to 6% for placebo. However, the potential benefit should be balanced by the potential risks of proarrhythmia and toxicity. Because sympathetic stimulation can antagonize the effects of many antiarrhythmic agents, concomitant therapy with a beta-blocker can improve efficacy.¹

Pharmacological management of ATs has not been well evaluated in controlled clinical trials. Depending on the mechanism responsible for the arrhythmia, beta-blockers or calcium channel blockers may be considered as first-line drug therapy. Class IC agents in combination with an AVN blocking agent, or class III agents (sotalol and amiodarone) are second-line therapy (see Chapter 11).

Patients with SVT should be educated on how to perform vagal maneuvers. Those with well-tolerated episodes of paroxysmal SVT that always terminate spontaneously or with vagal maneuvers do not require chronic prophylactic therapy. Selected patients may be treated only for acute episodes. Outpatients may use a single oral dose of verapamil, diltiazem, or propranolol to acutely terminate an episode of SVT. This so-called pill in the pocket is a reasonable treatment option for patients who have SVT episodes that are sustained but infrequent enough that daily preventive therapy is not desired. This approach necessitates the use of a drug that has a short onset of action (i.e., immediate-release preparations); crushing the drug tablet can potentially facilitate absorption. Candidate patients should be free of significant LV dysfunction, sinus bradycardia, and preexcitation.¹

For patients with ventricular preexcitation, antiarrhythmic drugs to block BT conduction are considered. Class IC agents (in patients without structural heart disease or ischemic heart disease), and class III drugs, such as sotalol and dofetilide, may be considered. Oral amiodarone is a last resort therapy, given the associated risks of long-term therapy. In general, antiarrhythmic drug therapy can offer symptomatic improvement in up to 90% of patients, although complete disappearance of symptoms is observed in only 30%. Chronic oral beta-blockers,

Fig. 20.4 Differential Diagnosis of Narrow QRS Tachycardia. Patients with junctional tachycardia may mimic the pattern of slow-fast atrioventricular nodal reentrant tachycardia (AVNRT) and may show atrioventricular (AV) dissociation and/or marked irregularity in the junctional rate. ^aRP refers to the interval from the onset of surface QRS to the onset of visible P wave (note that the 90-millisecond interval is defined from the surface electrocardiogram, as opposed to the 70-millisecond ventriculoatrial interval that is used for intracardiac diagnosis). AVRT, Atrioventricular reentrant tachycardia; MAT, multifocal atrial tachycardia; PJRT, permanent junctional reciprocating tachycardia. (From Page RL, Joglar JA, Caldwell MA, et al. 2015 ACC/AHA/HRS guideline for the management of adult patients with supraventricular tachycardia: a report of the American College of Cardiology/American Heart Association Task Force on Clinical Practice Guidelines and the Heart Rhythm Society. *J Am Coll Cardiol*. 2016;67:e27–e115.)

verapamil, and diltiazem may be used for the treatment of patients with WPW syndrome, particularly if their BT has been demonstrated to be incapable of rapid anterograde conduction. However, these agents must be used with caution and after a discussion with the patient concerning the potential risk of rapid conduction over the BT if AF develops. Digoxin, on the other hand, should be avoided because it can shorten the refractory period of the BT and, hence, is potentially harmful in patients with manifest BTs.¹

ELECTROCARDIOGRAPHIC FEATURES

Regularity of the Tachycardia

Most SVTs are associated with a regular ventricular rate. If the rhythm is irregular, the ECG should be scrutinized for discrete atrial activity and for any evidence of a pattern in the irregularity (e.g., grouped beating typical of Wenckebach periodicity). If the rhythm is irregularly irregular (i.e., no pattern can be detected), the mechanism of the arrhythmia is multifocal AT, AFL with variable AV conduction, or AF (Fig. 20.5). Multifocal AT is an irregularly irregular atrial rhythm characterized by more than three different P wave morphologies, with the P waves separated by isoelectric intervals and associated with varying P-P, R-R, and PR intervals (see Fig. 11.2). On the other hand, AF is characterized by rapid and irregular atrial fibrillatory activity and, in the presence of normal AVN conduction, by an irregularly irregular ventricular response. P waves cannot be detected in AF, although coarse fibrillatory waves and prominent U waves can sometimes give the appearance of P waves. At times, the fibrillatory activity is so fine as to

be undetectable. If the patient's rhythm is regular or has a clearly discernible pattern, the ECG should next be assessed for P waves (atrial activity).¹

Atrial Activity

The P waves may be easily discernible; however, frequently, comparison with a normal baseline ECG is needed and can reveal a slight alteration in the QRS, ST segment, or T waves, suggesting the presence of the P wave. If the P waves cannot be clearly identified, carotid sinus massage or the administration of IV adenosine may help clarify the diagnosis. These maneuvers may also terminate the SVT.¹

Atrial Rate

An atrial rate greater than 250 beats/min is usually caused by AFL. However, overlap exists, and AT and AVRT can occasionally be faster than 250 beats/min, especially in youngsters. Although AVRT tends to be faster than AVNRT and AT, significant overlap exists and this criterion does not usually help in distinguishing among different SVTs.¹⁰

P Wave Morphology

P waves indicate the result of atrial activation and may be broadly classified as concentric or eccentric. A P wave morphology identical to a sinus P wave suggests sinus tachycardia, inappropriate sinus tachycardia, sinoatrial nodal reentrant tachycardia, or AT arising close to the region of the sinus node. A nonsinus P wave morphology can be observed during AVNRT (P wave is concentric due to midline retrograde activation; see Fig. 17.8), AVRT (P wave can be eccentric or concentric due

Fig. 20.5 Supraventricular Tachycardia. Surface electrocardiogram of a narrow complex supraventricular tachycardia with a long RP interval. The tachycardia terminates spontaneously and sinus rhythm ensues (at left).

to retrograde conduction over the BT; **see Fig. 18.12**), AT (P wave can be eccentric or concentric), and AFL (lack of distinct isoelectric baselines between atrial deflections is suggestive of AFL, but can also be seen occasionally in AT; **see Fig. 12.6**). The P waves may not be discernible on the ECG, which suggests typical AVNRT or, less commonly, AVRT (especially in the presence of bundle branch block [BBB] contralateral to the BT).¹ It is best to characterize P waves during SVT morphologically at the outset (concentric, eccentric) rather than attaching a mode of activation (i.e., retrogradely activated); for example, upright P waves in the inferior leads, though usually due to AT, may nonetheless be retrogradely conducted over an anterior BT, and although inverted P waves in inferior leads are often retrogradely conducted, focal AT from the coronary sinus ostium (CS os) can have an identical appearance. Thus not all retrograde P waves are inverted in the inferior leads, and not all inverted P waves in inferior leads are retrogradely conducted.

Characterization of P/QRS Relationship

RP-PR Interval Ratio

In general, SVTs are classified according to the RP interval as “short RP” (RP < PR) or “long RP” (RP > PR) tachycardias (**see Fig. 20.5**). The RP-to-PR ratio is not diagnostic of any tachycardia type but does help in creating a differential diagnosis of the possible tachycardia types. During short RP SVTs, the ECG will show P waves inscribed within the ST-T wave with an RP interval that is less than half the tachycardia R-R interval. Such SVTs include typical AVNRT (most common), orthodromic AVRT, AT with prolonged AV conduction, and slow-slow AVNRT. A very short RP interval (less than 90 milliseconds) is consistent with typical AVNRT and excludes AVRT. In typical AVNRT, the P wave is not usually visible because of the simultaneous atrial and ventricular activation. The P wave may distort the initial portion of the QRS (mimicking a q wave in inferior leads) or lie just within the QRS (inapparent) or distort the terminal portion of the QRS (mimicking an s wave in inferior leads or r' in lead V₁; **see Fig. 17.8**).

Long RP SVTs (**see Fig. 20.1**) include AT (most common), atypical (fast-slow) AVNRT, and AVRT using a slowly conducting AV BT (e.g., PJRT). If the PR interval during the SVT is shorter than that during NSR, AT and AVRT are very unlikely, and atypical AVNRT, which is associated with an apparent shortening of the PR interval, is the likely diagnosis. ATs originating close to the AV junction are also a possibility.

The PR intervals during AT are appropriate for the AT rate and are usually longer than those during NSR. The faster the AT rate, the longer the PR interval. Thus the PR interval can be shorter than, longer than, or equal to the RP interval. The PR interval may also be equal to the RR, and the P wave may fall inside the preceding QRS, thus mimicking typical AVNRT.

Slow-slow AVNRT can be associated with RP intervals and P wave morphology similar to that during orthodromic AVRT using a posteroseptal AV BT. However, although both SVTs have the earliest atrial activation in the posteroseptal region, conduction time from that site to the HB region is significantly longer in AVNRT than in orthodromic AVRT. The results are a significantly longer RP interval in lead V₁ and a significantly larger difference in the RP interval between lead V₁ and inferior leads during AVNRT. Therefore Δ RP interval (V₁–III) of more than 20 milliseconds suggests slow-slow AVNRT (sensitivity, 71%; specificity, 87%).¹¹

When the P wave is not visible, typical AVNRT is the most likely diagnosis, but AT with a long PR interval (P wave is obscured within the QRS) and junctional tachycardia are also possible.

Atrial-Ventricular Relationship

SVTs with an A/V ratio of 1 (i.e., equal number of atrial and ventricular events) include AVNRT, AVRT, and AT. On the other hand, an A/V ratio

during the SVT of greater than 1 indicates the presence of AV block and that the ventricles are not required for the SVT circuit, thereby excluding AVRT and suggesting either AT (most common; **see Fig. 11.7**) or AVNRT (rare; **see Fig. 17.9**). AV dissociation (even complete AV block) can be observed during AT (most common) or AVNRT (rare).¹ VA block during SVT is rare, but can occur in automatic junctional tachycardia with retrograde VA block and orthodromic AVRT using a nodofascicular or nodoventricular BT for retrograde conduction. Intra-Hisian reentry is another potential mechanism, but it is a theoretical entity whose clinical occurrence has not convincingly been demonstrated.^{12–14}

QRS Morphology

The QRS morphology during SVT is usually the same as in NSR. However, SVT can present as a wide complex tachycardia (QRS duration greater than 120 milliseconds) due to rate-related aberrant conduction, pre-existing intraventricular conduction disturbance (IVCD), or ventricular preexcitation over an anterogradely conducting BT.¹

Functional aberration during SVT is much more common in orthodromic AVRT than AVNRT or AT (90% of SVTs with sustained left bundle branch block [LBBB] are orthodromic AVRTs). Thus the mere presence of LBBB aberrancy during SVT is suggestive of orthodromic AVRT, but can still occur in other types of SVTs.¹⁵

Preexcited SVTs include antidromic AVRT, whereby the BT is an essential part of the tachycardia circuit, and AVNRT and AT with ventricular preexcitation over a bystander BT.

QRS alternans during fast SVTs is most commonly seen in orthodromic AVRT but can also be seen with other types of SVTs as well. However, when QRS alternans occurs during a relatively slow SVT, the diagnosis is almost always orthodromic AVRT.

Effects of Interventions

Carotid sinus massage or adenosine can result in one of four possible effects: (1) temporary decrease in the atrial rate in patients with sinus tachycardia or automatic AT; (2) slowing of AVN conduction and AVN block, which can unmask atrial electrical activity—that is, reveal P waves or flutter waves in patients with AT or AFL by decreasing the number of QRS complexes that obscure the electrical baseline; (3) terminating the SVT; or (4) no effect is observed.

Carotid sinus massage or adenosine can terminate the SVT, especially if the rhythm is AVNRT or AVRT by transient slowing and block of AVN conduction and interrupting the reentry circuit; termination of focal AT can occur but is much less common. A continuous ECG tracing should be recorded during these maneuvers because the response can aid in the diagnosis and changes can be subtle (rate slowing or transient AV block). Termination of the tachycardia with a P wave after the last QRS complex is most common in AVRT and typical AVNRT and is rarely seen with AT (**see Fig. 18.36**), whereas termination of the tachycardia with a QRS complex is more common with AT, atypical AVNRT, and PJRT (**see eFig. 18.5**). If the tachycardia continues despite development of AV block, the rhythm is almost certainly AT or AFL; AVRT is excluded and AVNRT is very unlikely.¹

ELECTROPHYSIOLOGICAL TESTING

Discussion in this section will focus on differential diagnosis of narrow QRS complex paroxysmal SVTs, including focal AT, orthodromic AVRT, and AVNRT. The goals of EP testing in these patients include the following: (1) evaluation of baseline cardiac electrophysiology; (2) induction of SVT; (3) evaluation of the mode of initiation of the SVT; (4) definition of atrial activation sequence during the SVT; (5) definition of the A/V relationship at the onset and during the SVT; (6) evaluation of the effect of BBB on the tachycardia cycle length (TCL) and VA

interval; (7) evaluation of the SVT circuit and requirement for the atria, HB, or ventricles in the initiation and maintenance of the SVT; (8) evaluation of the SVT response to programmed atrial and ventricular stimulation; and (9) evaluation of the effects of drugs and physiological maneuvers on the SVT.

Baseline Observations During Sinus Rhythm

The presence of preexcitation during NSR suggests AVRT as the likely diagnosis; however, it does not exclude other causes of SVT during which the BT is an innocent bystander. Furthermore, the absence of preexcitation during NSR does not exclude the presence of an AV BT or the diagnosis of AVRT.

Programmed Electrical Stimulation During Sinus Rhythm

The programmed stimulation protocol typically includes: (1) ventricular burst pacing from the right ventricular (RV) apex (down to the pacing cycle length [PCL] at which VA block develops); (2) single and double ventricular extrastimulus (VES; down to the ventricular effective refractory period [ERP]) at multiple PCLs (600 to 400 milliseconds) from the RV apex; (3) atrial burst pacing from the high RA and CS (down to the PCL at which 2:1 atrial capture occurs); (4) single and double atrial extrastimulations (AESs) (down to the atrial ERP) at multiple PCLs (600 to 400 milliseconds) from the high RA and CS; and (5) administration of isoproterenol infusion (0.5 to 4 $\mu\text{g}/\text{min}$) or epinephrine (0.05 to 0.2 $\mu\text{g}/\text{kg}$ per minute) infusion as needed to facilitate tachycardia induction or sustenance.

Programmed Atrial Stimulation During Sinus Rhythm

Dual AVN physiology. Although the demonstration of dual AVN physiology during programmed atrial stimulation favors AVNRT as the mechanism of SVT (positive predictive value greater than 80%), it is not an uncommon finding in patients with other types of SVTs. Furthermore, failure to demonstrate dual AVN physiology does not exclude the possibility of AVNRT, and might be related to similar fast and slow AVN pathway ERPs. Then, dissociation of refractoriness of the fast and slow AVN pathways can be necessary (see Chapter 17).

Ventricular preexcitation. Atrial stimulation can help unmask preexcitation if it is not manifest during NSR because of fast AVN conduction, slow BT conduction, or distant (left lateral) BT location. AES and atrial pacing from any atrial site result in slowing of AVN conduction and, consequently, unmask or increase the degree of preexcitation over the AV BT (see Fig. 18.23). Moreover, atrial stimulation close to the BT insertion site results in maximal preexcitation and the shortest P-delta interval because of the ability to advance the activation of the AV BT down to its ERP from pacing at this site caused by the lack of intervening atrial tissue, whose conduction time and refractoriness can otherwise limit the ability of the AES to stimulate the BT prematurely (see Fig. 18.24).

The failure of atrial stimulation to increase the amount of preexcitation can be caused by: (1) markedly enhanced AVN conduction; (2) the presence of another AV BT; (3) pacing-induced block in the AV BT because of a long ERP of the BT (longer than that of the AVN); (4) total preexcitation already present at the basal state caused by prolonged or absent AVN-His-Purkinje system (HPS) conduction; (5) decremental conduction in the BT; or (6) the presence of a fasciculoventricular BT rather than an AV BT.

Extra atrial beats. AES and atrial pacing can trigger extra atrial beats or echo beats. Those beats can be caused by different mechanisms.

Intraatrial reentrant beats. These beats usually occur at short coupling intervals, and can originate anywhere in the atrium. Therefore

the atrial activation sequence depends on the site of origin of the beat. The more premature the AES, the more likely it will induce nonspecific intraatrial reentrant beats and short runs of irregular AT or AF.

Catheter-induced atrial beats. These beats usually have the earliest activation site recorded at that particular catheter tip and have the same atrial activation sequence as the atrial impulse produced by pacing from that catheter. Portions of the catheter proximal to the tip usually do not elicit mechanically induced ectopic impulses.

AVN echo beats. AVN echoes occur in the presence of anterograde dual AVN physiology (see Fig. 4.23). Such beats require anterograde block of the atrial stimulus in the fast AVN pathway, anterograde conduction down the slow pathway, and then retrograde conduction up the fast pathway. AVN echo beats have several features: they appear reproducibly after a critical A_2 - H_2 interval; the atrial activation sequence is consistent with retrograde conduction over the fast pathway, with the earliest atrial activation site in the HB; and the VA interval is very short, but it can be longer if the atrial stimulus causes anterograde concealment (and not just block) in the fast pathway.

AV echo beats. AV echo beats occur secondary to anterograde conduction of the atrial stimulus over the AVN-HPS and retrograde conduction over a BT (concealed or bidirectional BT). If preexcitation is manifest during atrial stimulation, the last atrial impulse inducing the echo beat will demonstrate loss of preexcitation because of anterograde block in the BT, and the atrial activation sequence and P wave morphology of the echo beat will depend on the location of the BT mediating VA conduction (see Fig. 3.9). These beats have a relatively short VA interval (QRS onset to earliest atrial activation) but always longer than 70 milliseconds. Moreover, the VA interval of the AV echo beat remains constant, regardless of the varying coupling interval of the AES triggering the echo beat ("VA linking"). Of note, AV echo beats also can occur secondary to anterograde conduction of the atrial stimulus over a manifest BT and retrograde conduction over the AVN, in which setting the last paced beat is associated with anterograde block in the AVN and fully preexcited QRS complex.

Programmed Ventricular Stimulation During Sinus Rhythm

Retrograde VA conduction. The absence of VA conduction (at ventricular PCLs greater than 600 milliseconds and despite isoproterenol administration) or the presence of decremental VA conduction makes the presence of a retrogradely conducting BT unlikely.

The normal AVN response to rate-incremental ventricular pacing or progressively premature single VESs is a gradual delay of VA conduction (manifest as gradual prolongation of the VA and His bundle-atrial [HA] intervals) as the PCL or VES coupling interval decreases. Non-decremental VA conduction suggests BT conduction, although fast pathway conduction in patients with AVNRT often shows minimal decrement. Nonetheless, some BTs with retrograde decremental conduction properties can also exhibit prolongation of conduction time and VA interval with ventricular pacing or VES. In addition, at short ventricular PCLs or VES coupling intervals, intramyocardial conduction delay can occur, resulting in prolongation in the VA interval; however, the local VA interval at the BT location remains unchanged. Furthermore, short ventricular PCLs or VES coupling intervals can encroach on the BT refractoriness, causing some decremental conduction, with a consequent increase in the surface VA interval and the local VA interval.

During the delivery of progressively premature single VESs, an abrupt increase in the VA conduction interval is often observed. This may be due to a variety of reasons including: (1) retrograde block in the AVN fast pathway and subsequent VA conduction over the slow pathway; (2) retrograde block in the right bundle branch (RB) and subsequent retrograde conduction over the left bundle branch (LB);

or (3) retrograde block in the BT and subsequent VA conduction only over the AVN.

Retrograde atrial activation sequence. VA conduction over the AVN produces a classic concentric atrial activation sequence starting in the anterosseptal or posteroseptal region of the RA because of retrograde conduction over either the fast or the slow AVN pathways, respectively. The duration of atrial activation is short because both atria are roughly simultaneously activated. Thus, if a normal P wave lasts 80 milliseconds (about 40 milliseconds for each atrium), a concentrically activated P wave (and total atrial activation time) approximates 40 milliseconds.

Eccentric retrograde atrial activation (i.e., lateral left atrium or RA earlier than AV junction and opposite chamber) can also occur. In the presence of a retrogradely conducting AV BT (whether manifest or concealed), atrial activation can result from conduction over the BT, over the AVN, or a fusion of both (see Fig. 18.25). Conduction over the BT alone is the most common pattern at short PCLs or short VES coupling intervals. In this setting, the VA conduction time is fairly constant over a wide range of PCLs and VES coupling intervals (given the absence of intraventricular conduction abnormalities or additional BTs). On the other hand, retrograde conduction over both the BT and HPS-AVN is especially common when RV pacing is performed in the presence of a left-sided BT at long PCLs or long VES coupling intervals. This occurs because it is easier to engage the RB and conduct retrogradely through the AVN than it is to reach a distant left-sided BT. In this setting, the atrial activation pattern depends on the refractoriness and conduction times over both pathways and usually exhibits a variable degree of fusion. In addition, VA conduction can proceed over the HPS-AVN alone, resulting in a normal pattern of VA conduction, or can be absent because of block in both the HPS-AVN and BT, which is especially common with short PCLs and very early VES.

An eccentric atrial activation sequence in response to ventricular stimulation suggests the presence of an AV BT mediating VA conduction (see Fig. 18.25). However, a concentric retrograde atrial activation sequence does not exclude the presence of a septal or paraseptal BT, or a free-wall BT located far from the pacing site, allowing for preferential VA conduction over the AVN. In addition, AVN slow pathway conduction can be associated with an eccentric atrial activation sequence in the CS. Accurate analysis of the atrial activation sequence frequently requires the use of multielectrode catheters around the tricuspid annulus and deep in the CS.¹⁶

Retrograde dual AVN physiology. Demonstration of retrograde dual AVN physiology during programmed ventricular stimulation suggests AVNRT (occurring most commonly during atypical AVNRT), but it can also be observed with other SVTs. Importantly, failure to demonstrate retrograde dual AVN physiology in patients with AVNRT can be the result of similar fast and slow AVN pathway ERPs, in which setting dissociation of refractoriness of the fast and slow AVN pathways is required (see Chapter 17).

VA block at a ventricular PCL greater than 600 milliseconds or decremental VA conduction during ventricular pacing makes the presence of a retrogradely conducting BT unlikely, except for decrementally conducting BTs and the rare catecholamine-dependent BTs. In addition, development of VA block during ventricular pacing in response to adenosine suggests the absence of a BT.

VES during His bundle refractoriness. A VES delivered when the HB is refractory (i.e., when the His potential is already manifest or within 35 to 55 milliseconds before the time of the expected His potential) that results in atrial activation is diagnostic of the presence of a retrogradely conducting BT. Because the HPS-AVN is already refractory and cannot mediate VA conduction, retrograde atrial

activation from ventricular stimulation will necessarily be mediated by a BT.

Furthermore, an earlier VES that does conduct to the HB and results in an atrial activation that either precedes HB activation (see Fig. 18.27) or is associated with an apparent HA interval shorter than that during drive complexes indicates “atrial preexcitation” via an AV BT.

Importantly, if a VES delivered when the HB is refractory does not result in atrial activation, this does not necessarily exclude the presence of a retrogradely conducting AV BT, because such a VES can be associated with retrograde block in the BT itself (see Fig. 18.25). In addition, the lack of such a response does not exclude the presence of unidirectional (anterograde-only) AV BTs.

Differential-site RV pacing. Differential-site RV pacing can help exclude the presence of a retrogradely conducting septal AV BT. The response to differential-site RV pacing can be evaluated by comparing two variables between RV basal and RV apical pacing: the VA interval (i.e., the stimulus-to-atrial [S-A] interval) and atrial activation sequence (see Fig. 18.28).

VA interval. In the absence of a septal BT, the RV apex, although anatomically more distant from the atrium than the RV base, is nonetheless electrically closer because of its proximity to the entrance to the HPS (i.e., RB terminus). Therefore the VA interval is shorter during pacing from the RV apex than that during RV basal pacing. In contrast, in the presence of a septal BT, the RV base is closer than the RV apex to the BT ventricular insertion site. As a result, the VA interval is shorter during RV basal pacing compared to apical pacing. Therefore, when the VA interval during RV apical pacing is longer than that during RV basal pacing, a retrogradely conducting AV BT is diagnosed (see Fig. 18.28), and when the VA interval during RV apical pacing is shorter than that during RV basal pacing, a retrogradely conducting septal BT is excluded. Importantly, while this maneuver suggests AVN conduction, it may not exclude the presence of a free wall or a slowly conducting BT. It is important to ensure that the basal pacing site captures neither the HB or the RB, nor the atrium, which would yield spurious results.

Atrial activation sequence. In the absence of a retrogradely conducting BT, the atrial activation sequence remains identical regardless of the RV pacing site because retrograde VA conduction propagates only over the AVN in both settings. In contrast, in the presence of a septal BT, atrial activation results from VA conduction over the BT during pacing at the RV base (because of its immediate proximity to the BT), and over the AVN, the BT, or a fusion of both during pacing at the RV apex. Therefore a change in retrograde atrial activation sequence in response to differential RV pacing (RV base vs. RV apex) indicates the presence of an AV BT, but a constant atrial activation sequence is not helpful in excluding the presence of a BT, because AVN-HPS conduction delay can allow retrograde VA conduction to occur over the BT during RV pacing from both the apex and the base.

Limitations. This maneuver does not exclude the presence of a distant right or left free-wall BT because the site of pacing is far from the BT; as a consequence, pacing from the RV apex or RV base may result in preferential VA conduction exclusively over the AVN and a constant atrial activation sequence. This can be avoided by moving the basal pacing site closer to the putative BT location along the tricuspid or mitral annulus.¹⁷

In addition, this maneuver does not exclude the presence of a slowly conducting BT. The VA interval criterion identifies the actual route of VA conduction and therefore the fastest path of this conduction; hence, a slowly conducting BT would be missed in the presence of fast VA conduction over the HPS-AVN.

The occurrence of right bundle branch block (RBBB) (but not LBBB) also can alter the significance of the VA interval criterion, especially

when VA conduction propagates over the HPS-AVN. In the presence of retrograde RBBB, VA conduction occurs over the LB-HB; therefore the VA interval depends on the distance between the pacing site and the LB rather than the RB, and access of the paced wavefront to the LB can be faster for RV basilar or septal pacing compared with pacing from the RV apex (Fig. 20.6).

Of note, the exact entrance to the HPS (i.e., the terminus of the RB) is difficult to identify; the entrance site can be located in the mid-septum and not at the RV apex. In such situations, both the RV base and apex can be equidistant from the entrance to the HPS so that pacing at either location will produce a constant VA interval during retrograde conduction over the AVN. Therefore patient-to-patient variability with regard to the distance of the pacing catheter to the RB terminus can potentially introduce conflicting results. This problem is largely resolved by first pacing from the HB region (while avoiding HB capture) and then moving the pacing catheter in a stepwise fashion along the septum toward the RV apex. Pacing from sequential sites in this path brings the catheter closer to the RB terminus (entrance of the

HPS), as reflected by shortening of the VA interval for AVN conduction, but not for BT conduction. As the pacing catheter is moved farther apically, the pacing sites become less useful diagnostically because the relative distance from the RB terminus to the insertion of the BT becomes less clear.¹⁷

Retrograde RBBB during VES. Retrograde RBBB occurs frequently during VES testing, and it can be diagnosed by observing the retrograde His potential during the drive train and its abrupt delay following the VES. Often, however, it is difficult to visualize the retrograde His potential during the pacing train; nevertheless, the sudden appearance of an easily distinguished retrograde His potential, separate from the ventricular electrogram following the VES, can be sufficient to recognize retrograde RBBB.

Prolongation of the VH interval is observed on development of retrograde RBBB because conduction must traverse the interventricular septum (which requires approximately 60 to 70 milliseconds in normal hearts), conduct retrogradely via the LB, and ascend to reach the HB. Although an increase in the VH interval necessarily occurs with retrograde

Fig. 20.6 Differential-Site Right Ventricular (RV) Pacing During Sinus Rhythm in the Presence of Right Bundle Branch Block (RBBB). Comparison between RV basal versus apical pacing during normal sinus rhythm (NSR, bottom panel) in a patient with typical atrioventricular nodal reentrant tachycardia (AVNRT) and RBBB (top panel) but no bypass tracts (BTs). RBBB is also observed during NSR (beginning of bottom panel). In the absence of a retrogradely conducting BT, pacing from the RV apex is expected to result in a shorter ventriculoatrial (VA) interval than pacing from the RV base. However, in this case, the presence of RBBB produces misleading results because retrograde VA conduction occurs over the left bundle branch–His bundle, and the VA interval depends on the distance between the pacing site to the left bundle branch, as opposed to the right bundle branch. CS_{dist}, Distal coronary sinus; CS_{prox}, proximal coronary sinus; HRA, high right atrium; RVA, right ventricular apex.

RBBB, whether a similar increase occurs in the VA interval depends on the nature of VA conduction (over the AVN vs. BT).

Measurement of the effect of the development of retrograde RBBB during VES on the retrograde VH and VA intervals can help in distinguishing between retrograde AVN and BT conduction. In the absence of a BT, the AVN can be activated in a retrograde fashion only after retrograde activation of the HB; as a consequence, VA activation will necessarily be delayed with retrograde RBBB, and the increase in the VA interval will be similar to the increase in the VH interval. On the other hand, when retrograde conduction is via a BT, there will be no expected increase in the VA interval when retrograde RBBB is induced. Thus the increase in the VA interval is minimal and always less than the increase in the VH interval.¹⁸

Extra ventricular beats. Ventricular stimulation can trigger extra ventricular beats or echo beats. These beats can be caused by different mechanisms.

Bundle branch reentrant beats. During RV stimulation at close coupling intervals, progressive retrograde conduction delay and block occur in the RB, so that retrograde HB activation occurs via the LB. At this point, the His potential usually follows the local ventricular electrogram. Further decrease in the VES coupling interval produces an increase in retrograde HPS conduction delay. When a critical degree of HPS delay (S_2 - H_2 interval) is attained, the impulse can return down the initially blocked RB and result in a QRS of similar morphology to the paced QRS at the RV apex—specifically, it will look like a typical LBBB pattern with left axis deviation because ventricular activation originates from conduction over the RB. The HV interval of the bundle branch reentry beat is usually longer than or equal to the HV interval during NSR. Retrograde atrial activation over the AVN, if present, follows the His potential (see Fig. 4.26); if over a left-sided BT, atrial activation follows the QRS.

AVN echo beats. AVN echoes are caused by reentry in the AVN in patients with retrograde dual AVN physiology (see Fig. 17.13). The last paced beat conducts retrogradely up the slow AVN pathway and then anterogradely down the fast pathway to produce the echo beat. AVN echoes appear reproducibly after a critical H_2 - A_2 interval (or V_2 - A_2 interval, when the His potential cannot be seen), and manifest as extra beats with a normal anterograde QRS morphology and atrial activity preceding the His potential before the echo beat. This phenomenon can occur at long or short coupling intervals and depends only on the degree of retrograde AVN conduction delay. In most cases, this delay is achieved before the appearance of a retrograde His potential beyond the local ventricular electrogram (i.e., before retrograde block in the RB).

AV echo beats. These beats occur secondary to retrograde block in the HPS-AVN and retrograde VA conduction over an AV BT, followed by anterograde conduction over the AVN. Alternatively, echo beats can result from retrograde block in the BT and retrograde VA conduction over the AVN-HPS, followed by anterograde conduction over the AV-BT. In the first setting, the echo beat displays a narrow QRS; in the latter setting, the echo beat is fully preexcited (see Fig. 18.25).

Intraventricular reentrant beats. This response occurs most commonly in the setting of a cardiac pathological condition, especially coronary artery disease, and usually occurs at short coupling intervals. It can have any QRS morphology, but more often RBBB than LBBB in patients with prior myocardial infarction. These responses are usually nonsustained (1 to 30 complexes) and typically polymorphic. In patients without prior clinical ventricular arrhythmias, such responses are of no clinical significance.

Catheter-induced ventricular beats. Such beats usually have the earliest ventricular activation site recorded at that particular catheter

tip and have the same QRS morphology as the QRS produced by pacing from that catheter.

Para-Hisian Pacing During Sinus Rhythm

Concept of para-Hisian pacing. The para-Hisian pacing site is unique because it is anatomically close but electrically distant from the HB. Para-Hisian pacing at high output simultaneously captures the HB or proximal RB, as well as the adjacent ventricular myocardium. At lower output, direct HB-RB capture is lost and retrograde activation of the HB is delayed because the HB and RB are insulated from the adjacent myocardium and the peripheral inputs to the Purkinje system are located far from the para-Hisian pacing site. By maintaining local ventricular capture while intermittently losing HB-RB capture, retrograde VA conduction can be classified as dependent on the timing of local ventricular activation (BT), HB activation (AVN), or both (fusion).

Para-Hisian pacing can result in capture of the ventricle (indicated by a wide paced QRS), the atrium (indicated by atrial activation in the HB region immediately following the pacing artifact), the HB (indicated by narrow paced QRS), or any combination of these (see Fig. 18.29). Careful attention must be given to minimize the atrial signal seen on the recording from the pacing electrode pair to ensure that local atrial capture does not occur during pacing.

Technique of para-Hisian pacing. Ideally, two quadripolar catheters (one for pacing and another for recording) or a single octapolar catheter (for both pacing and recording) is placed at the distal HB-RB region. Alternatively, a single quadripolar HB catheter (which is typically used during a diagnostic EP study) is used, taking into account that such an approach would limit the ability to record the retrograde His potential and HA interval.¹⁹

Overdrive ventricular pacing is performed (from the pair of electrodes on the HB catheter that records activation of the distal HB-RB) at a long PCL (greater than 500 milliseconds) and high output. During pacing, direct HB-RB capture is indicated by narrowing of the paced QRS width. The pacing output and pulse width are then decreased until the paced QRS widens, which is associated with a delay in the timing of the retrograde HB potential, indicating loss of HB-RB capture. The pacing output is increased and decreased to gain and lose HB-RB capture, respectively, while local ventricular capture is maintained. Occasionally, the HB can be captured uniquely (without myocardial capture), resulting in a QRS identical to the patient's normally conducted QRS.¹⁹

Response to para-Hisian pacing. When the ventricle and HB are captured simultaneously, the wavefront activates the ventricles over the HPS and results in a relatively narrow QRS. The wavefront can also travel retrogradely over the AVN to activate the atrium with an SA interval (i.e., the interval from the pacing stimulus to the atrial electrogram) that represents conduction time over the proximal part of the HB and AVN (i.e., SA interval = HA interval) because the onset of ventricular activation and HB activation occur simultaneously (i.e., stimulus-His bundle [SH] interval = 0).¹⁹

When the ventricle is captured but not the atrium or HB, the wavefront activates the ventricles by muscle-to-muscle conduction, resulting in a wide QRS with LBBB morphology caused by pacing in the RV. Once the wavefront reaches the RV apex, it conducts retrogradely up the RB and then over the HB and AVN to activate the atrium. In this setting, the SA interval represents the conduction time from the RV base to the HB (SH interval) plus the conduction time over the HB and AVN (HA interval). Thus, normally (in the absence of a retrogradely conducting BT), para-Hisian pacing results in a shorter SA interval when the HB (or HB plus RV) is captured than the SA interval when only the ventricle is captured.¹⁹

In the presence of a septal AV BT, the SA interval usually remains fixed regardless of whether the HB is being captured, because in both situations the paced impulse travels retrogradely over the BT, with constant conduction time to the atrium as long as local ventricular myocardium is being captured. Atrial activation in this setting can be secondary to activation over the BT, especially when only the ventricle is captured, or a result of fusion of conduction over both the BT and AVN, especially when both the ventricle and the HB are captured. Nevertheless, because VA conduction time over the BT is faster than that over the AVN, the timing of the earliest atrial activation (i.e., the SA and local VA intervals) remains constant, regardless of whether HB-RB capture occurs and regardless of whether atrial activation occurs exclusively over the AV BT or as a fusion of conduction over both the AV BT and AVN.¹⁹

Seven patterns of response to para-Hisian pacing can be observed (Box 20.1; see Figs. 18.29 and 18.30). In patients with retrogradely conducting BTs, in whom retrograde conduction occurs over both the

AVN and BT during para-Hisian pacing, the amount of atrial myocardium activated by each of the two pathways (atrial fusion) is dependent on four variables: (1) the magnitude of delay in retrograde activation of the HB (i.e., SH interval); (2) retrograde conduction time over the AVN (HA interval); (3) intraventricular conduction time from the para-Hisian pacing site to the ventricular end of the BT (SV_{BT}); and (4) retrograde conduction time over the BT (VA_{BT}). The first two variables (SH plus HA) form the SA interval resulting from retrograde VA conduction over the AVN, and the latter two variables (SV_{BT} plus VA_{BT}) form the SA interval resulting from retrograde VA conduction over the BT. The amount of the atria activated by the AVN is greater during HB-RB capture, secondary to a minimal SH interval (i.e., SA interval = HA interval). Loss of HB-RB capture results in prolongation of the SH interval and, therefore, an increase in the amount of atria activated by the BT, resulting in a change in the retrograde atrial activation sequence. Consequently, a change in the retrograde atrial activation sequence with loss of HB-RB capture always indicates the presence of

BOX 20.1 Response Patterns to Para-Hisian Pacing

Pattern 1 (AVN/AVN Pattern)

- Retrograde conduction occurs exclusively over the AVN regardless of whether the HB-RB is captured.
- Loss of HB-RB capture results in an increase in the SA interval in all electrograms equal to the increase in the SH interval, with no change in the atrial activation sequence. The HA interval remains essentially the same.
- This response indicates that retrograde conduction is dependent on HB activation and not on local ventricular activation.
- This pattern is observed in all patients with AVNRT and is not observed in any patient with a septal or right free-wall BT. However, this pattern can be observed in some patients with a left free-wall BT or PJRT, in which case retrograde AVN conduction masks the presence of retrograde BT conduction.

Pattern 2 (BT-BT Pattern)

- Retrograde conduction occurs exclusively over a single BT.
- The SA interval is identical during HB-RB capture and noncapture, indicating that retrograde conduction is dependent on local ventricular activation and not on HB activation.
- This pattern does not exclude the presence of retrograde conduction over the AVN with longer conduction time or a second BT with longer conduction time or located far from the pacing site.

Pattern 3 (BT-BT_L Pattern)

- Retrograde conduction occurs exclusively over a BT.
- Loss of HB-RB capture is associated with a delay in the timing of ventricular activation close to the BT. This results in an increase in the SA interval in all electrograms, with no change in the atrial activation sequence. The local VA interval, recorded close to the BT, remains approximately the same. The increase in the SA interval is less than the increase in the SH interval. Therefore the HA interval is shortened with loss of HB-RB capture, indicating that retrograde conduction cannot be occurring over the AVN. Two mechanisms have been identified accounting for the delay in timing of ventricular activation close to the BT.
- Activation of the HPS results in earlier ventricular activation near some BTs located far from the para-Hisian pacing site, such as left lateral or anterolateral BTs.
- Decreasing the pacing output to lose HB-RB capture occasionally results in a small delay in ventricular activation close to the pacing site.

- Pattern 3 is referred to as the BT-BT_L pattern, where BT_L refers to a lengthening of the SA interval with loss of HB-RB capture.

Pattern 4 (AVN-BT Pattern)

- Loss of HB-RB capture is associated with atrial activation exclusively over the BT.
- Loss of HB-RB capture results in an increase in SA and local VA intervals in all electrograms, with the least increase occurring in the electrogram closest to the BT.
- The HA interval shortens, indicating that the atrium near the AVN is activated by the BT before retrograde conduction over the AVN is complete.

Pattern 5 (AVN-Fusion Pattern)

- Loss of HB-RB capture results in activation of part of the atria by the AVN and part by the BT.
- Loss of HB-RB capture is associated with an increase in SA and local VA intervals in all electrograms.
- The HA interval remains constant, indicating that part of the atria was still activated by the AVN.

Pattern 6 (Fusion-BT Pattern)

- Loss of HB-RB capture results in atrial activation exclusively over the BT.
- Loss of HB-RB capture is associated with no change in the SA or local VA intervals recorded near the BT.
- In the HB electrogram, the SA interval increases, but not as much as the SH interval, leading to a decrease in the HA interval. This indicates that the atrial myocardium in that region is no longer activated by the AVN.

Pattern 7 (Fusion-Fusion Pattern)

- The atria continue to be activated by both the AVN and the BT during loss of HB-RB capture, with more of the atria activated by the BT than during HB-RB capture.
- Like pattern 6, loss of HB-RB capture is associated with minimal change in the SA or local VA intervals recorded close to the BT; however, the HA interval remains essentially the same, indicating that part of the atria is still activated by the AVN.

AVN, Atrioventricular node; AVNRT, atrioventricular nodal reentrant tachycardia; BT, bypass tract; HA, His bundle–atrial; HB-RB, His bundle–right bundle branch; HPS, His-Purkinje system; PJRT, permanent junctional reciprocating tachycardia; SA, stimulus-atrial; SH, stimulus–His bundle; VA, ventriculoatrial.

retrograde conduction over both the BT and AVN. There are four such patterns (patterns 4 through 7). In patterns 4 and 5, HB-RB capture is associated with activation of the atria exclusively by retrograde conduction over the AVN. In patterns 6 and 7, HB-RB capture results in atrial activation over both the AVN and the BT.¹⁹

Interpretation of results of para-Hisian pacing. The response to para-Hisian pacing can be determined by comparing the following four variables between HB-RB capture and noncapture while maintaining local ventricular capture and no atrial capture: (1) atrial activation sequence, (2) SA interval, (3) local VA interval, and (4) HA interval (see Figs. 18.29 and 18.30).

The SA interval is defined as the interval between the pacing stimulus and atrial electrogram. It should be recorded at multiple sites, including those close to the site of earliest atrial activation during SVT.

The local VA interval is defined as the local ventricular-to-atrial electrogram interval in the electrode position with the earliest retrograde atrial activation time. For the local VA to be relied on, it actually has to be measured at the site of earliest atrial activation (this requires positioning a catheter at the site of earliest atrial activation recorded during SVT). The high RA catheter, for example, may not be satisfactory for evaluation of the local VA interval in the presence of a septal BT.

The HA interval is recorded in the HB electrogram; however, this measurement can be obtained only if two catheters are placed in the HB position (one catheter for pacing and a second catheter for recording) or if an octapolar catheter is used for pacing and sensing around the HB. The use of a single quadripolar HB catheter, which is typically used during a diagnostic EP study, negates the ability to record the retrograde His potential and HA interval during pacing. However, the combination of the SA and local VA intervals is sufficient to identify the presence of a retrograde BT.

If the SA (and local VA) interval at any site remains fixed, regardless of whether HB-RB capture occurs, while the HA interval shortens, retrograde conduction is occurring only over an AV BT. In this setting, the HA interval shortens on loss of HB-RB capture because the HB and atrium are activated in parallel and HB activation is delayed because of prolongation of the SH interval, while atrial activation timing remains unchanged because it results from retrograde conduction over the AV BT and is independent of the timing of HB activation. On the other hand, if the SA (and local VA) interval increases in all electrograms (including the electrode recording the earliest atrial activation) coincident with loss of HB-RB capture, while the HA interval remains essentially the same, retrograde conduction is occurring only over the AVN.

An identical retrograde atrial activation sequence during HB-RB capture and noncapture indicates that retrograde conduction is occurring over the same system (either the BT or AVN) and does not help prove or exclude the presence of a BT (especially a septal BT; see Fig. 18.30). A change in the retrograde atrial activation sequence with loss of HB-RB capture, however, indicates the presence of retrograde conduction over both a BT and the AVN. Morphological change in the atrial electrogram recorded at the AV junction without overlapping the ventricular electrogram also seems to have diagnostic significance, indicating the presence of both BT and AVN conduction.

Limitations of para-Hisian pacing. The location of the BT and the retrograde conduction time over the BT must be taken into account when interpreting the results of para-Hisian pacing. For superoparaseptal BTs, the SV_{BT} interval is short. For BTs located progressively farther from the para-Hisian pacing site, the SV_{BT} increases progressively. This is not a significant factor for midseptal, posteroseptal, or most right free-wall BTs. However, for left free-wall BTs, which are located far from the pacing site, the SV_{BT} interval can be sufficiently long to have the

entire atria activated by the AVN, even during loss of HB-RB capture. In this setting, para-Hisian pacing can produce an AVN retrograde conduction pattern, regardless of whether the HB-RB is captured (pattern 1: AVN-AVN), and fail to identify the presence of retrograde BT conduction (because of the long SV_{BT}). However, a left lateral BT should not be a diagnostic challenge because of the obvious eccentric retrograde atrial activation sequence during orthodromic AVRT, and para-Hisian pacing is performed mainly to investigate the presence of a septal BT. In addition, for BTs located far from the para-Hisian pacing site, it is important to record atrial activation close to the suspected site of the BT. Otherwise, the change in the atrial activation sequence may not be identified, incorrectly suggesting that retrograde conduction is occurring over just the AVN. This is most likely to occur in patients with short retrograde AVN conduction (short HA interval) and a BT located far from the pacing site.

Para-Hisian pacing may fail to identify retrograde conduction over a slowly conducting BT (e.g., PJRT) because of the long VA_{BT} interval. Performing para-Hisian entrainment or resetting during SVT can help in these situations (see later). In addition, although para-Hisian pacing during NSR can help prove the presence of an AV BT, it does not show whether that BT is operative during the SVT.

In patients with very proximal retrograde RBBB, RB capture may fail to produce early retrograde activation of the HB, limiting the use of para-Hisian pacing in these patients. This observation suggests that HB-RB capture actually represents capture of the proximal RB and not HB capture. This is supported by the observation that, during HB-RB capture, the HB potential is often recorded 10 to 20 milliseconds after the pacing stimulus. Importantly, para-Hisian pacing has been performed successfully in many patients with more distal RBBB (see Fig. 18.29).

Assurance of lack of atrial capture by the pacing stimulus is important for correct interpretation of the results of para-Hisian pacing. Atrial capture is indicated by a very short SA interval in the electrodes just proximal to the pacing electrodes. It is sometimes helpful to withdraw the para-Hisian pacing catheter until atrial capture alone is seen; if the SA interval in the presence of ventricular capture is not longer than this, atrial capture was also present and the test should be repeated at a more distal pacing site.

Dual-Chamber Sequential Extrastimulation During Sinus Rhythm

Dual-chamber sequential extrastimulation is a useful maneuver for identifying retrogradely conducting AV BTs, even slowly conducting BTs and BTs with decremental properties. This maneuver relies on concealed AVN conduction during a critically timed AES to cause transient retrograde AVN blockade at the time a VES is delivered, thereby allowing the BT to become manifest with the VES (analogous to delivering a VES during HB refractoriness).²⁰

The dual-chamber sequential extrastimulation maneuver consists of an eight-beat drive train of simultaneous atrial and RV pacing at 600 milliseconds, followed by an AES (A_2) delivered at a coupling interval equal to the AVN ERP, followed by a VES (V_2) delivered at a coupling interval equal to the drive train cycle length (CL) (600 milliseconds). Repeat drives are then performed with decrements of 10 milliseconds for V_2 until VA block is observed.²⁰

The critically timed A_2 prolongs the AVN refractory period via concealed anterograde conduction, causing V_2 to block in the AVN when it would have conducted had A_2 not been delivered. If a BT is present, V_2 conducts back to the atrium while the AVN remains refractory, resulting in a retrograde atrial activation pattern consistent with exclusive BT conduction. Although there can also be some degree of concealed anterograde conduction into the BT during A_2 stimulation, the more pronounced decremental properties of AVN tissue should

prolong AVN refractoriness to a greater degree than that of the BT, allowing exclusive retrograde conduction over the BT to remain intact during V_2 stimulation.²⁰

This maneuver has several potential limitations. First, atrial ERP may exceed anterograde AVN ERP. In addition, local atrial ERP at the site of BT insertion can render the atrium refractory to the wavefront traveling retrogradely over the BT. Therefore atrial pacing during this maneuver ideally should be performed at a site in close proximity to the atrial insertion of the BT if possible. Furthermore, the AES may cause anterograde concealed conduction in the BT, potentially resulting in BT conduction block during delivery of V_2 . The success of this pacing maneuver relies on the differential effects of concealed conduction into the AVN and BT, with greater extension of refractoriness in the former than the latter.²⁰

Induction of Tachycardia

Initiation by Programmed Atrial Stimulation

Inducibility. All types of paroxysmal SVTs can be inducible with atrial stimulation (except automatic AT). Initiation can require catecholamines (isoproterenol) with any type of SVT, and this observation does not help for differential diagnosis. However, automatic AT can start spontaneously (without atrial stimulation) during isoproterenol or epinephrine infusion.

SVT initiation that is reproducibly dependent on a critical atrial–His bundle (AH) interval is classic for typical AVNRT (see Fig. 17.11). This is because anterograde block in the fast pathway in conjunction with sufficient delay in anterograde conduction over the slow pathway (“critical AH interval”) are necessary to allow for recovery of the fast pathway to conduct retrogradely and initiate AVN reentry. Atypical AVNRT is usually initiated with modest prolongation of the AH interval along the fast pathway with anterograde block in the slow pathway, followed by retrograde slow conduction over the slow pathway. Therefore a critical AH interval delay is not obvious (see Fig. 17.12).

Orthodromic AVRT usually requires some AV delay for initiation; however, the delay can occur anywhere along the AVN–HPS axis. In patients with baseline manifest preexcitation, initiation of orthodromic AVRT is usually associated with anterograde block in the AV BT and loss of preexcitation following the initiating atrial stimulus, which would then allow that BT to conduct retrogradely during the SVT.

No delay in the AH or PR interval is required for initiation of AT, although it can occur. AV block can also occur at initiation. Automatic ATs cannot be reproducibly initiated by AES or atrial pacing.

Warm-up. Progressive shortening of the TCL for several beats (warm-up) before its ultimate rate is achieved is characteristic of automatic AT, but may occur in other SVTs as well.

VA interval. If the VA interval of the first tachycardia beat is reproducibly identical to that during the rest of the SVT, AT is very unlikely, and such “VA linking” is suggestive of typical AVNRT and orthodromic AVRT.

Initiation by Programmed Ventricular Stimulation

Inducibility. Ventricular stimulation commonly induces AVRT and AVNRT. On the other hand, it is uncommon to initiate AT with VES or ventricular pacing because decremental retrograde conduction over the AVN prevents adequate prematurity of atrial activation.

Postpacing intervals. If SVT is induced during VES, the interval between the VES (delivered from the RV apex) that initiates SVT and the first cycle of tachycardia can provide information about the circuit that are essentially equivalent to those observed with ventricular entrainment (see later). The interval from the VES to atrial activation (surface VA or “S–A” interval) is compared to the surface VA interval during SVT, and the post-VES return cycle (i.e., the interval from the VES to

the subsequent RV apical depolarization) is compared to the TCL. An SA interval that exceeds the surface VA interval during SVT by less than 85 milliseconds is consistent with orthodromic AVRT. Similarly, when the post-VES return cycle exceeds the TCL by less than 115 milliseconds, orthodromic AVRT is indicated. The small differences between those intervals are related to the proximity of the RV apical pacing site to the AVRT reentry circuit. Larger differences in these intervals are observed in the setting of AVNRT or orthodromic AVRT utilizing a left lateral BT or a septal BT with decremental conduction. The unique advantage of this technique is that they do not have a requirement for sustained tachycardia that can be successfully entrained.²¹

Furthermore, when induction of the SVT is achieved by ventricular pacing at a CL similar to the subsequent TCL or by a VES that activates the HB at a coupling interval (i.e., H_1 – H_2 interval) similar to the H–H interval during the SVT (i.e., similar to the TCL), the HA interval following the initiating ventricular stimulus is then compared with that during the SVT. During AVNRT, the HA interval of the ventricular stimulus initiating the SVT is longer than the HA interval during the SVT, because both the HB and atrium are activated in sequence during ventricular stimulation but in parallel during AVNRT (see Fig. 17.14). This is even exaggerated by the fact that the AVN usually exhibits greater decremental conduction with repetitive engagement of impulses than to a single impulse at a similar coupling interval. Therefore the more prolonged the HA interval with the initiating ventricular stimulus, the more likely the SVT is AVNRT. On the other hand, if the SVT uses an AV BT for retrograde conduction, the HA interval during the initiating ventricular stimulus (at a coupling interval comparable to the TCL) is shorter than that during orthodromic AVRT because the HB and atrium are activated in parallel during ventricular pacing (when atrial activation is mediated by retrograde BT conduction), but in sequence during SVT.

Tachycardia Features

Atrial Activation Sequence

During typical AVNRT, the initial site of atrial activation is usually recorded in the HB catheter at the apex of the triangle of Koch. In contrast, the initial site of atrial activation during atypical AVNRT is usually recorded at the base of the triangle of Koch or CS os (see Fig. 17.2). On the other hand, in orthodromic AVRT, the initial site of atrial activation depends on the location of the AV BT, but is always near the AV groove, without multiple breakthrough points. It is comparable to that during ventricular pacing when VA conduction occurs exclusively over the AV BT. The atrial activation sequence during AT depends on the origin of the AT, and can simulate that of other types of SVTs.

In summary, eccentric atrial activation during SVT excludes typical and atypical AVNRT, except for the left variant of AVNRT, during which the earliest atrial activation occurs in the proximal or mid-CS. Furthermore, an eccentric atrial activation sequence that originates away from the AV rings is diagnostic of AT and excludes both AVNRT and AVRT.

Atrial-Ventricular Relationship

PR–RP intervals. During AT, the PR interval is appropriate for the AT rate and is usually longer than that during NSR. The faster the AT rate, the longer the PR interval. Thus the PR interval can be shorter, longer, or equal to the RP interval. The PR interval can also be equal to the R–R and the P wave can then fall within the preceding QRS, mimicking typical AVNRT.

During typical AVNRT, the RP interval is very short (–40 to 75 milliseconds); in contrast, during atypical fast-slow AVNRT, the RP interval is longer than the PR interval. On the other hand, during orthodromic AVRT, the RP interval is short but longer than that in typical AVNRT because the wavefront has to activate the ventricle before it

reaches the AV BT and subsequently conduct retrogradely to the atrium. Thus the ventricle and atrium are activated in sequence, in contrast to AVNRT, during which the ventricle and atrium are activated in parallel, resulting in abbreviation of the VA interval. Consequently, a very short VA interval (less than 70 milliseconds) or short V–high RA interval (less than 95 milliseconds) largely excludes orthodromic AVRT, and favors typical AVNRT. However, VA intervals shorter than 70 milliseconds have occasionally been observed in adult patients with orthodromic AVRT utilizing left lateral or left posteroseptal BTs.^{22,23}

Because the retrograde limb of the reentry circuit in PJRT is the slow BT (which conducts more slowly than the AVN), the RP interval is longer than the PR interval, similar to fast-slow AVNRT (see Figs. 18.14 and 18.39).

AV block. The presence of AV block during SVT excludes AVRT, is uncommon during AVNRT, and strongly favors AT (Fig. 20.7). AV block occurs commonly during AT, with either Wenckebach periodicity or fixed-ratio block. AV block may also occur during AVNRT because of block below the reentry circuit (usually below the HB and infrequently in the lower common pathway), which can occur especially at the onset of the SVT, during acceleration of the SVT, and following a PVC or a VES (see Fig. 17.9).

VA block. VA block during SVT is a rare phenomenon, and may occasionally be observed in infraatrial SVTs, including junctional ectopic tachycardia and orthodromic AVRT using a nodofascicular or nodoventricular BT for retrograde conduction. VA block during AVNRT has been reported (see eFig. 17.2). Intra-Hisian reentry is another potential mechanism, but it is a theoretical entity whose clinical occurrence has not been convincingly demonstrated.^{12–14}

Variation of the P/QRS relationship. Spontaneous changes in the PR and RP intervals with fixed atrial-atrial (A-A) interval favor AT and exclude orthodromic AVRT (Fig. 20.8). On the other hand, spontaneous changes in TCL accompanied by a constant VA interval (“VA linking”) suggest orthodromic AVRT (see Fig. 18.36). During orthodromic AVRT, the RP interval remains fixed, regardless of oscillations in TCL from whatever cause or changes in the PR (AH) interval. Thus the RP/PR ratio may vary, and the TCL is most closely associated with the PR interval (i.e., anterograde slow conduction). In contrast to the classic fast AV BTs, the RP interval during PJRT is not fixed because the BT serving as the retrograde limb of the reentrant circuit has decremental properties.

Variation of the P/QRS relationship (with changes in the AH interval, HA interval, and AH/HA ratio), with or without block, can occur during AVNRT, especially in atypical or slow-slow AVNRT. This phenomenon usually occurs during initiation or termination of the tachycardia or in cases of nonsustained tachycardias, likely because of decremental conduction in the lower common pathway.

The ECG manifestation of P/QRS variations, with or without AV block during tachycardia, should not be misdiagnosed as AT; they can be atypical or, rarely, typical forms of AVNRT. Moreover, the variations could be of such magnitude that a long RP tachycardia can masquerade for brief periods of time as short RP tachycardia.

Oscillation in Tachycardia Cycle Length

Analysis of TCL variability can provide useful diagnostic information that is available even when episodes of SVT are nonsustained. TCL variability of at least 15 milliseconds in magnitude was found to occur

Fig. 20.7 Supraventricular Tachycardia (SVT) With Concentric Atrial Activation Sequence and Intermittent Atrioventricular (AV) Block. *At left*, A wide complex tachycardia with left bundle branch block (LBBB) pattern and 1:1 AV ratio is shown. Simultaneous atrial and ventricular activation is observed, excluding atrioventricular reentrant tachycardia (AVRT) as the mechanism of the tachycardia, and favoring typical atrioventricular nodal reentrant tachycardia (AVNRT) or atrial tachycardia (AT) with a long PR interval. *At right*, 2:1 AV block is observed without disruption of the tachycardia. Normalization of QRS morphology is observed during the period of 2:1 AV block, suggesting that wide QRS morphology during 1:1 AV conduction was a result of functional LBBB. The development of AV block with continuation of the tachycardia confirms that the ventricle is not part of the tachycardia circuit and, thus, excludes AVRT. The presence of His potentials, even during the blocked beats, suggests that the block is infra-Hisian. The observation of AV block favors AT, but does not exclude AVNRT. The ventriculoatrial (VA) interval remains constant following both the narrow and wide QRS complexes, which suggests AVNRT. Other pacing maneuvers confirmed that this SVT was in fact typical AVNRT. CS_{dist}, Distal coronary sinus; CS_{prox}, proximal coronary sinus; HRA, high right atrium; RVA, right ventricular apex.

Fig. 20.8 Supraventricular Tachycardia (SVT) With Variable RP Intervals. Three surface electrocardiogram leads are shown. The P waves are inscribed within the T waves, and are more discernible with negative polarity in lead aVL. Note that the RP interval varies during the SVT (arrows) with constant atrial-atrial intervals, consistent with atrial tachycardia as the mechanism of the SVT and excludes orthodromic atrioventricular reentrant tachycardia.

in up to 73% of paroxysmal SVTs and was equally prevalent in AT, AVNRT, and orthodromic AVRT.

Changes in atrial CL preceding similar changes in subsequent ventricular CL strongly favor AT or atypical AVNRT (see Fig. 17.15). In contrast, when the change in atrial CL is predicted by the change in preceding ventricular CL, typical AVNRT (see eFig. 17.2) or orthodromic AVRT is the most likely mechanism (see Fig. 18.36).

The AVN participates either actively or passively in all types of narrow complex SVTs and the AV interval can vary depending on the preceding atrial CL and autonomic tone. A change in anterograde or retrograde AVN conduction can result in TCL variability in AVNRT or orthodromic AVRT. However, during AT, changes in anterograde AVN conduction produce only changes in ventricular CL, whereas the atrial CL remains unaffected. Therefore spontaneous changes in the ventricular CL in conjunction with fixed A-A interval (typically manifesting as variations in the PR and RP intervals) favor AT.²⁴

Changes in atrial CL during AT result from changes in the CL of the atrial focus itself, and this causes similar variability in the conducted ventricular CL. Therefore, when there is CL variability in both the atrium and ventricle, changes in atrial CL during AT would be expected to precede and predict the changes in ventricular CL. However, ventricular CL variability can be caused by changes in AV conduction instead of changes in the CL of an AT, in which case ventricular CL variability may not be predicted by a prior change in atrial CL during AT. Nevertheless, because there is no VA conduction during AT, ventricular CL variability alone would not be expected to result in atrial CL variability during AT.²⁴

In contrast to AT, typical AVNRT and orthodromic AVRT generally have CL variability because of changes in anterograde AVN conduction. Because retrograde conduction through a fast AVN pathway or a BT is generally much less variable than anterograde conduction through the AVN, the changes in ventricular CL that result from variability in anterograde AVN conduction would be expected to precede the subsequent changes in atrial CL. This explains why the change in atrial CL does not predict the change in subsequent ventricular CL in typical AVNRT and orthodromic AVRT. On the other hand, in atypical AVNRT, anterograde conduction occurs over the more stable fast AVN pathway and retrograde conduction is more subject to variability. This explains the finding that changes in atrial CL predict the changes in subsequent ventricular CL in atypical AVNRT (as is the case in AT).²⁴

In addition, orthodromic AVRT in the presence of dual AVN physiology can be associated with anterograde conduction alternating over

the slow and fast AVN pathways, resulting in a regular irregularity of the TCL (alternating long and short cycles). Importantly, the RP interval during the SVT remains constant, regardless of the PR interval.

Effects of Bundle Branch Block

The development of BBB during SVT that does not influence the TCL (A-A or H-H interval) or the VA interval is consistent with AT, AVNRT (see Fig. 17.9), and orthodromic AVRT using a BT in the ventricle contralateral to the BBB, because the ventricle affected by conduction delay is not part of the SVT circuit (see Fig. 18.35), but excludes orthodromic AVRT using a BT ipsilateral to the BBB.

BBB ipsilateral to the AV BT mediating orthodromic AVRT results in prolongation of the “surface VA interval” (QRS onset to atrial electrogram) compared to that during narrow QRS tachycardia because of the extra time required for the impulse to travel from the AVN down the HB and contralateral bundle branch, and transeptally to the ipsilateral ventricle to reach the AV BT and then activate the atrium (see Fig. 18.37). However, the “local VA interval” (measured at the site of BT insertion) remains constant. In addition, the TCL usually increases in concordance with the increase in the surface VA interval as a result of ipsilateral BBB because of the now-larger tachycardia circuit; however, because the time the wavefront spends outside the AVN is now longer, AVN conduction may improve, resulting in shortening in the AH interval (and PR interval), which can potentially counterbalance, at least in part, the effects of prolongation of the VA interval on the total TCL. Thus the surface VA interval and not the TCL should be used to assess the effects of BBB on the SVT (see Fig. 18.12).

Prolongation of the surface VA interval during SVT in response to BBB by more than 35 milliseconds suggests that an ipsilateral free-wall AV BT is present and is participating in the SVT (i.e., diagnostic of orthodromic AVRT). On the other hand, prolongation of the surface VA by 25 to 35 milliseconds suggests a septal AV BT (posteroseptal AV BT in association with LBBB, and superoparaseptal AV BT in association with RBBB) (Fig. 20.9). In contrast, BBB contralateral to the AV BT does not influence the VA interval or TCL because the contralateral ventricle is not part of the reentrant circuit (see Figs. 18.35 and 18.37).

Because the occurrence of BBB during SVT is much more common in orthodromic AVRT than AVNRT or AT (90% of SVTs with sustained LBBB are orthodromic AVRTs), the mere presence of LBBB aberrancy during SVT is suggestive of orthodromic AVRT, but can still occur in other types of SVTs.

Fig. 20.9 Effect of Right Bundle Branch Block (RBBB) on Supraventricular Tachycardia (SVT). RBBB is initially present during an SVT with short RP interval and concentric atrial activation. Introduction of a ventricular extrastimulus (S2) from the right ventricular apex (RVA) during the tachycardia is followed by resolution of RBBB ("peeling back" refractoriness). Note that the loss of RBBB is associated with shortening of the ventriculoatrial (VA) interval (by 21 milliseconds) and a milder degree of shortening of the tachycardia cycle length (by 8 milliseconds), indicating the presence and participation of a septal BT in the reentrant circuit, which establishes the diagnosis of orthodromic atrioventricular reentrant tachycardia. CS_{dist}, Distal coronary sinus; CS_{prox}, proximal coronary sinus; HRA, high right atrium.

Tachycardia Termination and Response to Physiological and Pharmacological Maneuvers

Spontaneous termination. Spontaneous termination of orthodromic AVRT usually occurs because of anterograde gradual slowing and then block in the AVN, sometimes causing initial oscillation in the TCL, with alternate complexes demonstrating a Wenckebach periodicity before block. However, termination with retrograde block in the AV BT can occur without any perturbations of the TCL during very rapid orthodromic AVRT or following a sudden shortening of the TCL (e.g., after resolution of ipsilateral BBB or shift of anterograde conduction from the slow to the fast AVN pathway).

Spontaneous termination of AVNRT occurs because of block in the fast or slow pathway. However, the better the retrograde fast pathway conduction, the less likely that it is the site of block.

Spontaneous termination of AT is usually accompanied by progressive prolongation of the A-A interval, with or without changes in AV conduction. During AT with 1:1 AV conduction, the last beat of AT is conducted to the ventricle. Spontaneous termination of SVT with a P wave not followed by a QRS practically excludes AT, except coincidentally or in the case of a nonconducted PAC terminating the AT (neither of which will be reproducible).

Termination with adenosine. Adenosine terminates the vast majority of orthodromic AVRTs (by blocking AVN conduction) and AVNRTs (by blocking slow pathway conduction). Also, a significant proportion of focal ATs can be terminated by adenosine, typically (80%) prior to the onset of AV block (i.e., termination occurs with a tachycardia P wave that is followed by a conducted QRS). Although adenosine may not terminate ATs, it can help confirm the diagnosis of AT when it causes transient AV block without terminating the tachycardia. In addition, adenosine can help identify automatic ATs, which are generally transiently slowed but not terminated, with gradual resumption of the AT rate.

Adenosine generally terminates atypical AVNRT by gradual slowing and then block in the retrograde slow pathway. Adenosine usually terminates PJRT by block in the AVN (two-thirds) or in the BT (one-third) (see eFig. 18.5). Although the mode of tachycardia termination by adenosine has been suggested to distinguish between PJRT and atypical AVNRT, one report has shown that termination of atypical AVNRT with adenosine can also result from block in the fast AVN pathway and, therefore, its value in distinguishing between atypical AVNRT and PJRT is questionable.

In summary, the mere termination of SVT in response to adenosine is usually not helpful in differentiating SVTs. However, the pattern of SVT termination can be helpful in two situations: First, reproducible termination of the SVT with a QRS not followed by a P wave excludes orthodromic AVRT using a rapidly conducting AV BT as the retrograde limb (adenosine blocks the AVN and not the BT), is unusual in typical AVNRT (adenosine blocks the slow pathway with little or no effect on fast pathway conduction), and is consistent with AT, PJRT, or atypical AVNRT. Second, reproducible termination of the SVT with a P wave not followed by a QRS excludes AT, because it occurs in AT only if adenosine terminates the AT at the same moment it causes AV block, which is an unlikely coincidence (Fig. 20.10).²⁵

Termination with vagal maneuvers. Carotid sinus massage and vagal maneuvers can slow or terminate sinus node reentrant tachycardia and 25% of microreentrant ATs (especially those with long TCLs and those arising in the RA), and, to a lesser degree, triggered-activity ATs. However, these interventions may slow but do not generally terminate automatic AT.

Orthodromic AVRT usually terminates with gradual slowing and then block in the AVN. Typical AVNRT usually terminates with gradual anterograde slowing and then block in the slow pathway; block in the fast pathway is uncommon. In addition, carotid sinus massage and vagal maneuvers terminate atypical AVNRT by gradual slowing and

Fig. 20.10 Termination of Supraventricular Tachycardia (SVT) With Adenosine. Administration of adenosine during an SVT with concentric atrial activation sequence and short RP interval results in termination of the SVT with an atrial complex not followed by a QRS, which is inconsistent with atrial tachycardia. Following termination of the SVT, complete atrioventricular (AV) block during sinus rhythm is observed; however, ventricular pacing is associated with intact ventriculoatrial (VA) conduction and a retrograde atrial activation sequence identical to that during the SVT, which suggests that VA conduction is not mediated by the atrioventricular node (AVN) but by an AV bypass tract (BT). The SVT is in fact an orthodromic atrioventricular reentrant tachycardia using a concealed septal BT, and termination with adenosine was the result of block in the AVN. Retrograde conduction over the BT was not affected by adenosine. *CS_{dist}*, Distal coronary sinus; *CS_{prox}*, proximal coronary sinus; *HRA*, high right atrium; *RVA*, right ventricular apex.

then block in the retrograde slow pathway (see Fig. 17.15). Carotid sinus massage usually terminates PJRT by block in either the AVN or the BT.

Diagnostic Maneuvers During Tachycardia

Atrial Extrastimulation During Tachycardia

Resetting. An AES can reset AT, AVNRT, and orthodromic AVRT, and demonstration of resetting by itself is not helpful in distinguishing among the different types of SVTs. However, several characteristics of tachycardia resetting can help in the differential diagnosis.

Manifest atrial fusion. Resetting with manifest atrial fusion (as demonstrated by intermediate P wave morphologies on the surface ECG, or partial activation change recorded by multiple endocardial electrodes) can be demonstrated only in orthodromic AVRT and macroreentrant atrial tachycardia (MRAT), but not with AVNRT or focal AT. For atrial fusion (i.e., fusion of atrial activation from both the tachycardia wavefront and the AES) to occur, the AES should be able to enter the reentrant circuit while at the same time the tachycardia wavefront should be able to exit the circuit. This requires spatial separation between the entry and exit sites to the reentrant circuit, a condition that seems to be lacking in the setting of AVNRT and focal AT.

Resetting response curve. AES can reset microreentrant AT, AVNRT, and orthodromic AVRT with a resetting response classic for reentry (increasing or mixed response). In contrast, triggered activity AT exhibits a decreasing resetting response curve, and automatic AT exhibits an increasing response curve.

Termination. Termination of SVT with an AES is not usually helpful for the differential diagnosis. An AES can reproducibly terminate reentrant AT, AVNRT, and orthodromic AVRT. Termination of triggered activity AT is less reproducible. AES generally does not terminate automatic AT.

Atrial Overdrive Pacing During Tachycardia

Entrainment. Overdrive pacing at a CL approximately 10 to 30 milliseconds shorter than the TCL is usually able to entrain reentrant AT, AVNRT, and orthodromic AVRT but not triggered activity or automatic ATs.

Manifest atrial fusion. As discussed earlier, entrainment with manifest atrial fusion can be demonstrated only in AVRT and MRAT, but not with AVNRT or focal AT (see Fig. 18.40). Therefore, during entrainment of AVNRT and focal AT by atrial pacing, the atrial activation sequence and P wave morphology are always similar to those of pure paced morphology. Importantly, variable degrees of surface P wave or intracardiac electrogram fusion can be observed at the beginning of overdrive pacing, and should not be mistaken for constant fusion during entrainment.^{26,27}

ΔAH interval. During entrainment at a PCL close to the TCL, the AH interval during entrainment is longer than that during AVNRT. In contrast, in the setting of AT and orthodromic AVRT, the AH interval is comparable during SVT and entrainment with atrial pacing.

Acceleration. Overdrive pacing during triggered activity-related AT generally produces acceleration of the atrial CL. Following atrial overdrive pacing during AT due to triggered activity, the return atrial CL tends to shorten with shortening of the PCL.

Overdrive suppression. Automatic AT cannot be entrained by atrial pacing; however, rapid atrial pacing results in overdrive suppression of the AT rate. The AT resumes after cessation of atrial pacing but at a slower rate and gradually speeds up (warms up) to return to prepacing TCL. The atrial return CL following cessation is progressively prolonged with an increase in the duration or rate of the overdrive pacing train. This is in contrast to the return cycles and postpacing intervals (PPIs) that remain fixed following entrainment of reentrant circuits (microreentrant AT, AVNRT, and orthodromic AVNRT), regardless of the length of the pacing drive.

Termination. Termination of SVT with atrial pacing is not usually helpful for differential diagnosis. Atrial pacing can reproducibly terminate reentrant AT, AVNRT, and orthodromic AVRT, but not automatic AT. Termination of triggered activity AT is less reproducible.

VA linking. Following cessation of overdrive atrial pacing during SVT, the VA interval (the interval between the last captured QRS complex and the first tachycardia atrial complex) can help distinguish between the different mechanisms of SVT.

VA linking following different pacing rates and durations. Overdrive atrial pacing is performed from the same atrial site

(e.g., proximal CS) at different PCLs (10, 20, and 30 milliseconds shorter than the TCL), and for different durations (e.g., 10 and 20 seconds). If “VA linking” is present (i.e., the VA interval is reproducibly constant despite pacing at different CLs or for different durations and is similar to that during SVT), AT is unlikely. If no VA linking is demonstrable, AT is more likely than other types of SVTs (see Fig. 18.40). VA linking occurs in the setting of typical AVNRT and orthodromic AVRT because the timing of atrial activation is dependent on the preceding ventricular activation and is the result of retrograde VA conduction over the AVN fast pathway (during typical AVNRT) or the BT (during orthodromic AVRT), which is relatively fixed and constant. As a consequence, postpacing VA intervals are fixed and similar to those during tachycardia (with less than 10 milliseconds variation) after different attempts at atrial entrainment, regardless of the site, duration, or CL of the entraining atrial pacing drive. Conversely, following cessation of overdrive pacing (with 1:1 AV conduction) during focal AT, the postpacing VA interval can vary significantly from the VA interval during AT (especially when pacing at different rates or durations), because the timing of the tachycardia atrial return cycle is not related to the preceding ventricular activation.^{11,22,28}

VA linking following different pacing sites. Overdrive atrial pacing is performed from the high RA and proximal CS, at the same PCL (10 to 30 milliseconds shorter than the TCL), and for the same duration. When comparing the postpacing VA intervals following overdrive pacing from the high RA versus from the proximal CS, a maximal difference in the postpacing VA intervals (Δ VA interval) of more than 14 milliseconds is diagnostic with AT, whereas a Δ VA interval of less than 14 milliseconds favors AVNRT or orthodromic AVRT. This is because, in the setting of AT, the first atrial return cycle following cessation of pacing is dependent on the distance between the AT origin and pacing site, atrial conduction properties, and mode of the resetting response of the AT, and it is not related to the preceding ventricular activation. Hence, the postpacing VA intervals vary among the pacing sites, and the Δ VA interval is relatively large (more than 14 milliseconds).²⁸

Ventricular Extrastimulation During Tachycardia

Resetting. Single VESs are delivered during tachycardia to scan diastole, initially at long coupling intervals (10 to 20 milliseconds shorter than the TCL), then with progressively shorter coupling intervals (10-millisecond decrements) until loss of ventricular capture.

VES can reset any SVT, and resetting by itself is not diagnostic of a specific type of SVT. Orthodromic AVRT is the easiest SVT to be reset and even terminated by VES (see Fig. 18.42).²² Significant portions of the ipsilateral ventricle or ventricular septum are requisite components of the orthodromic AVRT circuit, making it vulnerable to penetration and resetting even by a late-coupled VES. However, a VES delivered in the contralateral ventricle may not affect the circuit, and resetting is facilitated by delivery of the VES closer to the potential BT location.

For AVNRT, the ability of a VES to affect the SVT depends on its ability to activate the HB prematurely and penetrate the AVN. Even when HB activation is advanced by the VES, the ability of the paced impulse to invade the AVN will depend on the length of the lower common pathway; the longer the lower common pathway, the more the timing of HB activation must be advanced. In fast-slow or slow-slow AVNRT, which typically has a long lower common pathway, the HB activation must be advanced by more than 30 to 60 milliseconds. In contrast, in slow-fast AVNRT, the lower common pathway (if present) is shorter and the tachycardia is typically reset by the VES as soon as the HB activation is advanced.

During AT, a VES can advance the next atrial activation when given the chance to conduct retrogradely and prematurely to the atrium, which requires significantly shorter VES coupling intervals.¹¹

Certain situations during resetting can help discriminate between the different SVT mechanisms, including the following:

Preexcitation index. The preexcitation index (defined as the difference between the TCL and the longest VES coupling interval at which atrial capture occurs during tachycardia) of 100 milliseconds or more characterizes AVNRT, whereas an index less than 45 milliseconds is consistent with AVRT with a septal BT.⁴

Resetting with different atrial activation sequence. The retrograde atrial activation sequence following a VES that resets the tachycardia is usually similar to that during SVT in the setting of AVNRT and orthodromic AVRT, because it should conduct over the tachycardia retrograde limb (except in the presence of a bystander retrogradely conducting AV BT). In contrast, a retrograde atrial activation sequence following the VES is usually different from that during AT, except for ATs originating close to the AV junction.

Manifest ventricular fusion. Resetting with manifest QRS fusion can be observed during orthodromic AVRT, especially during pacing at a site closer to the BT ventricular insertion site than the entrance of the reentrant circuit to ventricular tissue (i.e., the HPS). Such a phenomenon, on the other hand, cannot occur during AVNRT or focal AT because of the lack of spatial separation of the entrance and exit to the tachycardia circuit.

Failure of resetting. Late-coupled VESs may fail to reset the SVT, even orthodromic AVRT, especially when delivered from a site far from the BT location. However, failure of early single or double VESs to reset the SVT, despite advancement of ventricular electrograms in the electrode recording the earliest atrial activation during the SVT (which would be close to the potential BT ventricular insertion site) by more than 30 milliseconds, excludes orthodromic AVRT.²⁹

Resetting without atrial activation. The ability of a VES to reset the SVT without atrial activation (i.e., the VES advances the subsequent His potential and QRS) excludes AT and orthodromic AVRT, because it proves that the atrium is not part of the SVT circuit.

Resetting with delay of atrial activation. The ability of a VES to delay the next atrial activation excludes AT. This can be observed more often during PJRT (see Fig. 18.39) and less commonly during AVNRT, and is caused by decremental conduction in the retrograde limb of the tachycardia circuit (the decrementally conducting concealed BT in the setting of PJRT).

Resetting during His bundle refractoriness. A VES delivered when the HB is refractory (i.e., when the His potential is already manifest or within 35 to 55 milliseconds before the time of the expected His potential) that advances (accelerates) the next atrial activation is diagnostic of the presence of a retrogradely conducting BT. Such a VES has to conduct and advance atrial activation via a BT because the HPS-AVN is already refractory and cannot mediate retrograde conduction of the VES to the atrium (Fig. 20.11; see Fig. 18.42). Although such an observation proves the presence of a retrogradely conducting AV BT, it does not prove its participation in the SVT (i.e., does not prove the diagnosis of orthodromic AVRT), because both AT and AVNRT can coexist with a bystander AV BT. However, if this VES advances atrial activation with an activation sequence identical to that during the SVT, this suggests that the SVT is orthodromic AVRT and the BT is participating in the SVT, although it does not exclude the rare case of an AT originating at a site close to the atrial insertion site of a bystander AV BT. Although such a VES can advance atrial activation during AT through fast retrograde conduction over a bystander BT, it should not be able to delay an AT beat by conduction over the AV BT. Thus a VES delivered when the HB is refractory that delays the next atrial activation indicates that the VES was conducted with some delay over the BT (due to decremental BT conduction) and that the next atrial activation was dependent on this slower conduction; hence, the BT is participating in the SVT, proving

Fig. 20.11 Ventricular Extrastimulation (VES) During Supraventricular Tachycardia (SVT). VESs were delivered at progressively shorter coupling intervals during a narrow complex SVT with concentric atrial activation sequence. Timing of the anticipated anterograde His bundle (HB) activation is indicated by the blue arrows. The first VES is delivered during HB refractoriness and fails to reset the tachycardia, a phenomenon that does not help in the differential diagnosis. The second VES is delivered slightly earlier but still during HB refractoriness, and it does accelerate the following atrial activation. Atrial activation sequence during the reset atrial complex is identical to that during SVT. This observation excludes atrioventricular nodal reentrant tachycardia (AVNRT), and favors orthodromic atrioventricular reentrant tachycardia (AVRT), but does not exclude the rare example of atrial tachycardia (AT) with a bystander bypass tract with atrial insertion close to the AT focus. The third VES is delivered during HB refractoriness (within 40 milliseconds before the anticipated anterograde HB activation) and it terminates the tachycardia without conducting to the atrium. This observation, when reproducible, excludes both AVNRT and AT, and proves that the tachycardia is an orthodromic AVRT. *CS_{dist}*, Distal coronary sinus; *CS_{prox}*, proximal coronary sinus; *HRA*, high right atrium; *RVA*, right ventricular apex.

orthodromic AVRT (e.g., PJRT or nodofascicular reentrant tachycardia) as the mechanism of the SVT. Similarly, a VES delivered when the HB is refractory that terminates the SVT without atrial activation is diagnostic of AVRT.^{4,30}

Termination. Termination of AVNRT with a single VES is difficult and occurs rarely when the TCL is less than 350 milliseconds; such termination favors the diagnosis of orthodromic AVRT, which can usually be readily terminated by single or double VESs. Termination of the SVT with a VES delivered when the HB is refractory excludes AVNRT and AT (see Fig. 20.11), except in the presence of an innocent bystander BT mediating VA conduction. Reproducible termination of the SVT with a VES not followed by atrial activation excludes AT (see Fig. 18.42) and, if this occurs with a VES delivered while the HB is refractory, it excludes both AT and AVNRT (see Fig. 20.11).

Ventricular Overdrive Pacing During Tachycardia

Ventricular pacing is performed at a CL 10 to 30 milliseconds shorter than the TCL; the PCL is then progressively reduced by 10 to 20 milliseconds in a stepwise fashion with cessation of ventricular pacing after each PCL to verify continuation versus termination of the SVT. The presence of ventricular capture during ventricular pacing should be verified. In addition, the presence of 1:1 VA conduction and acceleration of the atrial rate to the PCL should be carefully examined (Fig. 20.12). It is also important to verify the continuation of the SVT following cessation of ventricular pacing and whether SVT termination,

with or without reinduction of the SVT, has occurred during ventricular pacing (Fig. 20.13).

VA dissociation. When overdrive ventricular pacing during SVT fails to accelerate the atrial CL to the PCL (i.e., the ventricles are dissociated from the tachycardia), AVRT is excluded, AT is the most likely diagnosis, but AVNRT is still possible.

Atrial activation sequence. As noted, the retrograde atrial activation sequence during ventricular pacing is usually similar to that during the SVT in the setting of AVNRT and orthodromic AVRT because it should conduct over the tachycardia retrograde limb. On the other hand, the retrograde atrial activation sequence during ventricular pacing is usually different from that during AT, except for ATs originating close to the AV junction. A pitfall of this criterion is the presence of a bystander AV BT, which can provide another retrograde route capable of mediating retrograde conduction during ventricular pacing without being part of the SVT circuit. In this setting, ventricular pacing can result in a retrograde atrial activation sequence different from that of AVNRT or orthodromic AVRT. The presence of such an AV BT, however, is generally easy to verify with ventricular stimulation during NSR.

Entrainment. Ventricular pacing is almost always able to entrain AVNRT and orthodromic AVRT and, if 1:1 VA conduction is maintained, reentrant AT. Although the mere demonstration of tachycardia entrainment does not help discrimination between the different SVT mechanisms, several parameters during ventricular entrainment can help establish the lower portion of the tachycardia circuit as macroreentry

Fig. 20.12 Overdrive Ventricular Pacing During Supraventricular Tachycardia (SVT). The SVT has a long RP interval and concentric atrial activation sequence, which favors atypical atrioventricular nodal reentrant tachycardia (AVNRT), atrial tachycardia (AT) originating close to the atrioventricular junction, or orthodromic atrioventricular reentrant tachycardia (AVRT) using a slowly conducting septal bypass tract. Overdrive ventricular pacing during the tachycardia fails to entrain the tachycardia or capture the atrium (no ventriculoatrial [VA] conduction) because the tachycardia atrial cycle length (CL; 450 milliseconds) remains stable and unaltered by the faster ventricular pacing CL (400 milliseconds). Therefore analysis of the postpacing interval or VA interval during pacing versus SVT is invalid. Analysis of the response sequence following cessation of pacing (atrial-ventricular vs. atrial-atrial-ventricular [A-A-V] response) is also invalid in view of the lack of 1:1 VA conduction during ventricular pacing (resulting in a pseudo-A-A-V response). Nonetheless, the fact that ventricular pacing has dissociated the atrium from the ventricle excludes AVRT. However, other pacing maneuvers are required for differentiation between atypical AVNRT and AT. CS_{prox}, proximal coronary sinus; HRA, high right atrium; RVA, right ventricular apex.

involving the HPS/ventricle (AVRT) or not (AVNRT, AT).³⁰ These parameters include the presence of manifest ventricular fusion, VA interval during ventricular pacing as compared with that during SVT, the PPI, and differential-site ventricular entrainment.^{26,27}

Manifest ventricular fusion. As discussed previously, manifest ventricular fusion during SVT entrainment is proof that the ventricle is part of the SVT circuit (i.e., diagnostic of AVRT), excluding AVNRT, AT, and junctional tachycardia (see Fig. 18.43). During ventricular entrainment of AVNRT, AT, or junctional tachycardia, the QRS morphology is that of pure ventricular pacing. A requirement for the presence of fusion is spatial separation between the sites of entrance to and exit from the reentrant circuit, which is absent in the setting of AVNRT, AT, and junctional tachycardia, each of which has a single “gate” to the ventricles (the HB). In orthodromic AVRT, the entrance (HPS) and exit (BT ventricular insertion site) of the reentrant circuit to and from ventricular tissue are separated from each other. In this setting, the paced wavefront can activate a portion of the ventricles and enter the AVRT circuit and at the same time the tachycardia wavefront emerge from the reentry circuit at a distant exit site and activate another part of the ventricles. Also, the relative proximity of the pacing site to the entry and exit sites of the reentry circuit is a critical determinant for the occurrence of fusion during resetting and entrainment. Pacing at a site closer to the BT ventricular insertion site (e.g., LV pacing in the setting of left free-wall BTs, and RV basal pacing in the setting of right-sided or septal BTs) than the entrance of the reentrant circuit to ventricular tissue (i.e., the HPS) results in a larger degree of fusion of QRS morphology between baseline morphology during orthodromic AVRT and that of fully paced QRS (see Fig. 18.43).^{31,32}

It is important to understand, however, that overdrive pacing of a tachycardia of any mechanism (including focal AT, junctional tachycardia, and AVNRT) can result in a certain degree of fusion, especially when the PCL is only slightly shorter than the TCL. Such fusion, however, is unstable during the same pacing drive at a constant CL because the pacing stimuli fall on a progressively earlier portion of the tachycardia cycle, producing progressively less fusion and more fully paced morphology. Such phenomena should be distinguished from entrainment, and sometimes this requires pacing for long periods to demonstrate variable degrees of fusion.

ΔVA interval. Entrainment of the SVT by RV pacing can help differentiate orthodromic AVRT from AVNRT by evaluating the VA interval during SVT (measured from the onset of surface QRS to high RA electrogram) versus the VA interval during pacing (i.e., SA interval measured from the ventricular pacing stimulus to the high RA electrogram). The ventricle and atrium are activated in sequence during orthodromic AVRT and during ventricular pacing, but in parallel during AVNRT. Therefore the VA interval during orthodromic AVRT approximates that during ventricular pacing (see Fig. 18.43). In contrast, the VA interval during AVNRT would be much shorter than that during ventricular pacing (see Fig. 17.19). In general, a difference in the VA interval ($\Delta VA [VA_{\text{pacing}} - VA_{\text{SVT}}]$) greater than 85 milliseconds is consistent with AVNRT, whereas a ΔVA of less than 85 milliseconds is consistent with orthodromic AVRT (Fig. 20.14).^{33,34}

This measurement resembles the “stimulus-exit” interval versus “electrogram-exit” interval criterion used in entrainment mapping of macroreentrant AT and VT. In the setting of AVNRT and AVRT, the “electrogram” is represented by the QRS onset, and the “exit” is

Fig. 20.13 Overdrive Ventricular Pacing During Atrioventricular Nodal Reentrant Tachycardia (AVNRT).

The tachycardia has a short RP interval and concentric atrial activation sequence and simultaneous atrial and ventricular activation, consistent with typical AVNRT. Overdrive ventricular pacing (*S1*) started from the right ventricular apex (*RVA*) at a cycle length (*CL*) 18 milliseconds shorter than the tachycardia *CL*. The numbers 1 to 7 indicate the paced QRS complexes with stable (purely paced) morphology. Note that the first constant-appearing QRS complex to reset atrial activation is QRS #4 (as indicated by the *blue arrow*), which excludes atrioventricular reentrant tachycardia, and is consistent with AVNRT. Also note that the tachycardia terminates after that, and QRS #5 is not followed by atrial activation (*red arrow*). QRS #6 and #7 conduct retrogradely to the atrium (*green arrows*) and reinitiate typical AVNRT. Since the tachycardia was terminated and then reinitiated during the same pacing drive, entrainment is not present, and analysis of the postpacing interval is not valid. *CS_{dist}*, Distal coronary sinus; *CS_{prox}*, proximal coronary sinus; *HRA*, high right atrium.

represented by the subsequent atrial electrogram, which is orthodromically captured during ventricular entrainment and represents the exit site from the reentry circuit to the atrium. Hence, the stimulus to the subsequent atrial-entrained electrogram interval (SA interval) is compared to the electrogram (QRS onset) to the subsequent atrial electrogram during tachycardia (VA interval). As a consequence, the shorter the difference between the two intervals, the closer the pacing site to the reentry circuit.³²

Postpacing interval. The PPI reflects conduction time from the ventricular pacing site to the SVT circuit, once around the reentry circuit, and then back to the pacing site. The difference between the PPI and TCL ($PPI - TCL$) represents the conduction time from the pacing site to the reentry circuit and back. Thus the ($PPI - TCL$) difference can qualitatively estimate how far (in terms of conduction time) the reentrant circuit is from the pacing site; the greater the ($PPI - TCL$) difference, the longer the conduction time between the pacing site and reentry circuit, and the greater the “electrical” distance is between the pacing site and the circuit.³²

Because the RV is closer to the AVRT circuit as compared to the AVNRT circuit, the ($PPI - TCL$) difference following entrainment from the RV apex is smaller in the setting of AVRT than during AVNRT. In

fact, a ($PPI - TCL$) difference of more than 115 milliseconds was found to identify AVNRT (see Figs. 17.19 and Fig. 20.14), whereas a ($PPI - TCL$) difference of less than 115 milliseconds was consistent with orthodromic AVRT (see Fig. 18.43). For borderline values, ventricular pacing at the RV base can help exaggerate the ($PPI - TCL$) difference in the setting of AVNRT, but without significant changes in the setting of orthodromic AVRT (see differential-site RV entrainment later).^{11,35}

A relatively common phenomenon encountered during entrainment of orthodromic AVRT by ventricular pacing is the prolongation of the AH interval because of decremental conduction properties of the AVN or (in the presence of dual AVN physiology) a jump of anterograde conduction from the fast pathway to the slow pathway. The prolonged AH interval on the last entrained beat will contribute to prolongation of the PPI that is not reflective of the distance of the pacing site from the circuit. Thus the ($PPI - TCL$) differences obtained after entrainment of orthodromic AVRT employing a septal BT can actually overlap with those observed after entrainment of AVNRT. “Correction” of the PPI by subtracting the increment in AVN conduction time in the first PPI (postpacing AH interval minus prepacing AH interval) from the ($PPI - TCL$) difference (“corrected” [$PPI - TCL$]) has been found to improve the accuracy of this criterion. The difference between AV intervals

Fig. 20.14 Ventricular Entrainment of Supraventricular Tachycardia (SVT). Ventricular entrainment if achieved with pacing from the RVA. Several features in this tracing can help in the differential diagnosis of the SVT. First, atrial and ventricular activation occur simultaneously during the SVT, which excludes atrioventricular reentrant tachycardia (AVRT). Second, atrial activation during the SVT is eccentric, with earliest activation in the mid-coronary sinus (CS), which favors atrial tachycardia (AT) over atrioventricular nodal reentrant tachycardia (AVNRT). Third, the atrial activation sequence during ventricular pacing is identical to that during SVT, which favors AVNRT and AVRT over AT. Fourth, following cessation over ventricular pacing, the post-pacing interval (PPI) minus SVT cycle length (CL), ($PPI - SVT\ CL$), is more than 115 milliseconds, and the Atriculoatrial (VA) interval ($VA_{\text{pacing}} - VA_{\text{SVT}}$) is more than 85 milliseconds, which favors AVNRT over AVRT. Fifth, although characterization of the activation sequence following cessation of ventricular pacing (atrial-atrial-ventricular [A-A-V] vs. atrial-ventricular [A-V] response) is unclear (because of the simultaneous occurrence of atrial and ventricular activation in the first tachycardia complex, replacing ventricular activation with HB activation [i.e., characterizing the response as A-A-H or A-H instead of A-A-V or A-V, respectively]) reveals an A-H response, which favors AVRT and AVNRT over AT. In summary, AVRT can be reliably excluded by the simultaneous atrial and ventricular activation. AT is excluded by the A-H response following cessation of ventricular pacing and by the identical atrial activation sequence during the SVT and ventricular pacing. The left variant of typical AVRT (with an eccentric atrial activation sequence) is the mechanism of the SVT. CS_{dist}, Distal coronary sinus; CS_{prox}, proximal coronary sinus; HRA, high right atrium; PCL, pacing cycle length; RVA, right ventricular apex.

(postpacing AV interval minus prepacing AV interval) can be taken for the latter adjustment when a His deflection is not clearly visible (assuming the HV interval remains constant). In a study of patients with both typical and atypical forms of AVNRT, as well as orthodromic AVRT using septal and free-wall BTs, a corrected ($PPI - TCL$) difference of less than 110 milliseconds was found more accurate in identifying orthodromic AVRT from AVNRT than the uncorrected ($PPI - TCL$) difference.^{36–38}

Of note, determinations of the corrected ($PPI - TCL$) and ΔVA ($VA_{\text{pacing}} - VA_{\text{SVT}}$) after resetting with single or double VESs from the RV apex, are of similar value for discrimination between AVNRT and orthodromic AVRT even when the SVT is interrupted by ventricular pacing. Corrected ($PPI - TCL$) of more than 110 milliseconds and ΔVA of more than 110 milliseconds after resetting are consistent with AVNRT.³⁹

Importantly, there are several potential pitfalls to the ΔVA interval and PPI criteria discussed previously. The TCL and VA interval are often perturbed for a few cycles after entrainment. For this reason, care should be taken not to measure unstable intervals immediately after ventricular pacing. In addition, oscillations in the TCL and VA intervals can occur spontaneously during the SVT. The discriminant points chosen may not apply when the spontaneous variability is greater than 30 milliseconds. Also, it is possible to mistake isorhythmic VA dissociation for entrainment if the pacing train is not long enough or the PCL is

too close to the TCL. Furthermore, this test is less reliable and should be used with caution in patients with left lateral BTs. In addition, these criteria may not apply to BTs with significant decremental properties, although small decremental intervals are unlikely to provide a false result.

Conventional SVT criteria during entrainment from the ventricle establish the lower portion of the tachycardia circuit as macroreentrant involving the HPS/ventricle (AVRT) or not. Importantly, slow, decremental BT conduction (e.g., during PJRT or nodofascicular reentrant tachycardia) can affect the sensitivity of the ΔVA and ΔHA criteria for orthodromic AVRT, although the specificity of these criteria remains high. Therefore any standard criteria that is positive for orthodromic AVRT ($[PPI - TCL] < 115$ milliseconds, corrected $[PPI - TCL] < 110$ milliseconds, $\Delta VA < 85$ milliseconds, and $\Delta HA < 0$ milliseconds) is considered diagnostic for orthodromic AVRT, despite discordance among them, which can occur up to 50% of the time. In addition, a higher cutoff value of 125 milliseconds was found to increase the sensitivity for orthodromic AVRT while maintaining a high specificity.³⁰

Differential-site RV entrainment. Differential-site RV entrainment (from RV apex vs. RV base) can help distinguish AVNRT from orthodromic AVRT. Because the reentrant circuit in AVNRT is confined above the HB and does not involve the ventricle, the base of the RV is electrically more distant (although anatomically closer) from the tachycardia

circuit than the RV apex, given that the His-Purkinje network directly inserts near the RV apex. Consequently, the PPI after entrainment of AVNRT from the RV base is longer than that following entrainment from the RV apex. The difference in PPI from the RV base versus the RV apex is largely composed of the extra time required to reach the circuit from the base versus the apex (approximately 30 milliseconds). Conversely, in orthodromic AVRT, in which the ventricles are an obligatory part of the circuit, the basal pacing site relative to the RV apex is variably related to the circuit, closer than the RV apex with septal BTs and equidistant with free-wall BTs, but the paced wavefront from the RV apex or RV base tends to have, on average, approximately equal access and proximity to the reentrant circuit involved in orthodromic AVRT. Therefore the time taken to reach the circuit (and hence the PPI) tends to be similar, irrespective of the location of the BT.

Correction of the PPI (to avoid potential error introduced by decremental conduction within the AVN during ventricular pacing) increases the accuracy of this method, although the degree of decrement is not expected to be materially different from basal rather than apical pacing as long as the pacing rates are the same or similar. The “corrected PPI” is obtained by subtracting any increase in the AV interval of the return cycle beat (as compared with the AV interval during SVT). A differential corrected (PPI – TCL) difference of more than 30 milliseconds after transient entrainment was found to be consistent with AVNRT (i.e., corrected [PPI – TCL] difference following pacing from the RV base was consistently at least 30 milliseconds longer than that following pacing from the RV apex). In contrast, a corrected (PPI – TCL) difference of less than 30 milliseconds was observed in all cases of orthodromic AVRT. In addition, a differential VA interval (VA interval during entrainment from RV base vs. RV septum) of more than 20 milliseconds was consistent with AVNRT, whereas a differential VA interval of less than 20 milliseconds was consistent with orthodromic AVRT.^{40,41}

The main advantage of this technique is that the differential VA interval can be calculated from the last paced beat if the tachycardia is terminated after transient entrainment.

Length of pacing drive required for entrainment. Assessing timing and type of response of SVT to RV pacing can help differentiate orthodromic AVRT from AVNRT. In the setting of orthodromic AVRT, ventricular myocardium is the only intervening tissue between the pacing wavefront and the ventricular insertion site of the BT. Therefore once ventricular capture is achieved during RV pacing, the paced wavefront propagates to the ventricular insertion site of the BT quickly and resets the tachycardia (i.e., advances or delays atrial activation time). Consequently, RV pacing results in resetting of AVRT with septal or right-sided BT immediately once the RV is fully captured by the paced wavefront. During AVNRT, on the other hand, the pacing site is distant from the SVT circuit, and the paced wavefront has to propagate through ventricular tissue, then through the HPS, followed by AVN tissue prior to resetting the tachycardia. As a consequence, resetting of AVNRT is delayed for several captured paced beats as compared with orthodromic AVRT (eFig. 20.1). This observation is consistent with the concept that overdrive pacing begins to advance a reentrant tachycardia precisely when the total pacing prematurity exceeds the (PPI – TCL) after correcting for conduction velocity changes associated with the shorter CL.⁴²

After initiation of synchronized RV pacing during SVT at a CL 10 to 40 milliseconds shorter than the TCL, once constant-appearing paced QRS complexes (either pure capture or fixed fusion) are observed, the number of constant-appearing paced QRS complexes required to accelerate atrial activation timing to the PCL is determined. The first atrial beat accelerated to the PCL is identified by demonstrating a fixed ventricular stimulus-to-atrial capture interval (SA interval). One report demonstrated that resetting of the SVT occurring by the first beat with stable paced QRS morphology identifies all orthodromic AVRT and

essentially excludes AVNRT with high accuracy. On the other hand, resetting of the SVT occurring only after two or more beats with stable (fully paced) QRS morphology is consistent with AVNRT (see Fig. 20.13).

The major advantage of this method is its independence of tachycardia continuation after cessation of pacing. However, it is likely that these criteria may not be applicable at PCLs more than 40 milliseconds shorter than the TCL or with prematurity of more than 80% of the TCL (which can occur with poorly synchronized stimulation), because resetting of the tachycardia can occur earlier in AVNRT in response to a greater degree of penetration into the tachycardia circuit. In addition, these findings may not apply in cases in which AVNRT occurs in the setting of a bystander BT because SVT may be reset using the bystander BT. In addition, although this technique is effective for differentiating septal pathways from atypical AVNRT, it may be less useful in patients with BTs remote from the pacing stimulus (e.g., left free-wall BTs) (Fig. 20.15).^{43,44}

Atrial resetting during the transition zone. On initiation of synchronized RV pacing trains during SVT at a rate slightly faster than the TCL, there is a transition zone during which the pacing train fuses with anterograde ventricular activation (i.e., the zone in which the paced QRS complexes show progressive fusion with the SVT complexes) until a stable QRS morphology is observed (either completely paced or constantly fused). The transitional zone begins with progressive fusion beats between the paced and tachycardia wavefronts and ends with the first beat of stable QRS morphology, the latter representing constant fusion in the setting of orthodromic AVRT and a fully paced QRS morphology in patients with AVNRT or AT. In patients with AVNRT or AT, acceleration of the timing of atrial activation cannot occur through the AVN during the transition zone. The reason is that the HB is expected to be refractory, as indicated by at least some ventricular activation still occurring by anterograde conduction over the HPS. If perturbation of atrial timing occurs during the transition zone, it indicates the presence of a retrogradely conducting BT, which can be an integral part of the SVT circuit (i.e., orthodromic AVRT) or a bystander. In one report, these criteria showed excellent diagnostic accuracy and could be applied regardless of whether entrainment was achieved or whether the SVT terminated during pacing. Perturbation of atrial timing of at least 15 milliseconds or a fixed SA interval measured from the last beat of the transition zone was seen in all the patients with orthodromic AVRT and in none of the patients with AVNRT or AT (unless a bystander retrogradely conducting BT is present).^{41,45}

Atrial and ventricular electrogram sequence following cessation of ventricular pacing

Technique. During SVT, synchronized ventricular overdrive pacing is initiated at a PCL 10 to 30 milliseconds shorter than the TCL until 1:1 VA conduction occurs, at which point pacing is stopped. If pacing results in termination of the tachycardia, SVT is reinduced, and the maneuver is repeated. If ventricular pacing does not terminate the tachycardia and the presence of stable 1:1 VA conduction is verified, the electrogram sequence immediately after the last paced ventricular complex is categorized as an atrial-ventricular (A-V) or atrial-atrial-ventricular (A-A-V) pattern (see Fig. 11.16).

Interpretation. During AVNRT or orthodromic AVRT, when the ventricle is paced at a CL shorter than the TCL and all electrograms are accelerated to the pacing rate without terminating the tachycardia, VA conduction occurs through the retrograde limb of the circuit. Therefore, after the last paced ventricular complex, the anterograde limb of the tachycardia circuit is not refractory, and the last entrained retrograde atrial complex can conduct to the ventricle. This results in an A-V response following cessation of pacing. However, when the ventricle is paced during AT and 1:1 VA conduction is produced, retrograde conduction occurs through the AVN. In this setting, the last retrograde

Fig. 20.15 Overdrive Ventricular Pacing During Atrioventricular Reentrant Tachycardia (AVRT). The tachycardia has a short RP interval and an eccentric atrial activation sequence consistent with orthodromic AVRT utilizing a left lateral bypass tract as the retrograde limb. Overdrive ventricular pacing (S1) started from the right ventricular apex (RVA) at a cycle length (CL) 14 milliseconds shorter than the tachycardia CL. The numbers 1 to 6 indicate the paced QRS complexes with stable morphology. Note that the first constant-appearing QRS complex to affect atrial activation is QRS #3 (as indicated by the red arrow). Although this finding typically indicates atrioventricular nodal reentrant tachycardia, and excludes orthodromic AVRT utilizing a septal bypass tract (BT), it can also be observed in orthodromic AVRT when the BT is remote from the ventricular pacing site, like in this case. CS_{dist}, Distal coronary sinus; CS_{prox}, proximal coronary sinus; HRA, high right atrium.

atrial complex resulting from ventricular pacing is unable to conduct back to the ventricle because the AVN is refractory to anterograde conduction and there is no alternate route for anterograde conduction to the ventricle available (unlike AVNRT and AVRT), and the result is an A-A-V response.

Pitfalls. This pacing maneuver is not useful when 1:1 VA conduction during ventricular pacing is absent. Thus, when determining the response after ventricular pacing during SVT, the presence of 1:1 VA conduction must be confirmed. Isorhythmic VA dissociation can mimic 1:1 VA conduction, especially when the pacing train is not long enough or the PCL is too slow (see Fig. 11.17).

Pseudo-A-A-V response. A pseudo-A-A-V response can occur during atypical AVNRT (eFig. 20.2). Because retrograde conduction during ventricular pacing occurs through the slow pathway, the VA interval is long and can be longer than the PCL (V-V interval), so that the last paced QRS is followed first by the atrial complex resulting from slow VA conduction of the preceding paced QRS and then by the atrial complex resulting from the last paced QRS. To avoid this potential pitfall, the A-A intervals are measured during and after ventricular overdrive pacing, and the last atrial electrogram resulting from VA conduction during ventricular pacing is carefully examined. The last retrograde atrial complex characteristically occurs at an A-A interval equal to the ventricular PCL, whereas the first tachycardia atrial complex usually occurs at a longer return CL.

A pseudo-A-A-V response can also occur when 1:1 VA conduction is absent during overdrive ventricular pacing (see Fig. 20.12), during typical AVNRT with long HV intervals or short HA intervals (whereby atrial activation may precede ventricular activation), and in patients with a bystander BT. Replacing ventricular activation with His activation (i.e., characterizing the response as A-A-H or A-H instead of A-A-V or A-V, respectively) can be more accurate and can help eliminate the pseudo-A-A-V response in patients with AVNRT and long HV intervals, short HA intervals, or both.⁴⁶

Pseudo-A-V response. A pseudo-A-V response can occur with an automatic AT when the maneuver is performed during isoproterenol infusion. Ventricular pacing with 1:1 VA conduction can result in overdrive suppression of the atrial focus, and isoproterenol can enhance junctional automaticity, so that an apparent A-V response occurs. Therefore, when ventricular pacing is performed during an isoproterenol infusion, it is important to determine that the response after cessation of ventricular pacing is reproducible.²⁸

A pseudo-A-V response can theoretically occur when AT coexists with retrograde dual AVN pathways or a bystander BT. In such cases, the last retrograde atrial complex would have an alternative route for anterograde conduction to the ventricle, other than the one used for retrograde VA conduction during ventricular pacing, thus resulting in an A-V response. However, clinical occurrence of these theoretical scenarios has not been observed, probably because of retrograde penetration

A

B

Fig. 20.2 Antitachycardia Pacing (ATP) During Supraventricular Tachycardia (SVT). (A) Intracardiac atrial and ventricular electrograms (A-EGM and V-EGM, respectively) stored by the implantable cardioverter defibrillator (ICD) during an episode of SVT at a cycle length (CL) of 280 to 290 milliseconds and a 1:1 atrioventricular relationship. The SVT inappropriately triggered ATP therapy by the ICD with a burst of eight ventricular paced beats at a CL of 250 milliseconds. ATP fails to terminate the tachycardia, which resumes at the baseline CL. (B) Magnification of a portion of the upper panel showing atrial and ventricular intracardiac electrograms during ATP. Arrows track ventriculoatrial (VA) conduction following the last four paced ventricular complexes. VA conduction during ATP is present and can be verified by demonstrating acceleration of the atrial rate to that of the paced ventricular rate. After cessation of ATP, the tachycardia resumes with an atrial-atrial-ventricular (A-A-V) electrogram sequence, which is evident on interrogation of the atrial and ventricular channel electrograms (lower panel). However, careful analysis to identify the last reset atrial complex (occurring at a CL similar to the pacing CL) indicates a pseudo-A-A-V response rather than an A-A-V electrogram sequence, which is consistent with atypical AV nodal reentrant tachycardia as the mechanism of the SVT. See text for discussion.

of both AVN pathways or of the AVN and the BT during ventricular pacing, so that both pathways are refractory to anterograde conduction on cessation of pacing.²⁸

Termination. Ventricular pacing can easily terminate orthodromic AVRT, and failure to terminate the SVT with ventricular pacing argues against orthodromic AVRT. Termination of AVNRT is also common, but AT is less likely to be terminated by ventricular pacing.

Para-Hisian Pacing During Tachycardia

Para-Hisian entrainment or resetting

Technique. Entrainment of the tachycardia is performed by pacing at the para-Hisian region using the HB catheter at a PCL 10 to 30 milliseconds shorter than the TCL. Entrainment is confirmed when the atrial CL accelerates to the PCL, without a change in the atrial activation sequence, and the tachycardia continues after pacing is discontinued.⁴⁷

Para-Hisian entrainment is performed by alternately pacing at high-energy output for HB-RB capture or lower energy output for HB-RB noncapture. Entrainment with HB-RB capture is recorded separately from that without HB-RB capture. The SA (stimulus-to-earliest atrial activation) and local VA intervals during HB-RB capture and noncapture are then examined.

One must be cautious about performing the para-Hisian entrainment maneuver by simply decreasing the pacing energy output during the same run to achieve HB-RB noncapture. That is, even though the SVT may have been entrained during HB-RB capture, on loss of HB-RB capture, the initial paced complexes typically do not entrain the SVT. This initial failure of entrainment occurs because of the sudden increase in the distance from the pacing site to the actual reentrant circuit. During HB-RB capture of AVNRT, the pacing site is near the circuit (the HB-RB); however, during HB-RB noncapture, the pacing site (the basal RV myocardium) is well outside the circuit. This limitation would not apply if HB-RB noncapture is performed *prior* to HB-RB capture. That is, if the pacing output is increased while the SVT is being entrained during HB-RB noncapture, the circuit almost certainly will be entrained on HB-RB capture (unless the SVT terminates).

If para-Hisian entrainment cannot be performed because of repetitive termination of the tachycardia during entrainment attempts, isoproterenol or epinephrine infusion may be used to help sustain the rhythm. Alternatively, single or double VESs can be given to reset the tachycardia (para-Hisian resetting). These VESs are delivered at progressively shorter coupling intervals until the first VES that reliably advances or resets the tachycardia. This is performed alternately with high- or low-energy outputs to achieve HB-RB capture and noncapture, respectively. As with para-Hisian entrainment, the retrograde atrial activation sequence and timing are compared during para-Hisian resetting to characterize the response.

Interpretation. In AVNRT (typical or atypical), the AVN-AVN pattern is observed in response to para-Hisian entrainment or resetting. Both the SA and the local VA intervals increase during HB-RB noncapture compared with HB-RB capture.

In orthodromic AVRT, the BT-BT pattern or BT-BT_L pattern is observed. In the setting of a BT-BT pattern, the SA and local VA intervals are usually not significantly different between HB-RB capture and noncapture. Conversely, in the case of a BT-BT_L pattern, the SA interval increases on HB-RB noncapture, but without significant change in the local VA interval.

A Δ SA interval of less than 40 milliseconds was found to be a reasonable guide to separating the AVN-AVN from the BT-BT response. Patients with AVNRT uniformly have a Δ SA interval of greater than 40 milliseconds, whereas those with AVRT have a Δ SA interval of less than 40 milliseconds (except for rare patients with a left lateral BT). Using the Δ local VA interval (instead of the Δ SA interval) pro-

vides a more accurate parameter for discrimination between AVNRT and AVRT.

Fusion patterns during para-Hisian entrainment or resetting have not been observed in patients with AVNRT. This is a potential advantage over para-Hisian pacing during NSR in identifying the presence of a BT. Because retrograde VA conduction can only proceed over a single route during entrainment of the SVT (assuming that a complex scenario such as multiple BTs is not present), the various forms of retrograde fusion that might be seen with para-Hisian pacing during NSR cannot occur with para-Hisian entrainment or resetting.

Para-Hisian overdrive pacing

Technique. During SVT, para-Hisian pacing is performed at a PCL 10 to 30 milliseconds shorter than the TCL. Responses to this maneuver are then classified as follows: (1) entrainment occurs when the atrial CL is accelerated to the PCL, without a change in the atrial activation sequence, and the tachycardia resumed after pacing was discontinued; (2) termination occurs when pacing results in termination of the tachycardia; and (3) AV dissociation occurs when HB capture is confirmed and no change in the atrial CL is observed.

When response 1 or 2 is observed, the number of beats required to enter the tachycardia circuit is determined. Any change in atrial timing (advance or delay of at least 10 milliseconds) or termination of the SVT is considered to represent entry into the tachycardia circuit. The surface ECG is examined to determine the first beat where a consistent nonfused paced QRS morphology is observed. This beat is taken as beat 1 for the purposes of analysis. The number of beats required to enter the tachycardia circuit is determined by counting from beat 1 each time the maneuver is performed.

Interpretation. Because the HB is a necessary component for the circuit in AVRT, overdrive capture of the HB during AVRT should result in immediate entry into the tachycardia. In contrast, HB overdrive pacing during AVNRT may not immediately enter the circuit because the HB is not an obligate component. Therefore entry into the tachycardia circuit within 1 beat indicates AVRT, whereas entry into the circuit occurring only after 3 or more beats is consistent with AVNRT.⁴⁸

This technique does not require confirmation of both HB capture and noncapture. In addition, unlike para-Hisian entrainment whereby termination of the SVT occurs frequently and precludes analysis of Δ SA interval, termination of SVT during para-Hisian overdrive pacing serves as confirmation that the pacing stimulus has entered and perturbed the tachycardia circuit.⁴⁸

Of note, this principle should apply to any tachycardia using a BT and the HB, including atriofascicular, concealed nodofascicular, decremental, and left lateral BTs. Moreover, it should be useful in distinguishing AVNRT with bystander pathway participation from antidromic AVRT.⁴⁸

Diagnostic Maneuvers During Sinus Rhythm After Tachycardia Termination

When pacing the atrium or ventricle at the TCL, it is important that the autonomic tone be similar to its state during the tachycardia because alterations of autonomic tone can independently influence AV or VA conduction.

Atrial Pacing at the Tachycardia Cycle Length

Δ AH interval. The difference in the AH interval between atrial pacing (at the TCL) and SVT can allow differentiation of fast-slow AVNRT from other types of long RP tachycardias. A Δ AH ($HA_{\text{pacing}} - AH_{\text{SVT}}$) greater than 40 milliseconds favors AVNRT. In contrast, during AT and orthodromic AVRT utilizing a septal BT, the AH interval during SVT approximates that during atrial pacing. In contrast, a Δ AH of less than 20 milliseconds favors AT and orthodromic AVRT. This has only

been tested with RA pacing during right ATs and should be applied with caution when a left AT is suspected.¹¹

The ΔAH ($\text{AH}_{\text{pacing}} - \text{AH}_{\text{SVT}}$) can also help differentiate typical (slow-fast) AVNRT from AT with a long PR interval. Atrial pacing during NSR at the TCL yields an AH interval that is similar to that during AT but shorter than the AH interval during typical AVNRT. During atrial pacing and AT, AV conduction occurs preferentially over the fast pathway and, hence, is expected to be associated with similar AH and PR intervals (under comparable autonomic tone). In contrast, AV conduction during typical AVNRT occurs over the slow pathway, resulting in a long AH interval.

Ventricular Pacing at the Tachycardia Cycle Length

ΔHA interval. To help distinguish between orthodromic AVRT and AVNRT, ventricular pacing is performed during NSR (with PCL equal to the TCL), and the HA interval during SVT is compared to that during ventricular pacing. The HA interval is measured from the *end* of the His potential (where the impulse leaves the HB to enter the AVN) to the atrial electrogram in the high RA recording and the ΔHA interval ($\text{HA}_{\text{pacing}} - \text{HA}_{\text{SVT}}$) is calculated.

In the setting of orthodromic AVRT, the ΔHA interval is typically less than -10 milliseconds. Ventricular pacing results in HA and VA intervals that are shorter than those during orthodromic AVRT, because the HB and atrium are activated sequentially during orthodromic AVRT but in parallel during ventricular pacing whereby the atrium is activated via the BT (see Fig. 18.43).

In contrast, in the setting of AVNRT the ΔHA interval is typically more than -10 milliseconds because the HA interval during AVNRT is shortened by parallel activation of both the HB and the atrium during the tachycardia (i.e., the HA interval is a “pseudo-interval” that represents activation times of the HB and atrium), whereas the HB and atrium are activated sequentially during ventricular pacing in the absence of a BT (i.e., the HA interval represents a true conduction time interval from the HB to the atrium). The ΔHA interval is even more pronounced in atypical AVNRT, which has a lower common pathway that is longer than that in typical AVNRT. In focal junctional tachycardia, the ΔHA interval is typically close to 0.⁴⁹

The main limitation of the ΔHA interval criterion is the ability to record the retrograde His potential during ventricular pacing. Retrograde His potential generally appears before the local ventricular electrogram in the HB tracing, and can be verified by the introduction of a VES that causes the His potential to occur after the local ventricular electrogram. Moreover, pacing from different sites (e.g., midseptum) may allow earlier penetration into the HPS and facilitate observation of a retrograde His potential. When the retrograde His potential is not visualized, using the ΔVA interval instead of the ΔHA interval is not as accurate in discriminating orthodromic AVRT from AVNRT.⁴

Another limitation is that VA conduction during ventricular pacing may not occur over the BT but propagates preferentially over the HPS-AVN, leading to earlier atrial activation over this pathway than over the BT. If this were the case, the HA interval during ventricular pacing would be shorter than that observed if the atrium were activated via the BT. This would yield a more negative ΔHA interval.

VA block. In the setting of AT and AVNRT, and under comparable autonomic tone, 1:1 VA conduction over the AVN may or may not be maintained during ventricular pacing at a PCL similar to the TCL because of possible retrograde block in the AVN or the lower common pathway. Anterograde conduction properties of the AVN or the lower common pathway may allow 1:1 conduction from the AT or AVNRT circuit down to the ventricle, but its retrograde conduction properties may not allow 1:1 retrograde conduction from the ventricle up to the atrium during ventricular pacing at a CL similar

to the TCL. On the contrary, in the setting of orthodromic AVRT, 1:1 VA conduction is expected to be maintained because of the presence of an AV BT that is capable of mediating VA conduction at rate at least as fast as that during the AVRT. Therefore, if VA block is observed during ventricular pacing at the TCL, orthodromic AVRT is excluded (with the exception of orthodromic AVRT using a slowly conducting AV BT), and AT or AVNRT with lower common pathway physiology is more likely.

Atrial activation sequence. The retrograde atrial activation sequence during ventricular pacing is usually similar to that during SVT in the setting of AVNRT, but slight differences of activation sequence can also be observed when the retrogradely conducting AVN pathway during AVNRT is different from that utilized during ventricular pacing. In the setting of orthodromic AVRT, a retrograde atrial activation sequence during ventricular pacing can be similar to or different from that during tachycardia, depending on whether retrograde VA conduction during ventricular pacing propagates over the AVN, the BT, or both. For AT, the retrograde atrial activation sequence during ventricular pacing is usually different from that during AT, except for ATs originating close to the AV junction.

PRACTICAL APPROACH TO ELECTROPHYSIOLOGICAL DIAGNOSIS OF SUPRAVENTRICULAR TACHYCARDIA

It is important to understand that there is no single diagnostic maneuver or algorithm that is adequate in distinguishing among the different types of SVTs in all cases. Each maneuver has its own applications and limitations, and almost all described diagnostic maneuvers have exceptions to their primary interpretation.⁴ Although several diagnostic criteria were found to have high specificity, sensitivity is frequently limited. Therefore the investigator will often need to use a combination of SVT features and pacing maneuvers to establish an accurate diagnosis. Systematic evaluation of all possibilities and adherence to fundamental EP principles will help establish the correct diagnosis. Each step during the EP study in these patients can offer valuable information to the vigilant investigator that, if recognized, can potentially reduce procedure time and improve outcome.

It is important for the electrophysiologist to be fully conversant with the maneuvers used for the differential diagnosis of the different arrhythmias. Exercising the application of these techniques on a routine basis, even when the diagnosis of the underlying arrhythmia mechanism has been established, helps the operator to correctly apply those diagnostic maneuvers in the more challenging cases and become familiar with the pitfalls, exceptions, and the spectrum of behavior of each technique.

Tables 20.1 to 20.3 and Fig. 20.16 outline some of the proposed strategies for the EP diagnosis of narrow complex SVTs. Baseline tachycardia features, atrial and ventricular programmed stimulation during the tachycardia and then during sinus rhythm after tachycardia termination, provide a diagnosis of the mechanism of SVT in the vast majority of cases.

Step 1

Characterize the A/V relationship, RP-PR ratio, and atrial activation sequence during tachycardia (see Table 20.1). The differential diagnosis is most challenging in the setting of SVTs with a concentric atrial activation sequence and a 1:1 A/V relationship. SVTs with very short RP intervals (simultaneous atrial and ventricular activation) and a concentric atrial activation sequence include: (1) typical AVNRT; (2) AT with a focus close to the AV junction with a long PR interval; (3) and junctional tachycardia. The differential diagnosis of a short

TABLE 20.1 Diagnostic Strategy for Narrow QRS Supraventricular Tachycardia: Tachycardia Features

Atrial activation sequence	<ul style="list-style-type: none"> Eccentric atrial activation sequence excludes AVNRT (except for the left variant of AVNRT). An initial atrial activation site away from the AV groove and AV junction is diagnostic of AT and excludes both AVNRT and orthodromic AVRT.
RP-PR interval ratio	<ul style="list-style-type: none"> Short RP with VA interval of <70 msec or a ventricular-to-high RA interval of <95 msec during SVT excludes orthodromic AVRT, and is consistent with AVNRT (most common), but can occur during AT with a long PR interval or junctional tachycardia (rare). Short RP with VA interval of >70 msec suggests orthodromic AVRT (most common), slow-slow AVNRT, and AT with a long PR interval. Long RP suggests fast-slow AVNRT, PJRT, and AT.
AV block	<ul style="list-style-type: none"> Spontaneous or induced AV block with continuation of the tachycardia is consistent with AT, excludes AVRT, and is uncommon in AVNRT.
VA block	<ul style="list-style-type: none"> VA block excludes orthodromic AVRT, and rarely occurs during AVNRT. Other potential mechanisms of SVT with VA block include junctional tachycardia with retrograde VA block and nodofascicular or nodoventricular reentrant tachycardia.
Effects of BBB	<ul style="list-style-type: none"> BBB does not affect the TCL or VA interval in AT, AVNRT, or orthodromic AVRT using a BT contralateral to the BBB. BBB that prolongs the VA interval, with or without affecting the TCL, is diagnostic of orthodromic AVRT using an AV BT ipsilateral to the BBB and excludes AT and AVNRT.
Tachycardia CL variations	<ul style="list-style-type: none"> Spontaneous changes in PR and RP intervals with a fixed A-A interval is consistent with AT, and excludes orthodromic AVRT. Spontaneous changes in the TCL accompanied by a constant VA interval ("VA linking") favor orthodromic AVRT. Changes in atrial CL preceding similar changes in subsequent ventricular CL strongly favor AT or atypical AVNRT. Changes in ventricular CL preceded by similar changes in the atrial CL favor typical AVNRT or orthodromic AVRT.
Tachycardia termination	<ul style="list-style-type: none"> Termination of SVT (spontaneous or in response to adenosine or vagal maneuvers) with a P wave not followed by a QRS practically excludes AT, except in the case of a nonconducted PAC terminating the AT. Reproducible SVT termination in response to adenosine with a QRS not followed by a P wave excludes orthodromic AVRT using a rapidly conducting AV BT as the retrograde limb, is unusual in typical AVNRT, and is consistent with AT, PJRT, or atypical AVNRT.

A-A, Atrial-atrial; AT, atrial tachycardia; AV, atrioventricular; AVNRT, atrioventricular nodal reentrant tachycardia; AVRT, atrioventricular reentrant tachycardia; BBB, bundle branch block; BT, bypass tract; CL, cycle length; PAC, premature atrial complex; PJRT, permanent junctional reciprocating tachycardia; RA, right atrium; SVT, supraventricular tachycardia; TCL, tachycardia cycle length; VA, ventriculoatrial.

Fig. 20.16 Algorithm for Diagnosis of Narrow Complex Supraventricular Tachycardia (SVT). Items in parentheses are rarely seen. AVNRT, Atrioventricular nodal reentry; CL, cycle length; PPI, postpacing interval; PVC, premature ventricular complex; SA, stimulus-to-atrial interval; TCL, tachycardia cycle length; VA, ventriculoatrial interval.

TABLE 20.2 Diagnostic Strategy for Narrow QRS Supraventricular Tachycardia: Programmed Electrical Stimulation During Tachycardia**Ventricular Extrastimulation**

Resetting with ventricular fusion	<ul style="list-style-type: none"> Resetting with manifest QRS fusion is consistent with orthodromic AVRT and excludes both AVNRT and focal AT.
Preexcitation index	<ul style="list-style-type: none"> Preexcitation index (the difference between the TCL and the longest VES coupling interval at which atrial capture occurs during tachycardia) ≥ 100 msec characterizes AVNRT, whereas an index < 45 msec is consistent with AVRT with a septal BT.
VA interval	<ul style="list-style-type: none"> ΔVA interval ($VA_{\text{pacing}} - VA_{\text{SVT}}$) > 110 msec (after resetting with single or double VESs from the RV apex) is consistent with AVNRT.
Postpacing interval	<ul style="list-style-type: none"> Corrected (PPI – TCL) > 110 msec (after resetting with single or double VESs from the RV apex) is consistent with AVNRT.
When the VES advances the next atrial activation	<ul style="list-style-type: none"> Advancement of the next atrial impulse occurring with a VES delivered when the HB is not refractory usually does not help differentiate among the different types of SVTs. If advancement occurs when the HB is refractory, AVNRT is excluded. If advancement occurs with an atrial activation sequence similar to that during SVT, regardless of the timing of the VES, AT is less likely than AVNRT or orthodromic AVRT.
When the VES delays the next atrial activation	<ul style="list-style-type: none"> When advancement occurs when the HB is refractory, with an atrial activation sequence similar to that during SVT, AVNRT is excluded, AT is unlikely, and orthodromic AVRT is the most likely diagnosis.
When the VES resets the next QRS without atrial activation	<ul style="list-style-type: none"> When the VES causes delay in the next atrial activation, regardless of the timing of the VES, AT is excluded, and when such delay occurs with a VES delivered when the HB is refractory, both AVNRT and AT are excluded.
When the VES terminates the SVT	<ul style="list-style-type: none"> When a VES resets the SVT without atrial activation (i.e., the VES advances the subsequent His potential and QRS), both AT and orthodromic AVRT are excluded. When termination occurs reproducibly with a VES delivered when the HB is refractory, AVNRT is excluded, and the presence of a retrogradely conducting AV BT is diagnosed. If the atrial activation sequence following the VES is similar to that during the SVT, orthodromic AVRT is indicated and AT is practically excluded, except for the rare case in which AT originates close to the atrial insertion site of an innocent bystander AV BT. When termination occurs reproducibly with a VES that does not activate the atrium, regardless of the timing of the VES in relation to the HB, AT is excluded; when this phenomenon is observed with a VES delivered when the HB is refractory, both AT and AVNRT are excluded and orthodromic AVRT is diagnosed.
When the VES fails to affect the next atrial activation	<ul style="list-style-type: none"> If resetting does not occur with a relatively late VES, this usually does not help in the differential diagnosis of SVT. If resetting does not occur with an early VES, despite advancement (by > 30 msec) of the local ventricular activation at ventricular sites near the site of earliest atrial activation, orthodromic AVRT and the presence of a retrogradely conducting AV BT are excluded.

Ventricular Pacing

VA dissociation	<ul style="list-style-type: none"> When overdrive ventricular pacing during SVT fails to accelerate atrial CL to the PCL (i.e., the ventricles are dissociated from the tachycardia), AVRT is excluded, AT is the most likely diagnosis, but AVNRT is still possible.
VA interval	<ul style="list-style-type: none"> ΔVA interval ($VA_{\text{pacing}} - VA_{\text{SVT}}$) > 85 msec is consistent with AVNRT. ΔVA of < 85 msec is consistent with orthodromic AVRT.
Postpacing interval	<ul style="list-style-type: none"> (PPI – TCL) > 115 msec (or corrected [PPI – TCL] > 110 msec) is consistent with AVNRT. (PPI – TCL) < 115 msec (or corrected [PPI – TCL] < 110 msec) is consistent with orthodromic AVRT.
Entrainment with ventricular fusion	<ul style="list-style-type: none"> Manifest ventricular fusion during entrainment indicates AVRT and excludes both AVNRT and AT.
Differential-site right ventricular entrainment	<ul style="list-style-type: none"> Differential corrected (PPI – TCL) of > 30 msec after transient entrainment from the RV apex vs. the RV base is consistent with AVNRT. Differential corrected (PPI – TCL) of < 30 msec is consistent with orthodromic AVRT. Differential VA interval (ventricular stimulus-to-atrial interval during entrainment from RV base vs. RV septum) of > 20 msec is consistent with AVNRT. Differential VA interval of < 20 msec is consistent with orthodromic AVRT.
Atrial resetting during the transition zone	<ul style="list-style-type: none"> Atrial resetting (perturbation of atrial timing by > 15 msec) during the transition zone is consistent with orthodromic AVRT and excludes AVNRT or AT (unless a bystander retrogradely conducting BT is present).
Length of pacing drive required for entrainment	<ul style="list-style-type: none"> Acceleration of the SVT to the PCL occurring by the first beat with stable paced QRS morphology is consistent with orthodromic AVRT and essentially excludes AVNRT. Acceleration of the SVT to the PCL occurring only after ≥ 2 beats with stable paced QRS morphology is consistent with AVNRT and excludes orthodromic AVRT.
Atrial activation sequence during ventricular pacing	<ul style="list-style-type: none"> Atrial activation sequence during pacing different from that during the SVT is consistent with AT and practically excludes both orthodromic AVRT and AVNRT. Atrial activation sequence during pacing similar to that during the SVT favors orthodromic AVRT or AVNRT over AT.
Atrial and ventricular electrogram sequence following cessation of ventricular pacing	<ul style="list-style-type: none"> A-A-V response is consistent with AT (as long as pseudo-A-A-V response is excluded). A-V response is consistent with AVNRT and orthodromic AVRT.

Continued

TABLE 20.2 Diagnostic Strategy for Narrow QRS Supraventricular Tachycardia: Programmed Electrical Stimulation During Tachycardia—cont'd**Atrial Extrastimulation**

Resetting with atrial fusion

- Demonstration of resetting with manifest atrial fusion excludes AVNRT and focal AT.

Atrial Pacing

Entrainment during atrial pacing

- Demonstration of entrainment excludes automatic and triggered activity ATs.

Entrainment with atrial fusion

- Demonstration of entrainment with manifest atrial fusion excludes AVNRT and focal AT.

Overdrive suppression

- Overdrive suppression of the SVT favors automatic AT and excludes AVNRT and orthodromic AVRT.

AH interval

- ΔAH interval ($AH_{\text{pacing}} - AH_{\text{SVT}}$) of >40 msec favors AVNRT over AT and orthodromic AVRT.

- ΔAH interval of <20 msec favors AT and orthodromic AVRT over AVNRT.

VA linking

- On cessation of overdrive atrial pacing (with 1:1 AV conduction), if the VA interval following the last entrained QRS is reproducibly constant (<10 msec variation), despite pacing at different CLs or for different durations (VA linking) and similar to that during SVT, AT is unlikely.

- If no VA linking is demonstrable, AT is more likely than other types of SVT.

Differential-site atrial pacing

- On cessation of overdrive atrial pacing (with 1:1 AV conduction) from different atrial sites (high RA and proximal CS) at the same PCL, a maximal difference in the postpacing VA intervals (the interval from last captured ventricular electrogram to the earliest atrial electrogram of the initial tachycardia beat after pacing) among the different atrial pacing sites (ΔVA interval) of >14 msec is consistent with AT.

- ΔVA interval of <14 msec favors AVNRT or orthodromic AVRT over AT.

Para-Hisian Entrainment or Resetting

SA and local VA intervals

- Prolongation of the SA and the local VA intervals on loss of HB capture, compared with that during HB capture is consistent with AVNRT.

- SA and the local VA intervals that remain constant regardless of whether the HB-RB is being captured indicate orthodromic AVRT.

- SA interval prolongation on HB-RB noncapture, but without significant change in the local VA interval, indicates orthodromic AVRT.

- The change in the stimulus to earliest atrial activation time (ΔSA interval) with loss of HB-RB capture >40 msec is consistent with AVNRT.

- ΔSA interval <40 msec indicates AVRT (except for rare patients with a left lateral BT).

The number of beats required to capture the atrium with para-Hisian pacing during SVT

- Entry into the tachycardia circuit within 1 beat indicates AVRT, whereas entry into the circuit occurring only after 3 or more beats is consistent with AVNRT.

A-A-V, Atrial-atrial-ventricular; A-V, atrial-ventricular; AH, atrial-His bundle interval; AT, atrial tachycardia; AV, atrioventricular; AVNRT, atrioventricular nodal reentrant tachycardia; AVRT, atrioventricular reentrant tachycardia; BT, bypass tract; CL, cycle length; CS, coronary sinus; HB, His bundle; PCL, pacing cycle length; PPI, postpacing interval; RA, right atrium; RB, right bundle branch; RV, right ventricle; SA, stimulus-atrial; SVT, supraventricular tachycardia; TCL, tachycardia cycle length; VA, ventriculoatrial; VES, ventricular extrastimulus.

TABLE 20.3 Diagnostic Strategy for Narrow QRS Supraventricular Tachycardia: Programmed Electrical Stimulation During Sinus Rhythm**Tachycardia Induction**

Catecholamine administration

- Spontaneous SVT initiation during isoproterenol administration is consistent with automatic AT or junctional tachycardia.

AES

- "Critical AH" required for SVT induction is consistent with typical AVNRT.

- If the VA interval of the first tachycardia beat is reproducibly identical to that during the rest of the SVT ("VA linking"), AT is very unlikely, and is suggestive of typical AVNRT and orthodromic AVRT.

VES

- ΔVA ($VA_{\text{VES}} - VA_{\text{SVT}}$) <85 msec is consistent with orthodromic AVRT.

- ΔVA interval >85 msec favors AVNRT.

- $(PPI_{\text{VES}} - TCL) <115$ msec is consistent with orthodromic AVRT.

- $(PPI_{\text{VES}} - TCL) >115$ msec favors AVNRT.

Atrial Pacing From High Right Atrium at Tachycardia Cycle Length

AH interval

- ΔAH interval ($AH_{\text{pacing}} - AH_{\text{SVT}}$) of >40 msec favors AVNRT over AT and orthodromic AVRT.

- ΔAH interval of <20 msec favors AT and orthodromic AVRT over AVNRT.

Ventricular Pacing From Right Ventricular Apex at Tachycardia Cycle Length

HA interval

- ΔHA interval ($HA_{\text{pacing}} - HA_{\text{SVT}}$) of more than -10 msec favors AVNRT.

- ΔHA interval of less than -10 msec favors orthodromic AVRT.

TABLE 20.3 Diagnostic Strategy for Narrow QRS Supraventricular Tachycardia: Programmed Electrical Stimulation During Sinus Rhythm—cont'd

Retrograde atrial activation sequence	• Retrograde atrial activation sequence during ventricular pacing similar to that during SVT favors orthodromic AVRT and AVNRT over AT.
VA block	• The presence of VA block or decremental VA conduction during ventricular pacing at a CL similar to the TCL and under comparable autonomic tone argues against orthodromic AVRT and favors AT and AVNRT.
Differential-Site Right Ventricular Pacing	
VA interval	<ul style="list-style-type: none"> • When the VA (S-A) interval during RV apical pacing is shorter than that during RV basal pacing, a retrogradely conducting septal BT is excluded. • When the VA (S-A) interval during RV apical pacing is longer than that during RV basal pacing, a retrogradely conducting AV BT is diagnosed.
Atrial activation sequence	<ul style="list-style-type: none"> • Retrograde atrial activation sequence that is different depending on the site of ventricular pacing indicates the presence of a BT. • Constant atrial activation sequence does not help exclude or prove the presence of an AV BT.
Para-Hisian Pacing	
Atrial activation sequence	<ul style="list-style-type: none"> • Identical retrograde atrial activation sequence, with and without HB capture, indicates that retrograde conduction is occurring over the same system during HB-RB capture and noncapture (either the BT or AVN) and does not help prove or exclude the presence of BT. • Retrograde atrial activation sequence that is different depending on whether HB is captured indicates the presence of a BT.
HA and VA intervals	<ul style="list-style-type: none"> • VA (S-A) interval (recorded at multiple sites, including close to the site of earliest atrial activation during SVT) that is constant regardless of whether the HB-RB is being captured indicates the presence of a BT. • Prolongation of the VA (S-A) interval on loss of HB capture, compared with that during HB capture, excludes the presence of a retrogradely conducting BT, except for slowly conducting and far free-wall BTs.
Dual-Chamber Sequential Extrastimulation	
VA conduction	• VA conduction of V_2 indicates the presence of a retrogradely conducting BT.

AES, Atrial extrastimulation; AH, atrial-His bundle interval; AT, atrial tachycardia; AV, atrioventricular; AVN, atrioventricular node; AVNRT, atrioventricular nodal reentrant tachycardia; AVRT, atrioventricular reentrant tachycardia; BT, bypass tract; CL, cycle length; HA, His bundle–atrial; HB, His bundle; PPI, postpacing interval; RB, right bundle branch; RV, right ventricle; S-A, stimulus-atrial; SVT, supraventricular tachycardia; TCL, tachycardia cycle length; VA, ventriculoatrial; VES, ventricular extrastimulus.

RP SVT with a concentric atrial activation sequence includes (1) AT with a focus close to the AV junction; (2) orthodromic AVRT using a septal or paraseptal BT; and (3) slow-slow AVNRT. Long RP SVTs with a concentric atrial activation sequence include: (1) atypical (fast-slow) AVNRT; (2) PJRT; and (3) nodofascicular reentrant tachycardia (orthodromic AVRT using a concealed nodofascicular/nodoventricular BT). Narrow-complex tachycardia with VA block is rare; the differential diagnosis includes (1) typical AVNRT; (2) junctional tachycardia; and (3) nodofascicular reentrant tachycardia (orthodromic AVRT using a concealed nodofascicular/nodoventricular BT).

Step 2

Overdrive Ventricular Pacing During the Supraventricular Tachycardia

Ventricular pacing during the SVT represents the single most important diagnostic maneuver and can provide several clues to the diagnosis of most SVTs. Therefore it is preferable to employ this maneuver as an initial step in the diagnostic approach. When sustained SVT is inducible, overdrive pacing from the RV apex and RV base is performed at a PCL 10 to 30 milliseconds shorter than the TCL; the PCL is then progressively reduced by 10 to 20 milliseconds in a stepwise fashion with cessation of ventricular pacing after each PCL to verify continuation versus termination of the SVT. Several diagnostic criteria can be applied including the VA interval during pacing versus tachycardia, PPI, atrial activation sequence, presence of manifest ventricular fusion, and the length of pacing drive required to enter the tachycardia circuit, and

the atrial and ventricular electrogram sequence following cessation of pacing (see Table 20.2).³⁰

Step 3

Ventricular Extrastimulation During Supraventricular Tachycardia

Subsequently, a VES is delivered when the HB is refractory and then at progressively shorter VES coupling intervals (approximately 10-millisecond stepwise shortening of the VES coupling interval) so as to scan all of diastole. First, ventricular capture of the VES should be verified, and then the effect of the VES on the following atrial activation (advancement, delay, termination, or no effect) should be evaluated, as well as the timing of the VES in relation to the expected His potential during the SVT. Furthermore, conduction of the VES to the atrium and sequence of atrial activation following the VES should be carefully examined (see Fig. 20.11).³⁰

Step 4

Overdrive Atrial Pacing During the Supraventricular Tachycardia

Atrial pacing is performed at a PCL 10 to 20 milliseconds shorter than the TCL. The PCL is then progressively reduced by 10 to 20 milliseconds in a stepwise fashion, with discontinuation of atrial pacing after each PCL to ensure continuation versus termination of the SVT. The AH interval, and presence of entrainment, atrial fusion, and VA linking should be evaluated (see Table 20.2).³⁰

Step 5

After tachycardia termination, ventricular and atrial pacing at the TCL, differential site RV pacing (RV apex vs. base), and para-Hisian pacing maneuvers are performed (see Table 20.3).

CLINICAL CONSIDERATIONS

Causes of Wide Complex Tachycardias

A narrow QRS complex (120 milliseconds or less) requires rapid, highly synchronous electrical activation of the right ventricle (RV) and left ventricle (LV), which can only be achieved through the specialized, rapidly conducting His-Purkinje system (HPS). A wide QRS complex implies less synchronous ventricular activation of longer duration, which can be due to intraventricular conduction disturbances (IVCDs), or ventricular activation not mediated by the His bundle (HB) but by a bypass tract (BT) (preexcitation) or from a site within a ventricle (ventricular arrhythmias). IVCDs can be fixed and present at all heart rates, and they can be intermittent and related to either tachycardia or bradycardia. IVCDs can be caused by structural abnormalities in the HPS or ventricular myocardium or by functional refractoriness in a portion of the conduction system (i.e., aberrant ventricular conduction).¹

Wide complex tachycardia (WCT) is a rhythm with a rate of more than 100 beats/min and a QRS duration of more than 120 milliseconds (Fig. 21.1). Several arrhythmias can manifest as WCTs (Table 21.1); the most common is ventricular tachycardia (VT), which accounts for 80% of all cases of WCT. Supraventricular tachycardia (SVT) with aberrancy accounts for 15% to 20% of WCTs. SVTs with bystander preexcitation and atrioventricular reentrant tachycardia (AVRT) account for 1% to 6% of WCTs.

In the stable patient who will undergo a more detailed assessment, the goal of evaluation should include determination of the cause of the WCT (particularly distinguishing between VT and SVT). Accurate diagnosis of the WCT requires information obtained from the history, physical examination, response to certain maneuvers, and careful inspection of the electrocardiogram (ECG), including rhythm strips and 12-lead tracings. Comparison of the ECG during the tachycardia with that recorded during sinus rhythm, if available, can also provide valuable information.

Clinical History

Age

WCT in a patient older than 35 years is likely to be VT (positive predictive value of up to 85%). SVT is more likely in the younger patient (positive predictive value of 70%).

Symptoms

Some patients with WCT present with few or no symptoms (e.g., palpitations, lightheadedness, diaphoresis), whereas others can have severe manifestations, including chest pain, dyspnea, syncope, seizures, and cardiac arrest. The severity of symptoms during a WCT is not useful in determining the tachycardia mechanism because symptoms are primarily related to the fast heart rate, associated heart disease, and the presence and extent of LV dysfunction, rather than to the mechanism of the tachycardia. It is important to recognize that VT does not necessarily result in hemodynamic compromise or collapse; on the other hand, rapid SVT can cause decompensation in susceptible patients. Misdiagnosis of VT as SVT on the basis of hemodynamic stability is a common error that can lead to inappropriate and potentially dangerous therapy.

Duration of the Arrhythmia

SVT is more likely if the tachycardia has recurred over a period of more than 3 years. The first occurrence of a WCT after myocardial infarction (MI) strongly implies VT.

Presence of Underlying Heart Disease

The presence of structural heart disease, especially coronary heart disease and a previous MI, strongly suggests VT as the cause of WCT. In one report, more than 98% of patients with a previous MI had VT as the cause of WCT, whereas only 7% of those with SVT had an MI. It should be realized, however, that VT can occur in patients with no apparent heart disease, and SVT can occur in those with structural heart disease.

Fig. 21.1 Wide Complex Tachycardia. Electrocardiogram obtained in a patient with prior inferior wall infarction. The underlying mechanism is ventricular tachycardia related to the left ventricular inferior wall scar.

TABLE 21.1 Causes of Wide QRS Complex Tachycardia

Cause	Description, Examples
VT	Macroreentrant VT Focal VT
SVT with aberrancy	Functional BBB Preexisting BBB
Preexcited SVT	Antidromic AVRT AT or AVNRT with bystander BT
SVT with preexisting nonaberrant QRS	Bizarre QRS patterns in repaired congenital heart disease, cardiac malpositions, unusual hypertrophy patterns
SVT with antiarrhythmic drugs	Class IA and IC agents
Electrolyte abnormalities	Hyperkalemia
Ventricular pacing	

AT, Atrial tachycardia; AVNRT, atrioventricular nodal reentrant tachycardia; AVRT, atrioventricular reentrant tachycardia; BBB, bundle branch block; BT, bypass tract; SVT, supraventricular tachycardia; VT, ventricular tachycardia.

Pacemaker or Implantable Cardioverter-Defibrillator Implantation

A history of pacemaker or implantable cardioverter-defibrillator (ICD) implantation should raise the possibility of a device-associated tachycardia. Ventricular pacing can be associated with a small and almost imperceptible stimulus artifact on the ECG. The presence of an ICD is also of importance because such a device should identify and treat a sustained tachyarrhythmia, depending on device programming, and because the presence of an ICD implies that the patient is known to have an increased risk of ventricular tachyarrhythmias.

Medications

Many different medications have proarrhythmic effects. The most common drug-induced tachyarrhythmia is torsades de pointes. Frequently implicated agents include antiarrhythmic drugs (such as sotalol, dofetilide, and quinidine) and certain antimicrobial drugs (such as erythromycin). Diuretics are a common cause of hypokalemia and hypomagnesemia, which can predispose to ventricular tachyarrhythmias, particularly torsades de pointes in patients taking antiarrhythmic drugs. Furthermore, class I antiarrhythmic drugs, especially class IC agents, can decrease conduction velocity at faster heart rates (use dependency). As a result, these drugs can cause aberration and widening of the QRS complex during any tachyarrhythmia.

Digoxin can cause almost any cardiac arrhythmia, especially with increasing plasma digoxin concentrations above 2.0 ng/mL (2.6 mmol/L). Digoxin-induced arrhythmias are more frequent at any given plasma concentration if hypokalemia is also present. The most common digoxin-induced arrhythmias include monomorphic VT (often with a relatively narrow QRS complex), bidirectional VT (a regular alternation of two wide QRS morphologies, each with a different axis), and nonparoxysmal junctional tachycardia.

Physical Examination

Most of the elements of the physical examination, including the blood pressure and heart rate, are of importance primarily in determining the presence and severity of hemodynamic instability and, thus, how urgently a therapeutic intervention is required. In patients with significant hemodynamic compromise, a thorough diagnostic evaluation should be postponed until acute management has been addressed. In this setting, emergency cardioversion is the treatment of choice and does not require knowledge of the mechanism of the arrhythmia.

Evidence of underlying cardiovascular disease should be sought, including the sequelae of peripheral vascular disease or stroke. A healed sternal incision is obvious evidence of previous cardiothoracic surgery. A pacemaker or defibrillator, if present, can typically be palpated in the

left or, less commonly, right pectoral area below the clavicle, although some older devices are found in the anterior abdominal wall or subaxillary region.

An important objective of the physical examination in the stable patient is to attempt to document the presence of AV dissociation. The presence of AV dissociation strongly suggests VT, although its absence is less helpful. AV dissociation, when present, is typically diagnosed on ECG; however, it can produce a number of characteristic findings on physical examination. Intermittent cannon A waves may be observed on examination of the jugular pulsation in the neck, and they reflect intermittent simultaneous atrial and ventricular contraction. Cannon A waves must be distinguished from the continuous and regular prominent A waves seen during some SVTs. Such prominent waves result from simultaneous atrial and ventricular contraction occurring with every beat. In addition, highly inconsistent fluctuations in the blood pressure can occur because of the variability in the degree of LA contribution to LV filling, stroke volume, and cardiac output. Moreover, variability in the occurrence and intensity of heart sounds (especially S_1) can also be observed and is heard more frequently when the rate of the tachycardia is slower.

The response to carotid sinus massage can suggest the cause of the WCT. The heart rate during sinus tachycardia and automatic AT will gradually slow with carotid sinus massage and then accelerate on release. The ventricular rate during AT and AFL can transiently slow with carotid sinus massage because of slowing and block of atrioventricular node (AVN) conduction. The arrhythmia itself, however, is unaffected. Atrioventricular nodal reentrant tachycardia (AVNRT) and AVRT will either terminate or remain unaltered with carotid sinus massage. VTs are generally unaffected by carotid sinus massage, although this maneuver can potentially slow the atrial rate and, in some cases, expose AV dissociation. Some VTs, such as idiopathic VT from the RV outflow tract, can infrequently terminate in response to carotid sinus massage.

Laboratory Testing

The plasma potassium and magnesium concentrations should be measured as part of the laboratory evaluation. Hypokalemia and hypomagnesemia can predispose to the development of ventricular tachyarrhythmias; however, correction of abnormalities of electrolytes is never sufficient for therapy. Hyperkalemia can cause a wide QRS complex rhythm, usually with a slow rate, with loss of a detectable P wave (the putative sinoventricular rhythm; eFig. 21.1) or abnormalities of AVN conduction. In patients taking digoxin, quinidine, or procainamide, plasma concentrations of these drugs should be measured to assist in evaluating possible drug toxicity.

Pharmacological Intervention

The administration of certain drugs can be useful for diagnostic, as opposed to therapeutic, purposes. Termination of the arrhythmia with lidocaine suggests, but does not prove, that VT is the mechanism. Infrequently an SVT, especially AVRT, can terminate with lidocaine. On the other hand, termination of the tachycardia with procainamide or amiodarone does not distinguish between VT and SVT. Termination of the arrhythmia with digoxin, verapamil, diltiazem, or adenosine strongly implies SVT. However, VT can also occasionally terminate after the administration of these drugs.

Unless the cause for the WCT is definitely established, however, verapamil and diltiazem should not be administered because they have been reported to cause severe hemodynamic deterioration in patients with VT and can even provoke VF and cardiac arrest. Adenosine is suggested in the 2010 Adult Advanced Cardiac Life Support (ACLS) guidelines if a WCT is monomorphic, regular, and hemodynamically tolerated, because adenosine may help convert the rhythm to sinus and

may help in the diagnosis. When doubt exists, it is safest to assume any WCT is VT, particularly in patients with known cardiovascular disease.² Direct current cardioversion in unstable patients and IV procainamide or amiodarone in hemodynamically stable patients are the appropriate management approach.

ELECTROCARDIOGRAPHIC FEATURES

Ventricular Tachycardia Versus Aberrantly Conducted Supraventricular Tachycardia

Because the diagnosis of a WCT cannot always be made with complete certainty, the unknown rhythm should be presumed to be VT in the absence of contrary evidence. This conclusion is appropriate both because VT accounts for up to 80% of cases of WCT and because making this assumption guards against inappropriate and potentially dangerous therapy. As noted, the IV administration of drugs used for the treatment of SVT (verapamil, diltiazem, or beta-blockers) can cause severe hemodynamic deterioration in patients with VT and can even provoke VF and cardiac arrest. Therefore these drugs should not be used when the diagnosis is uncertain.

In general, most WCTs can be classified as having one of two patterns: right bundle branch block (RBBB)-like pattern (QRS polarity is predominantly positive in leads V_1 and V_2), or left bundle branch block (LBBB)-like pattern (QRS polarity is predominantly negative in leads V_1 and V_2). The determination that the WCT has an RBBB-like pattern or an LBBB-like pattern does not, by itself, assist in making a diagnosis; however, this assessment should be made initially because it has further implications for evaluating several other features on the ECG, including the QRS axis, the QRS duration, and the QRS morphology (Box 21.1; Fig. 21.2).³

Rate

The rate of the WCT is of limited value in distinguishing VT from SVT because there is wide overlap in the distribution of heart rates for SVT and VT. When the rate is around 150 beats/min, AFL with 2:1 AV conduction and aberrancy should be considered.

Regularity

Regularity of the WCT is not helpful in distinguishing VT from SVT because, in general, both are regular. However, VT is often associated with slight irregularity of the RR intervals, QRS morphology, and ST-T waves. Although marked irregularity strongly suggests AF, VTs can be particularly irregular within the first 30 seconds of onset and in patients treated with antiarrhythmic drugs.

Atrioventricular Dissociation

AV dissociation is characterized by atrial activity (P waves) that is completely independent of ventricular activity (QRS complexes). The atrial rate is usually slower than the ventricular rate (Fig. 21.3). A regular R-R interval in the presence of AF would most likely be AV dissociated.

AV dissociation is the hallmark of VT (specificity is almost 100%). However, although the presence of AV dissociation establishes VT as the cause, its absence (because of retrograde atrial capture) is not as helpful (sensitivity is 20% to 50%). AV dissociation can be present but not obvious on the surface ECG because of rapid ventricular rates. In addition, AV dissociation is absent in a large subset of VTs (especially those at a slower rate); in fact, approximately 30% of VTs have 1:1 retrograde VA conduction (see Fig. 21.2) and an additional 15% to 20% have second-degree (2:1 or Wenckebach) VA block (Fig. 21.4). Furthermore, AV dissociation can be observed during subatrial SVT, such as junctional ectopic tachycardia and nodofascicular reentrant tachycardia.

eFig. 21.1 Wide QRS Complex Rhythm Caused by Hyperkalemia.

BOX 21.1 Electrocardiographic Criteria Favoring Ventricular Tachycardia**AV Relationship**

- Dissociated P waves
- Fusion beats
- Capture beats
- A/V ratio <1

QRS Duration

- >160 ms with LBBB pattern
- >140 ms with RBBB pattern
- QRS during WCT is narrower than in NSR

QRS Axis

- Shift of >40 degrees between NSR and WCT
- Right superior (northwest) axis (−90 degrees to ±180 degrees)
- Left axis deviation with RBBB morphology
- Right axis deviation with LBBB morphology

Precordial QRS Concordance

- Positive concordance
- Negative concordance

QRS Morphology

- Contralateral BBB in WCT and NSR
- Absence of RS patterns in all precordial leads
- RS interval >100 ms in precordial leads with an RS morphology
- Lead II R wave peak time ≥50 ms

• Criteria in lead aVR:

- Presence of an initial R wave
- Presence of an initial r or q wave with width >40 ms
- Notching on the descending limb of a negative onset of a predominantly negative QRS complex
- $V_i/V_t \leq 1$

QRS Morphology in RBBB-Like WCT Pattern

- Lead V_1 :
 - Monophasic R, biphasic qR, Rs, or Rr' complex
 - Broad initial R wave (≥40 msec)
 - Rabbit ear sign: Double-peaked R wave with the left peak taller than the right peak
- Lead V_6 :
 - rS, QS, QR, or R complex
 - R/S ratio <1

QRS Morphology in LBBB-Like WCT Pattern

- Lead V_1/V_2 :
 - Broad initial R wave (≥30 msec)
 - RS interval >70 msec
 - R wave during WCT taller than the R wave during NSR
 - Slow descent to the nadir of the S (notching in the downstroke of the S wave)
- Lead V_6 :
 - Any Q wave or QS complex

AV, Atrioventricular; BBB, bundle branch block; LBBB, left bundle branch block; NSR, normal sinus rhythm; RBBB, right bundle branch block; WCT, wide complex tachycardia.

Several ECG findings are helpful in establishing the presence of AV dissociation, including the presence of dissociated P waves, fusion beats, or capture beats.

Dissociated P waves. When the P waves can be clearly seen and the atrial rate is unrelated to and slower than the ventricular rate, AV dissociation consistent with VT is present (Fig. 21.5). An atrial rate faster than the ventricular rate is more often seen with SVTs having AV conduction block. However, during a WCT, the P waves are often difficult to identify; they can be superimposed on the ST segment or T wave (resulting in altered morphology). Sometimes the T waves and initial or terminal portions of the QRS complex can resemble atrial activity and be mistaken for P waves. If the P waves are not obvious on the ECG, several alternative leads or modalities can help in their identification, including a modified chest lead placement (Lewis leads), an esophageal lead (using an electrode wire or nasogastric tube), RA recording (obtained by an electrode catheter in the RA), carotid sinus pressure (to slow VA conduction and therefore change the atrial rate in the case of VT), or invasive EP testing.

Fusion beats. Ventricular fusion occurs when a ventricular ectopic beat and a supraventricular beat (conducted via the AVN and HPS) simultaneously activate the ventricular myocardium. The resulting QRS complex has a morphology intermediate between the appearance of a sinus QRS complex and that of a purely ventricular complex. Intermittent fusion beats during a WCT are diagnostic of AV dissociation and therefore of VT (see Fig. 21.5). However, it is also possible for PVCs during SVT with aberration to produce fusion beats, which would erroneously be interpreted as evidence of AV dissociation and VT.

Capture beats. A capture beat (once called “Dressler beat”) is a normal QRS complex, identical to the sinus QRS complex, occurring

during the VT at a rate *faster* than the VT. The term *capture beat* indicates that the normal conduction system has momentarily captured control of ventricular activation from the VT focus (see Fig. 21.5). Fusion and capture beats are more commonly seen when the tachycardia rate is slower. These beats do not alter the rate of the VT, although a change in the preceding and subsequent RR intervals is frequently observed.

QRS Duration

In general, a wider QRS duration favors VT. In the setting of RBBB-like WCT, a QRS duration more than 140 milliseconds suggests VT, whereas for LBBB-like WCT, a QRS duration more than 160 milliseconds suggests VT. In an analysis of several studies, a QRS duration more than 160 milliseconds overall was a strong indicator of VT (likelihood ratio greater than 20:1). On the other hand, a QRS duration less than 140 milliseconds is not helpful for excluding VT because VT can sometimes be associated with a relatively narrow QRS complex, especially if it originates from the septum.

A QRS duration more than 160 milliseconds is not helpful in identifying VT in several settings including: (1) preexisting BBB, although it is uncommon for the QRS to be wider than 160 milliseconds in this situation; (2) preexcited SVT (see Chapter 18); and (3) the presence of drugs capable of slowing intraventricular conduction (e.g., class IA and IC drugs). Of note, a QRS complex that is narrower during WCT than during normal sinus rhythm (NSR) suggests VT. However, this is rare, occurring in less than 1% of VTs.

Rarely (4% in one series), VT can have a relatively narrow QRS duration (less than 120 to 140 milliseconds). This can be observed in VTs of septal origin or those with early penetration into the HPS, as occurs with fascicular (verapamil-sensitive) VT.

Fig. 21.2 Electrocardiogram Morphology During Normal Sinus Rhythm (NSR) Versus Ventricular Tachycardia (VT). (A) VT with right bundle branch block (RBBB) pattern, positive concordance, and long RS interval. Note the monophasic R in lead V₁ during VT and the significant shift in the frontal plane axis in VT versus NSR. (B) VT with an RBBB pattern and long RS interval. Note the superior (“northwest”) frontal plane axis during VT. (C) VT with a left bundle branch block (LBBB) pattern, long RS interval, and 1:1 ventriculoatrial conduction. Retrograde P waves (red arrows) are visible following the QRSs during VT. (D) VT with LBBB pattern and negative concordance. Note that the second QRS (blue arrows) is a fusion between the sinus beat and the VT beat.

QRS Axis

In general, the more leftward the axis, the greater the likelihood of VT. In addition, a significant axis shift (more than 40 degrees) between the baseline NSR and WCT is suggestive of VT (see Fig. 21.2A). Also, a right superior (“northwest”) axis (axis from -90 degrees to ± 180 degrees) is rare in SVT and strongly suggests VT (sensitivity 20%, specificity 96%; see Fig. 21.2B).

In a patient with an RBBB-like WCT, a QRS axis to the left of -30 degrees suggests VT (see Fig. 21.2A), and in a patient with an LBBB-like WCT, a QRS axis to the right of $+90$ degrees suggests VT. Furthermore, RBBB with a normal axis is uncommon in VT (less than 3%) and is suggestive of SVT.

Precordial QRS Concordance

Concordance is present when the QRS complexes in the six precordial leads (V₁ through V₆) are either all positive in polarity (tall R waves) or all negative in polarity (deep QS complexes). Negative concordance is strongly suggestive of VT (see Fig. 21.2D). Rarely, SVT with LBBB aberrancy will demonstrate negative concordance, but there is almost

always some evidence of an R wave in the lateral precordial leads. Positive concordance is most often caused by VT (see Fig. 21.2A); however, this pattern may also be caused by preexcited SVT using a left posterior BT. Although the presence of precordial QRS concordance strongly suggests VT (greater than 90% specificity), its absence is not helpful diagnostically (approximately 20% sensitivity).

QRS Morphology

As a general rule, if the WCT is caused by SVT with aberration, then the QRS complex during the WCT must be compatible with some form of BBB that could result in that QRS configuration. If there is no combination of bundle branch or fascicular blocks that could result in such a QRS configuration, then the diagnosis, by default, is VT or preexcited SVT.⁴ As noted, WCTs can be classified as having RBBB-like pattern or LBBB-like pattern. Certain features of the QRS complex have been described that favor VT in RBBB-like or LBBB-like WCTs (Fig. 21.6).⁵

RBBB pattern. Development of RBBB alters the activation sequence of the RV, whereas the LV is activated normally. Because the LB is not

Fig. 21.3 Atrioventricular Dissociation During Ventricular Tachycardia. Note that the P waves (arrows) are completely independent of QRS complexes. The atrial rate is slower than the ventricular rate.

affected, the initial septal activation (the initial 30 milliseconds of the QRS complex), which depends on the LB, remains normal, occurring from left to right, and results in septal q waves in leads I, aVL, and V₆ and r waves in leads V₁, V₂, and aVR.

Septal activation is followed by activation of the LV (within the subsequent 40 to 60 milliseconds), occurring over the LB in a leftward and posterior vector and resulting in R waves in the leftward leads (I, aVL, and V₆), as well as s (or S) waves in the anterior precordial leads (V₁ and V₂). This appearance is usually similar to that in normal subjects because the LV is normally electrically predominant during this phase of the QRS.¹

The asynchronous depolarization caused by RBBB is primarily manifested in the later portion of the QRS, beyond the first 80 milliseconds of the QRS. During this time, RV activation spreads slowly by conduction through working muscle fibers rather than the specialized Purkinje system, and it occurs predominantly after activation of the LV has completed. The forces generated by the late, unopposed RV free wall activation result in a terminal rightward and anterior positivity, manifesting as a second positive deflection that can be small (r') or large (R') in the anterior precordial leads (V₁ and V₂) and S waves in the leftward leads (I, aVL, and V₆; see Fig. 10.10). The QRS axis is unaffected by RBBB; left or right axis deviation can indicate concurrent LAF or LPF block, respectively (see Fig. 10.10).⁶

Lead V₁. In the patient with a WCT and positive QRS polarity in lead V₁ (RBBB pattern), a triphasic RSR', rSr', rR', or rSR' complex in lead V₁ favors SVT (where the capital letter indicates large-wave amplitude or duration, and the lowercase letter indicates small-wave amplitude and duration; see Fig. 21.6). In contrast, a monophasic R, biphasic qR complex, or broad R (greater than 30 milliseconds) in lead V₁ favors VT (sensitivity of these patterns for recognizing VT is 97%, specificity is 88%; Fig. 21.7). In addition, a double-peaked R wave in lead V₁ favors VT if the left peak is taller than the right peak (the so-called rabbit ear sign; likelihood ratio greater than 50:1). A taller right rabbit ear does not help in distinguishing SVT from VT.⁵

Lead V₆. An Rs complex in lead V₆ favors SVT, whereas a qRS, qrS, rS, QS pattern, or an R/S ratio less than 1 in lead V₆ is a strong indicator of VT (likelihood ratio greater than 50:1; see Fig. 21.7).⁵

LBBB pattern. The normal sequence of ventricular activation is altered dramatically in LBBB. Complete LBBB results in delayed and abnormal activation and diffuse slowing of conduction throughout the LV. During LBBB, activation of the LV originates from the right bundle (RB) in a right to left direction, in contrast to the normal situation in which the first part of the LV myocardium to be activated is the septum in a left to right direction via a small septal branch of the LB. Thus LBBB results in reversal of the direction of the initial septal activation sequence (within the initial 30 milliseconds of the QRS complex), with the activation traveling from right to left and from apex to base and to the RV apex and free wall. RV activation is typically completed within the first 45 milliseconds of the onset of the QRS, before the onset of LV activation. However, because the septum is a larger structure than the RV free wall, septal activation predominates, eliciting a leftward and usually anterior vector and resulting in loss of the normal small q waves and initiation of a wide, slurred R wave in leads I, aVL, and V₆ and an rS or QS pattern in lead V₁ (see Fig. 10.11). As a consequence, Q waves of a prior MI can disappear, and new Q waves can emerge.¹

Following septal activation, LV activation (starting as late as 44 to 58 milliseconds into the QRS) spreads slowly by conduction through working muscle fibers rather than the HPS, with spatial vectors oriented to the left and posteriorly because the LV is a leftward and posterior structure. As a consequence, the delayed LV activation (unopposed by the now completed RV activation) produces large, broad, and notched or slurred R waves (without q or s waves) in the leftward leads (I, aVL, and V₆), with delayed R wave peak time in the left precordial leads (more than 60 milliseconds). The slowing and notching of the mid-QRS portion are caused by slow transseptal conduction. The terminal activation vector results from depolarization of the anterolateral LV wall that produces a small vector that is also directed to the left and posteriorly.¹

Fig. 21.4 Ventricular Tachycardia (VT) With Type 1 Second-Degree (Wenckebach) Ventriculoatrial (VA) Block. The first beat is sinus with normal atrioventricular (AV) conduction. VT develops with an initially short VA interval (blue arrows), which then slightly prolongs (red arrows), and then VA block occurs (green arrows). Note that the VT has a right bundle branch block with long RS interval (in lead V₂).

LBBB may cause no shift or variable degrees of left and superior shift of the frontal plane QRS axis. Pronounced left axis deviation can be associated with additional delay in activation in the LV secondary to myocardial disease. Right axis deviation in the setting of LBBB is rare and can be caused by RV hypertrophy or MI. A superior axis may also be observed in patients with RV enlargement.⁷

Importantly, recent evidence proposed more “strict” ECG criteria for identification of LBBB, including a terminal negative deflection in

V₁, mid-QRS notching/slurring in at least two of the leads V₁, V₂, V₅, V₆, I, and/or aVL, and a higher cutoff for QRS duration (140 milliseconds or longer for men and 130 milliseconds or longer for women). During true complete LBBB, mid-QRS notching/slurring (beginning after the first 40 milliseconds and ending at approximately two-thirds through the QRS duration) likely corresponds to the time of breakthrough of activation to the LV endocardium (first notch) and then to the LV posterolateral wall epicardium (second notch).⁸ In a simulation

Fig. 21.5 Ventricular Tachycardia (VT) With Atrioventricular (AV) Dissociation. Sustained monomorphic VT with a cycle length (CL) of 488 milliseconds with AV dissociation coexists with sinus rhythm with a CL of 616 milliseconds. The sinus P waves can be clearly seen (arrows) marching throughout the different phases of the VT QRS complexes, and the atrial rate is unrelated to and slower than the ventricular rate. Because of the relatively slow VT rate, capture (C) and fusion (F) beats are observed frequently.

Fig. 21.6 QRS Morphologies in Wide Complex Tachycardias. Diagrammatic representation of common QRS morphologies encountered in ventricular tachycardia (VT) and supraventricular tachycardia (SVT) with aberration in leads V₁ and V₆ for both left bundle branch block (LBBB) and right bundle branch block (RBBB) patterns. Note the initial portions of the QRS complex in normal and aberrant QRS complexes, contrasted with the initial QRS forces in VT complexes. The RS configurations can be designated as an RBBB or LBBB type (grouped with LBBB-type morphologies).

study, these “strict” ECG criteria for LBBB were found to be have greater specificity (100% vs. 48%) and equivalent sensitivity (100%) in diagnosing complete LBBB as compared with the conventional LBBB criteria.⁹

Lead V₁. In the patient with a WCT and a negative QRS polarity in lead V₁ (LBBB pattern), the absence of an initial R wave (or a small initial R wave of less than 30 milliseconds) in lead V₁ or V₂ favors SVT, whereas a broad initial R wave of 30 milliseconds or more in lead V₁ or V₂ favors VT (see Fig. 21.7). In addition, an R wave in lead V₁ during a WCT taller than that during NSR favors VT. Furthermore, a slow descent to the nadir of the S wave, notching in the downstroke of the S wave, or an RS interval (from the onset of the QRS complex to the nadir of the S wave) of more than 70 milliseconds in lead V₁ or V₂ favors VT. In contrast, a swift, smooth downstroke of the S wave in lead V₁ or V₂ with an RS interval of less than 70 milliseconds favors SVT. In an analysis of several studies, the presence of any of these three criteria in lead V₁ (broad R wave, slurred or notched downstroke of the S wave, and delayed nadir of S wave) was a strong indicator of VT (likelihood ratio greater than 50:1). In addition, an Rs, or “W” complex in lead V₁ and fragmentation of QRS (notching, which usually represents myocardial scar) strongly favor VT.⁵

Lead V₆. The QRS morphology in lead V₆ is also of value; the presence of any Q or QS wave in lead V₆ favors VT (likelihood ratio

Fig. 21.7 Electrocardiogram Morphology During Normal Sinus Rhythm (NSR) With Bundle Branch Block (BBB) Versus Ventricular Tachycardia (VT). (A) NSR with right bundle branch block (RBBB) and VT with RBBB pattern. Note the loss of the initial r wave in V_1 and the larger S wave in V_6 during VT compared with NSR with RBBB. In addition, note the shift in the frontal plane QRS axis from $+90$ degrees during NSR with RBBB to the northwest quadrant during VT. (B) NSR with RBBB and VT with RBBB pattern. Note the change in QRS morphology in lead V_1 (from rsR during NSR with RBBB to monophasic R during VT) and lead V_6 (from RS during NSR with RBBB to QS during VT). In addition, no RS complexes are observed in the precordial leads during VT. (C) NSR with left bundle branch block (LBBB) and VT with RBBB pattern. Note the positive precordial concordance during VT. (D) NSR with LBBB and VT with RBBB pattern. Note the positive precordial concordance during VT. The second QRS (blue arrows) is a fusion between the sinus beat and the VT beat, and the fusion QRS is narrower than both the sinus and VT complexes.

greater than 50:1; see Fig. 21.2D), whereas the absence of a Q wave in lead V_6 favors SVT.⁵

BBB during sinus rhythm. When a previous 12-lead surface ECG is available, comparison of the QRS morphology during NSR and WCT is helpful. In general, if the QRS complexes during tachycardia are identical to those during NSR, the tachycardia is supraventricular (since all beats of supraventricular origin should conduct exclusively over the contralateral bundle and the QRS morphological pattern is expected to remain unaltered); otherwise, the arrhythmia is more likely to be ventricular in origin. Contralateral BBB in WCT and NSR (i.e., LBBB during WCT and RBBB during NSR, or vice versa) strongly favors VT (see Fig. 21.7C and D).

It is important to note, however, that identical QRS morphology during NSR and WCT, although strongly suggestive of SVT, can also occur in BBR and interfascicular reentrant VTs.

In addition, in patients with fixed BBB during NSR (especially those with chronic RBBB), rapid tachycardia rates can potentially provoke changes in QRS morphology, which can erroneously suggest VT as the mechanism. This can potentially be caused by more slowing in the blocked bundle branch (due to the presence of conduction delay, rather than complete BBB during NSR), appearance or disappearance of fascicular hemiblock in cases of RBBB (whether complete or incomplete), or appearance or disappearance of distal blocks in the Purkinje network. Thus, in patients with preexisting BBB and QRS morphology during WCT different from that during NSR, but with the same BBB pattern,

it does not necessarily imply that the tachycardia is VT. In these cases, superior accuracy to diagnose VT was observed with “R wave peak time of 50 milliseconds or more at lead II” and for an algorithm with the combination of two criteria “R wave peak time of 50 milliseconds or more at lead II” and “absence of RS patterns in precordial leads.”^{4,10}

Variation in QRS and ST-T Morphology

Subtle, non-rate-related fluctuations or variations in the QRS and ST-T wave configuration among complexes during the same or different episodes suggest VT and reflect variations in the VT reentrant circuit within the myocardium. In contrast, because most SVTs follow fixed conduction pathways, they are generally characterized by complete uniformity of QRS and ST-T shape, unless the tachycardia rate changes.

Algorithms for the Electrocardiographic Diagnosis of Wide Complex Tachycardia

The various criteria for the diagnosis of WCT listed are difficult to apply in isolation because most patients will have some, but not all, of the features described.³ Several algorithms have been proposed to guide integrating ECG findings into a diagnostic strategy. Fig. 21.8 illustrates an example of one approach.¹¹ The effect of history of prior MI, preexcited tachycardias, antiarrhythmic medication usage, precordial lead placement, heart transplantation status, and the presence of congenital heart disease on QRS morphology criteria should be taken into account while applying these elements. Preexcited tachycardias

Fig. 21.8 Differential Diagnosis for Wide QRS Complex Tachycardia. A, Atrial; AF, atrial fibrillation; AFL, atrial flutter; AT, atrial tachycardia; AV, atrioventricular; AVRT, atrioventricular reentrant tachycardia; BBB, bundle branch block; LBBB, left bundle branch block; MI, myocardial infarction; NSR, normal sinus rhythm; RBBB, right bundle branch block; SVT, supraventricular tachycardia; V, ventricular; VT, ventricular tachycardia. (From Blomström-Lundqvist C, Scheinman MM, Aliot EM, et al. ACC/AHA/ESC guidelines for the management of patients with supraventricular arrhythmias—executive summary: a report of the American College of Cardiology/American Heart Association Task Force on Practice Guidelines and the European Society of Cardiology. *Circulation*. 2003;108:1871–909.)

may not be differentiated consistently with the proposed criteria, especially those using epicardial left-sided paraseptal or left-sided inferoposterior BTs.

Brugada Criteria

The most commonly used algorithm is the so-called Brugada algorithm or Brugada criteria. This is a stepwise, decision tree–like algorithm in which four criteria for VT are sequentially considered (Fig. 21.9).¹²

Step 1. All precordial leads are inspected to detect the presence or absence of an RS complex (i.e., complexes with both R and S waves of any amplitude, but QR, QRS, QS, monophasic R, or rSR complexes are not considered RS complexes). If an RS complex cannot be identified in any precordial lead, the diagnosis of VT can be made with 100% specificity.

Step 2. If an RS complex is clearly identified in one or more precordial leads, the interval between the onset of the R wave and the nadir

Fig. 21.9 Brugada Algorithm for Distinguishing Ventricular Tachycardia (VT) From Supraventricular Tachycardia (SVT). As indicated in the inset, the RS interval is between the onset of the R wave and the nadir of the S wave. AV, Atrioventricular; *sens*, sensitivity; *spec*, specificity. (From Brugada P, Brugada J, Mont L, et al. A new approach to the differential diagnosis of a regular tachycardia with a wide QRS complex. *Circulation*. 1991;83:1649–1659.)

of the S wave (the RS interval) is measured. The longest RS interval is considered if RS complexes are present in multiple precordial leads. If the longest RS interval is more than 100 milliseconds, the diagnosis of VT can be made with a specificity of 98% (see Fig. 21.9).

Step 3. If the longest RS interval is less than 100 milliseconds, either VT or SVT still is possible and the presence or absence of AV dissociation must therefore be determined. Evidence of AV dissociation is 100% specific for the diagnosis of VT, but this finding has a low sensitivity. The rationale proposed for the RS interval criterion is that during myocardial VTs, initial ventricular activation is slow because of muscle-to-muscle conduction close to the site of origin of the tachycardia. This results in prolongation of the initial portion of the QRS (time to the intrinsicoid deflection), as reflected by the RS interval utilized in this algorithm. This is in contrast to SVT with aberrancy, whereby initial ventricular activation is fast since it is mediated by the conducting bundle branch and HPS.

Step 4. If the RS interval is less than 100 milliseconds and AV dissociation cannot clearly be demonstrated, the QRS morphology criteria for V_1 -positive and V_1 -negative WCTs are considered. The QRS morphology criteria consistent with VT must be present in lead V_1 or V_2 and in lead V_6 to diagnose VT. A supraventricular origin of the tachycardia is assumed if either the V_1 and V_2 or V_6 criteria are not consistent with VT.

The Brugada algorithm was originally prospectively applied to 554 patients with electrophysiologically diagnosed WCTs. The reported sensitivity and specificity were 98.7% and 96.5%, respectively. Other authors also found the Brugada criteria useful, although they reported

a lower sensitivity (79% to 92%) and specificity (43% to 70%). The presence of preexisting BBB and the use of antiarrhythmic drugs result in a low specificity (63%) of the second Brugada criterion.

Griffith Algorithm

According to the Griffith algorithm, SVT is diagnosed only if the QRS morphology matches typical BBB. Typical LBBB manifests an rS or QS wave in leads V_1 and V_2 , delay to S wave nadir less than 70 milliseconds, and R wave and no Q wave in lead V_6 . Typical RBBB manifests an rSR' wave in lead V_1 and an RS wave in lead V_6 , with R wave height greater than S wave depth. When morphology criteria for the diagnosis of SVT are satisfied, inspecting the ECG for the presence of AV dissociation (which establishes the diagnosis of VT) further improves the overall accuracy. The Griffith algorithm had a sensitivity for VT of 95% and a specificity 64%.¹³

Bayesian Algorithm

The Bayesian algorithm is based on the likelihood ratio. It uses a list of 19 ECG features effective in discriminating VT from SVT with corresponding likelihood ratios. The Bayesian algorithm correctly diagnosed 52% of SVTs, 95% of VTs, and 97% of fascicular VTs. This algorithm, however, is cumbersome and impractical to use in most clinical settings.¹³

Vereckei Algorithm

A newer algorithm for differential diagnosis of WCT was analyzed in 453 monomorphic WCTs recorded from 287 patients, based on the following: (1) the presence of AV dissociation; (2) the presence of an initial R wave in lead aVR; (3) QRS morphology; and (4) estimation of the initial (V_i) and terminal (V_t) ventricular activation velocity ratio (V_i/V_t), determined by measuring the voltage change (i.e., the vertical excursion in millivolts) on the ECG tracing during the initial 40 milliseconds (V_i) and the terminal 40 milliseconds (V_t) of the same biphasic or multiphasic QRS complex (Fig. 21.10).^{14,15}

This algorithm had superior overall total accuracy than that of the Brugada algorithm (90.3% vs. 84.8%). The total accuracy of the fourth Brugada criterion was significantly lower (68% vs. 82.2%) than that of the V_i/V_t criterion in the fourth step, accounting for most of the difference in outcome between the two methods.^{14,15}

The rationale proposed for the V_i/V_t criterion is that during WCT caused by SVT the initial activation of the septum should be invariably rapid (mediated by the HPS) and the intraventricular conduction delay causing the wide QRS complex occurs in the mid to terminal part of the QRS. In contrast, in WCT caused by VT, there is initial slower muscle-to-muscle spread of activation until the impulse reaches the HPS, after which the rest of the ventricular muscle is more rapidly activated, resulting in a V_i/V_t ratio less than 1 during VT.^{14,15}

The vector of initial ventricular activation during SVT and NSR is directed away from lead aVR, yielding a negative QRS (QS) complex. Thus an initial dominant R or Rs complex in lead aVR suggests VT. However, an rS complex in lead aVR (but with an R/S ratio less than 1) can occur as a normal variant or in patients with inferior MI due to loss of initial inferiorly directed forces.

Antiarrhythmic drugs that impair conduction in the HPS or ventricular myocardium (e.g., class I drugs and amiodarone) would be expected to decrease the V_i and V_t approximately to the same degree; therefore the V_i/V_t ratio should not change significantly. Although the V_i/V_t ratio reflects the electrophysiology of many VTs, there are a number of exceptions to these criteria. First, disorders involving the myocardium locally can alter the V_i or V_t . For example, a decreased V_i with unchanged V_t can be present in the case of an SVT occurring in the presence of an anteroseptal MI, leading to the misdiagnosis of VT. Similarly, a scar situated at a late activated ventricular site can result in a decreased V_t

Fig. 21.10 Verecke Algorithm for Distinguishing Ventricular Tachycardia (VT) From Supraventricular Tachycardia (SVT). Fig. 21.11 The aVR Algorithm for Differential Diagnosis of Wide QRS Complex Tachycardia. SVT, Supraventricular tachycardia; V_i/V_t , ratio of initial (V_i) to terminal (V_t) ventricular activation velocity; VT, ventricular tachycardia. (From Verecke A, Duray G, Szénási G, et al. New algorithm using only lead aVR for differential diagnosis of wide QRS complex tachycardia. *Heart Rhythm.* 2008;5:89–98.)

in the presence of VT, leading to the misdiagnosis of SVT. Second, in the case of a fascicular VT, the V_i is not slower than the V_t . Third, if the exit site of the VT reentry circuit is very close to the HPS, it might result in a relatively narrow QRS complex, and the slowing of the V_i can last for such a short time that it cannot be detected by the surface ECG.^{14,15} A limitation of the initial R wave in lead aVR criterion can rarely be observed in patients with chronic cor pulmonale or severe emphysema associated with RV hypertrophy.¹⁶

The aVR Algorithm

The positive aVR criterion in the Verecke algorithm suggesting VT was further tested in 483 WCTs in 313 patients, and another algorithm based solely on QRS morphology in lead aVR was developed for distinguishing VT from SVT (Fig. 21.11).¹⁷ This algorithm classifies VTs into two main groups: (1) VTs arising from the inferior or apical region of the ventricles yielding an initial R wave in lead aVR, and (2) VTs arising from other regions and lacking an initial R wave in aVR.¹⁶ VTs originating from sites other than the inferior or apical wall of the ventricles, but not showing an initial R wave in aVR, should yield a slow, initially upward vector component of variable size pointing toward lead aVR (absent in SVT), even if the main vector in these VTs points downward, yielding a totally or predominantly negative QRS in lead aVR.

Thus, in VT without an initial R wave in lead aVR, the initial part of the QRS in lead aVR should be less steep (“slow”), which may be manifested as (1) an initial r or q wave with a width of more than 40 milliseconds, (2) notching on the descending limb (downstroke) of a negative onset, predominantly negative QRS complex, or (3) a slower ventricular activation during the initial 40 milliseconds than during the terminal 40 milliseconds of the QRS (i.e., $V_i/V_t \leq 1$) in lead aVR.

In contrast, in SVT with BBB, the initial part of the QRS in lead aVR is steeper (fast) because of the invariably rapid septal activation going away from lead aVR, resulting in a narrow (≤ 40 milliseconds) initial r or q wave and V_i/V_t ratio of more than 1.¹⁷

The overall accuracy of the aVR algorithm was 91.5%, which is similar to the Verecke algorithm and superior to the Brugada algorithm (90.3% and 84.8%, respectively). The aVR algorithm can be difficult to apply when the QRS in lead aVR is low amplitude and multiphasic. In addition, assessment of the V_i/V_t ratio in the lead aVR can be challenging using printed ECGs without a magnifying glass.¹⁷

Lead II R Wave Peak Time

The time interval necessary for full depolarization of the ventricular free wall (from the endocardium to the epicardium) beneath any given ECG electrode corresponds to the interval from the beginning of the QRS complex to the time of initial downstroke of the R wave after it has peaked (or to the time of initial upstroke of the S wave after it has reached its nadir). This interval is termed *R wave peak time* (in preference to the term *intrinsicoid deflection*). Normally the upper limit of normal for R wave peak time is 35 milliseconds in the right precordial leads, and 45 milliseconds in the left precordial leads. During NSR or SVT with RBBB, the R wave peak time is delayed in the right precordial leads (greater than 50 milliseconds), whereas in LBBB the R wave peak time is delayed in the left precordial leads (greater than 60 milliseconds).

A recent report found that the R wave peak time in lead II was significantly longer in VT compared with SVT with aberrancy, and a cutoff value of 50 milliseconds or greater identified VT with high sensitivity, specificity, and positive predictive values (93%, 99%, and 98%, respectively). However, this criterion has not been tested prospectively

or validated in patients with preexisting conduction system disease, antiarrhythmic drug therapy, electrolyte imbalance, prior MI, or pre-excited tachycardias. In addition, certain types of VTs such as fascicular VT, BBR VT, and septal myocardial VTs can have a shorter QRS onset-to-peak time because of their origin within or in close proximity to the His-Purkinje network.¹⁸

Ventricular Tachycardia Versus Preexcited Supraventricular Tachycardia

Differentiation between VT and preexcited SVT is particularly difficult because ventricular activation begins outside the normal intraventricular conduction system in both tachycardias (see Fig. 12.10). Thus ventricular activation mediated by a typical AV BT will mimic a VT originating from the base of the ventricles at the site of BT insertion. As a result, the algorithms for WCT, and most of the traditional QRS morphology criteria discussed above, tend to misclassify SVTs with preexcitation as VT. However, preexcitation is an uncommon cause of WCT, particularly if other factors, such as age and past medical history, suggest another diagnosis.

For cases in which preexcitation is thought to be likely, such as a young patient without structural heart disease or a patient with a known BT, a separate algorithm has been developed by Brugada and colleagues (Fig. 21.12). This algorithm consists of three steps.

Step 1

The predominant polarity of the QRS complex in leads V_4 through V_6 is defined as positive or negative. If predominantly negative, the diagnosis of VT can be made with 100% specificity. This is because the vast majority of BTs insert at the base of the RV or LV, ventricular preexcitation should yield a predominantly positive QRS complex in the apical precordial leads.

Step 2

If the polarity of the QRS complex is predominantly positive in V_4 through V_6 , the ECG should be examined for the presence of a qR

Fig. 21.12 Brugada Algorithm for Distinguishing Ventricular Tachycardia (VT) From Preexcited Supraventricular Tachycardia (SVT). AV, Atrioventricular; EP, electrophysiology; sens, sensitivity; spec, specificity. (From Antunes E, Brugada J, Steurer G, Andries E, Brugada P. The differential diagnosis of a regular tachycardia with a wide QRS complex on the 12-lead ECG. *Pacing Clin Electrophysiol.* 1994;17:1515–1524.)

complex in one or more of precordial leads V_2 through V_6 . If a qR complex can be identified, VT can be diagnosed with a specificity of 100%. QR or qR complexes should not be observed in those leads during ventricular preexcitation in the absence of structural heart disease.

Step 3

If a qR wave in leads V_2 through V_6 is absent, the AV relationship is then evaluated. If a 1:1 AV relationship is not present and there are more QRS complexes present than P waves, VT can be diagnosed with a specificity of 100%.

If the ECG of the WCT does not display any morphological characteristics diagnostic of VT after using this algorithm, the diagnosis of preexcited SVT must be considered. Although this algorithm has a specificity of 100% for VT, it has a sensitivity of only 75% for the diagnosis of preexcited SVT when all three steps are answered negatively (i.e., 25% of such cases are actually VT).

Limitations of Electrocardiographic Criteria for Diagnosis of Wide Complex Tachycardia

Unfortunately, the value of QRS morphological criteria in the diagnosis of a WCT is subject to several limitations. Most of the associations between the QRS morphology and tachycardia origin are based on statistical correlations, with substantial overlap. Moreover, most of the morphological criteria favoring VT are also present in a substantial number of patients with intraventricular conduction delay present during sinus rhythm, limiting their applicability in these cases. In addition, morphological criteria tend to misclassify SVTs with preexcitation as VT. However, preexcitation is an uncommon cause of WCT (1% to 6% in most series), particularly if other factors (e.g., age, history) suggest another diagnosis. Finally, in patients with VT in the absence of structural heart disease, many of the criteria are unreliable due to rapid muscle-muscle conduction.

In addition, independent studies utilizing the algorithms discussed above could not reproduce the high sensitivity, specificity, and predictive values initially reported by the original authors. In a study comparing five ECG methods (including the R wave peak time criterion, Brugada criteria, Griffith algorithm, Bayesian algorithm, and the aVR algorithm) for WCT differential diagnosis, the diagnostic accuracy was only modest (69% to 78%), and was equivalent between the various ECG methods (Table 21.2). Nonetheless, these methods differed in terms of sensitivity, specificity, and likelihood ratios. Therefore a diagnosis of VT or SVT by one test does not have the same diagnostic value as the same diagnosis made using another algorithm.¹³ The R wave peak time criterion was very specific for VT (i.e., unlikely to misclassify SVT as VT), but lacked sensitivity. Although the Griffith algorithm had high sensitivity (i.e., unlikely to miss a diagnosis of VT), its major limitation was low specificity for VT (it misclassified 60% of SVTs as VT). Hence the Griffith algorithm may be considered when a highly sensitive method for VT diagnosis is desired, and the R wave peak time criterion may be preferred when a high degree of specificity for VT diagnosis is required.¹³

In a pediatric population, the overall test accuracy was found to be lower for both Brugada and aVR algorithms (69% and 66%, respectively). When compared to the R wave peak time criterion, the aVR algorithms had superior accuracy (84% vs. 79%) and sensitivity (92% vs. 79%) but lower specificity (65% vs. 81%).¹⁶

ELECTROPHYSIOLOGICAL TESTING

Baseline Observations During Normal Sinus Rhythm

The presence of preexcitation during NSR or atrial pacing suggests SVT, and the absence of preexcitation during NSR and atrial pacing excludes preexcited SVT.

TABLE 21.2 Sensitivity, Specificity, Positive and Negative Likelihood Ratios for Ventricular Tachycardia Diagnosis, and Overall Diagnostic Accuracy (Percentage of Correct Diagnoses) for Five Methods of Wide QRS-Complex Tachycardia Differentiation

	Brugada	Griffith	Bayesian	Lead aVR	Lead II RWPT	P
Accuracy (%)	77.5 (71.8–82.5)	73.1 (67.2–78.5)	74.7 (68.9–79.9)	71.9 (66.0–77.4)	68.8 (62.7–74.4)	.04 ^a
Specificity (%)	59.2 (48.8–69.0)	39.8 (30.0–50.2)	52.0 (41.7–62.2)	48.0 (37.8–58.3)	82.7 (73.7–89.6)	<.001 ^{b,c}
Sensitivity (%)	89.0 (83.0–93.5)	94.2 (89.3–97.3)	89.0 (83.0–93.5)	87.1 (80.8–91.9)	0.60 (0.52–0.68)	<.001 ^{b,d}
LR(+)	2.18 (1.71–2.78)	1.56 (1.33–1.85)	1.86 (1.50–2.30)	1.67 (1.37–2.04)	3.46 (2.20–5.43)	—
LR(–)	0.18 (0.11–0.30)	0.15 (0.07–0.29)	0.21 (0.13–0.34)	0.27 (0.17–0.42)	0.48 (0.39–0.60)	—

From Jastrzebski M, Kukla P, Czarnecka D, Kawecka-Jaszcz K. Comparison of five electrocardiographic methods for differentiation of wide QRS-complex tachycardias. *Europace*. 2012;14:1165–1171.

Induction of Tachycardia

The mode of induction cannot distinguish between SVT and VT. Both atrial and ventricular stimulation may induce SVT or VT. VTs that can be induced with atrial pacing include verapamil-sensitive VT, adenosine-sensitive VT, and BBR VT.

Tachycardia Features

Atrioventricular Relationship

A 1:1 AV relationship can occur in VT and SVT. When the atrial rate is faster than the ventricular rate, VT is unlikely, except in the rare case of coexistent atrial and VTs (Fig. 21.13). In contrast, when the ventricular rate is faster than the atrial rate, VT is more likely, except for the rare case of junctional tachycardia, or AVNRT or orthodromic nodofascicular or nodoventricular reentry with VA block.

Oscillation in the Tachycardia Cycle Length

Variations in the tachycardia cycle length (TCL; the V-V intervals) that are dictated and preceded by similar variations in the A-A intervals (in WCTs with 1:1 AV relationship) or by similar variations in the H-H intervals (in WCTs with positive HV intervals) are consistent with SVT with aberrancy or BBR VT (Fig. 21.14). In contrast, variations in the V-V intervals that predict the subsequent H-H or A-A interval changes are consistent with myocardial VT or preexcited SVT.¹⁹

Atrial Activation Sequence

A concentric atrial activation sequence can occur in SVT and VT, whereas an eccentric atrial activation sequence practically excludes VT.

QRS Morphology

As noted, when the QRS configuration of the WCT is not compatible with any known form of aberration, the rhythm is likely to be VT or preexcited SVT. QRS morphology during WCT that is identical to that during NSR may occur in SVT with BBB, preexcited SVT (when NSR is also fully preexcited), BBR VT, and interfascicular VT.

His Bundle–Ventricular Interval

When the HV interval is positive (i.e., the His potential precedes the QRS onset), an HV interval during the WCT shorter than that during NSR ($HV_{WCT} < HV_{NSR}$) indicates VT or preexcited SVT. In contrast, an HV_{WCT} equal to or longer than HV_{NSR} indicates SVT with aberrancy or BBR VT (see Figs. 18.41 and 26.3).

When the HV interval is negative (i.e., the His potential follows the onset of the QRS), BBR VT and SVT with aberrancy are excluded. However, myocardial VTs and preexcited SVT generally have negative HV intervals (see eFig. 22.5).

Response to Right Bundle Branch Block

Abrupt prolongation of the VH interval when retrograde RBBB occurs (caused by catheter-induced trauma or introduction of ventricular extrastimuli [VESs]) is consistent with retrograde HB activation via the RB, which is typical for antidromic AVRT using a right-sided BT, but can also occur in preexcited AVNRT and in VTs originating in the RV.

However, if VH prolongation is accompanied by prolongation of the VA interval (without a change in the activation sequence) and the TCL, true antidromic tachycardia (using the AV conduction system as the retrograde limb) can be diagnosed and preexcited AVNRT is excluded.

On the other hand, continuation of the WCT after development of RBBB excludes BBR VT, except for the rare case of intrafascicular reentry. Lack of effects on the VH interval excludes antidromic AVRT using a right-sided BT, but can occur in (1) preexcited AVRT (utilizing a second BT as the retrograde limb) or (2) antidromic AVRT utilizing a left-sided BT, (3) antidromic AVNRT utilizing an atriofascicular BT inserting into the RB proximal to the site of RBBB, (4) preexcited AVNRT, and (5) VTs originating in the LV.²⁰

His Bundle–Right Bundle Electrogram Sequence

When both the HB and RB potentials are recorded, an HB–RB–V activation sequence occurs in SVT with aberrancy and in BBR VT with an LBBB pattern. In either case, the HB–RB interval during WCT is equal to or longer than that in NSR. On the other hand, an RB–HB–V activation sequence occurs in antidromic AVRT using an atriofascicular or right-sided BT, the uncommon type of BBR VT with RBBB pattern, or myocardial VT originating in the RV. An RB–V–HB activation sequence occurs in antidromic AVRT using atriofascicular BT, and a V–RB–HB or a V–HB–RB activation sequence can occur in VT.

Effects of Adenosine

Termination of WCT with adenosine can occur in SVT and adenosine-sensitive VT. Adenosine can cause transient AV block and unmask atrial activity in the setting of aberrantly conducted AFL, AF, or AT. On the other hand, adenosine can have no effect on the WCT, whether it is a VT or SVT.

Fig. 21.13 Coexistent Atrial and Ventricular Tachycardias. Surface electrocardiogram of atrial tachycardia (AT) with a narrow QRS complex with the development of ventricular tachycardia (VT) with a left bundle branch block (LBBB)-like pattern. Although the atrial rate is faster than the ventricular rate, aberrant conduction during AT as the mechanism of the widening of the QRS can be excluded by observation of QRS morphology in lead V₆ (QS) inconsistent with LBBB aberrancy, a significant shift in the frontal plane QRS axis between AT and VT, and the presence of fusion beats (*arrows*). In addition, the atrial rate continues unperturbed, whereas the ventricular rate is slightly irregular.

Diagnostic Maneuvers During Tachycardia

Atrial Extrastimulation

An atrial extrastimulation (AES), regardless of its timing, that advances the next ventricular activation with similar QRS morphology to that of the WCT excludes VT (see Fig. 18.41). Also, an AES (regardless of its timing) that delays the next ventricular activation excludes VT (see Fig. 19.3).

With a late-coupled AES delivered when the AV junctional portion of the atrium is refractory (as indicated by the lack of advancement of local atrial activation in the HB or coronary sinus [CS] os recording), if the AES advances the next ventricular activation, it proves the presence of an anterogradely conducting AV BT and excludes any arrhythmia

mechanism that involves anterograde conduction over the AVN in the absence of a bystander BT. Moreover, if the AES advances the next ventricular activation with similar QRS morphology as that of the WCT, it proves that the BT is mediating ventricular activation during the WCT (as an integral part of the SVT circuit or as a bystander) and that the WCT is a preexcited SVT, and VT is excluded. In addition, if the AES advances the timing of both the next ventricular activation and the subsequent atrial activation, it proves that the SVT is an antidromic AVRT using an AV or atriofascicular BT anterogradely, and excludes preexcited AVNRT and VT (see Fig. 18.41). Also, if the AES delays the next ventricular activation, it proves that the SVT is an antidromic AVRT using an atrioventricular or atriofascicular BT anterogradely, and excludes preexcited AVNRT and VT (see Fig. 19.3).^{21,22}

Fig. 21.14 Oscillation in the Tachycardia Cycle Length. Intracardiac atrial electrogram (A-EGM) and ventricular electrogram (V-EGM) and shock lead electrograms stored by the implantable cardioverter-defibrillator during an episode of tachycardia with a 1 : 1 atrioventricular relationship. Note that variations in the tachycardia cycle length (the V-V intervals; blue double-headed arrow) are dictated and preceded by similar variations in the A-A intervals (red double-headed arrow), which is consistent with supraventricular tachycardia rather than ventricular tachycardia sensed marker event (VT). AF, Atrial fibrillation sensed marker event; AS, atrial sensed marker event; VS, ventricular sensed marker event.

Atrial Pacing

The ability to entrain the WCT with atrial pacing can occur in VT and SVT. However, the ability to entrain the WCT with similar QRS morphology to that of the WCT (i.e., entrainment with concealed QRS fusion) excludes myocardial VT and is consistent with SVT, but can also occur in BBR VT. On the other hand, atrial entrainment of WCT with manifest QRS fusion can occur in VT in the presence of a bystander BT, or in AVRT with multiple BTs, but not in antidromic AVRT without another BT, nor in SVT with aberrancy.²¹

The ability to dissociate the atrium with rapid atrial pacing without influencing the TCL (V-V interval) or QRS morphology suggests VT and excludes preexcited SVTs, AT with aberrancy, and orthodromic AVRT with aberrancy. However, it does not exclude junctional ectopic tachycardia, nodofascicular reentrant tachycardia, or the rare case of AVNRT with aberrancy associated with anterograde block in an upper common pathway during rapid atrial pacing.

The response to atrial overdrive pacing during WCTs with a 1 : 1 AV relationship can help distinguish VT from SVT. The concept is analogous to examination of the response to ventricular overdrive pacing during narrow complex tachycardia. During VT, atrial overdrive pacing at a pacing cycle length (PCL) 20 to 60 milliseconds shorter than the TCL with 1 : 1 AV conduction results in anterograde capture with changing or narrowing of the tachycardia QRS morphology. When the tachycardia resumes after cessation of pacing, the earliest event (after the last reset ventricular complex) occurs in the ventricle because the atrium is being passively driven by the ventricle during the tachycardia. This results in a “V-V-A response.” On the contrary, during antidromic AVRT or aberrantly conducted SVT, anterograde conduction occurs over a BT or AVN; and on cessation of atrial pacing, the last reset ventricular activation conducts to the atrium over the retrograde limb of the circuit, resulting in a “V-A response” and continuation of the tachycardia

(Fig. 21.15). This pacing maneuver is not useful when 1 : 1 AV conduction during atrial pacing is absent. Thus, when determining the response after atrial pacing during WCT, the presence of 1 : 1 VA conduction must be confirmed. Isorhythmic AV dissociation can mimic 1 : 1 AV conduction, especially when the pacing train is not long enough or the PCL is too slow. It is also important to ensure that atrial pacing does not terminate the tachycardia.^{21,22}

A “pseudo-V-V-A response” can occur during SVTs associated with a long AV interval during atrial pacing (Fig. 21.16). Because anterograde conduction during atrial pacing occurs through the slow AVN pathway, the AV interval can be longer than the PCL (A-A interval), so that the last paced P wave is followed first by the QRS complex resulting from slow AV conduction of the preceding paced atrial beat, and then by the QRS complex resulting from the last paced P wave. Careful examination of the last QRS complex that resulted from AV conduction during atrial pacing helps avoid this potential pitfall; the last controlled QRS complex characteristically occurs at an R-R interval equal to the atrial PCL, whereas the first tachycardia QRS complex usually occurs at a different return cycle length (CL). Furthermore, a “pseudo-V-A response” can theoretically occur in the setting BBR VT or in those with intra- or interfascicular reentrant VT, whereby the return atrial impulse may precede the first non-reset QRS complex.^{21,22}

Ventricular Extrastimulation

In WCTs with 1 : 1 AV relationship, a VES that resets (advances or delays) the next QRS without affecting the A-A interval is consistent with VT and practically excludes SVT. In addition, a VES delivered when the HB is refractory and that terminates the WCT without atrial activation is consistent with VT, but can also occur in orthodromic AVRT with aberrant conduction or in antidromic AVRT using a second BT as the retrograde limb of the circuit.

Fig. 21.15 V-A Response to Atrial Overdrive Pacing During Wide QRS Complex Tachycardia. The QRS morphology and His bundle–ventricular interval (45 milliseconds) during atrial pacing (*arrows*) are similar to those during tachycardia. On cessation of pacing, the last atrial-paced beat is followed by a “V-A response” consistent with supraventricular tachycardia as the mechanism. This tachycardia was an atypical atrioventricular nodal tachycardia with right bundle branch block aberrancy. *CS_{dist}*, Distal coronary sinus; *CS_{prox}*, proximal coronary sinus; *HRA*, high right atrium; *RVA*, right ventricular apex.

Fig. 21.16 Pseudo-V-V-A Response to Atrial Overdrive Pacing During Wide QRS Complex Tachycardia. The QRS morphology and His bundle–ventricular interval (45 milliseconds) during atrial pacing are similar to those during tachycardia. On cessation of pacing, the last atrial-paced beat is followed by a “V-V-A response” suggestive of ventricular tachycardia as the mechanism. However, although the last atrial-paced beat is followed by two QRS complexes, the last captured QRS complex (which characteristically occurs at an R-R interval equal to the atrial pacing cycle length [CL]) is actually the second one (as indicated by *blue arrows*), due to anterograde conduction over the slow atrioventricular (AV) nodal pathway, resulting in an AV interval longer than the pacing CL. Therefore the actual response is a “V-A response” consistent with supraventricular tachycardia. This supraventricular tachycardia was atrioventricular nodal tachycardia with left bundle branch aberrancy. *HRA*, High right atrium; *RV*, right ventricle.

Ventricular Pacing

When overdrive ventricular pacing during the WCT fails to accelerate the atrial CL to the PCL (i.e., the ventricles are dissociated from the tachycardia), VT and AVRT are excluded, AT is the most likely diagnosis, but AVNRT is still possible (eFig. 21.2). In addition, entrainment with manifest QRS fusion can occur in VT or AVRT but excludes AT and AVNRT, whereas entrainment with concealed fusion excludes SVT with aberrancy. Furthermore, entrainment from the RV apex followed by a postpacing interval that is equal (within 30 milliseconds) to the TCL excludes AVNRT, AT, and myocardial VT, but can occur with BBR VT and AVRT using a right-sided BT.

Fig. 21.2 Response to Overdrive Ventricular Pacing During Tachycardia. (A) Intracardiac atrial and ventricular electrograms (A-EGM and V-EGM, respectively) stored by the implantable cardioverter-defibrillator (ICD) during an episode of tachycardia at a cycle length (CL) of 290 milliseconds and a 1 : 1 AV relationship. The tachycardia triggered antitachycardia pacing (ATP) therapy by the ICD with a ramp of nine ventricular paced beats. ATP fails to terminate the tachycardia, which resumes at the baseline CL. (B) A plot of atrial versus ventricular CLs during the tachycardia and two sequences of ramp ATP. Note that the atrial rate continues unperturbed during ventricular pacing (i.e., ventriculoatrial dissociation was evident during ATP), which excludes ventricular tachycardia and orthodromic atrioventricular reentrant tachycardia and is consistent with either atrial tachycardia or atrioventricular nodal reentrant tachycardia.

CLASSIFICATION OF VENTRICULAR TACHYARRHYTHMIAS

Ventricular tachycardia (VT) is defined as a tachycardia (rate greater than 100 beats/min) with three or more consecutive beats that originates below the bifurcation of the His bundle (HB), in the specialized conduction system, the ventricular muscle, or in a combination of both tissues, independent of atrial and atrioventricular node (AVN) conduction.^{1,2}

Classification According to Tachycardia Morphology

Monomorphic VT has a single stable QRS morphology from beat to beat, indicating repetitive ventricular depolarization with the same activation sequence (Fig. 22.1).

Multiple monomorphic VTs refers to more than one morphologically distinct monomorphic VT, occurring as different episodes or induced at different times.

Polymorphic VT has clearly defined QRS complexes with a continuously changing morphology or multiform QRS morphology (i.e., no constant morphology for more than five complexes, no clear isoelectric baseline between QRS complexes, or QRS complexes that have different morphologies in multiple simultaneously recorded leads), indicating a variable sequence of ventricular activation and no single site of origin.¹

Torsades de pointes is a polymorphic VT associated with a long QT interval, and is electrocardiographically characterized by twisting of the peaks of the QRS complexes around the isoelectric line during the arrhythmia.

Fig. 22.1 Surface Electrocardiogram of Different Types of Ventricular Tachycardia (VT).

Pleomorphic VT has more than one morphologically distinct QRS complex occurring during the same episode of VT, but the QRS morphology is not continuously changing.

Bidirectional VT is a VT associated with a beat-to-beat alternans in the QRS frontal plane axis, often associated with digitalis toxicity or catecholaminergic VT.

Ventricular flutter is a term that has been applied to a rapid (250 to 350 complexes/min) VT that has a sinusoidal QRS configuration that prevents clear identification of the QRS morphology.

Ventricular fibrillation (VF) is a rapid (usually greater than 300 complexes/min), chaotic tachycardia without consistently identifiable QRS complexes.¹

Classification According to Tachycardia Duration

Sustained VT lasts for more than 30 seconds or requires termination (e.g., cardioversion) in less than 30 seconds because of hemodynamic compromise, whereas *nonsustained VT* is a tachycardia at more than 100 beats/min lasting for three or more complexes but for less than 30 seconds and not requiring termination.

During electrophysiological (EP) testing, nonsustained VT is defined as more than five or six complexes of non–bundle branch reentrant (BBR) VT, regardless of morphology. BBR complexes are frequent (50%) in normal individuals in response to ventricular extrastimulus (VES) and have no relevance to clinical nonsustained VT.

Repetitive polymorphic responses are also common (up to 50%) during programmed ventricular stimulation, especially in response to multiple (three or more) VESs with very short coupling intervals (less than 180 milliseconds). The clinical significance of induced polymorphic nonsustained VT is questionable.

Incessant VT is a continuous sustained VT that recurs promptly over several hours despite repeated interventions (e.g., electrical cardioversion) for termination. Less commonly, incessant VT manifests as repeated bursts of VT that spontaneously terminate for a few intervening sinus

beats, followed by the next tachycardia burst. The latter form is more common with the idiopathic VTs (see Fig. 23.1).

Classification According to QRS Morphology in Lead V₁

Monomorphic VT can be classified as having one of two patterns: a right bundle branch block (RBBB)–like pattern or a left bundle branch block (LBBB)–like pattern. VTs with an LBBB-like pattern have a predominantly negative QRS polarity in lead V₁ (QS, rS, qrS), whereas VTs with a RBBB-like pattern have a predominantly positive QRS polarity in lead V₁ (rsR', qR, RR, R, RS). Importantly, this classification pertains to QRS morphology only in lead V₁; the VT may not show features consistent with the same BBB configuration in other leads. Also, the determination that the VT has an RBBB-like pattern or an LBBB-like pattern does not, by itself, assist in making a diagnosis; however, this assessment should be made initially because it has further implications for evaluating several other features on the ECG, including the QRS axis, the QRS duration, and the QRS morphology.

Classification According to Tachycardia Mechanism

Focal VT has a point source of earliest ventricular activation with a centrifugal spread of activation from that site. The mechanism can be abnormal automaticity, triggered activity, or microreentry. *Scar-related reentrant VT* describes arrhythmias that have characteristics of reentry and originate from an area of myocardial scar identified from electrogram characteristics or myocardial imaging. Large reentry circuits that can be defined over several centimeters are commonly referred to as “macroreentry” circuits.

PATHOPHYSIOLOGY

Mechanisms of Ventricular Arrhythmias Associated With Acute Ischemia

Acute myocardial ischemia leads to local tissue hypoxia, depletion of adenosine triphosphate (ATP), and anaerobic glycolysis causing intracellular

acidosis. ATP depletion impairs the function of the ATP-dependent $\text{Na}^+\text{-K}^+$ pump, causing net K^+ leakage from the myocyte and elevation of extracellular K^+ concentration. This results in depolarization of the resting membrane potential of the surviving Purkinje fibers and, as a consequence, abnormal automaticity.^{3,4}

In addition, intracellular acidification and accumulation of H^+ ions activate the $\text{Na}^+\text{-H}^+$ exchanger, which extrudes H^+ in exchange for Na^+ entry, causing increased intracellular Na^+ concentration. The latter activates the $\text{Na}^+\text{-Ca}^{2+}$ exchanger in the reverse mode, which extrudes Na^+ in exchange for Ca^{2+} entry, causing intracellular Ca^{2+} overload in the ischemic myocardium which, in turn, leads to delayed afterdepolarizations (DADs) and triggered arrhythmias.⁵

Furthermore, membrane depolarization causes Na^+ channel inactivation and, as a result, reduced fast Na^+ current and reduced action potential upstroke, leading to slowed conduction and altered refractoriness.

Although an initial prolongation of the action potential duration can be observed (likely caused by an increase in the late Na^+ current), abbreviation of the action potential duration develops shortly afterward secondary to reduced Na^+ entry (due to Na^+ channel inactivation), reduced Ca^{2+} entry (due to inhibition of Ca^{2+} channels by acidosis), and enhanced K^+ efflux (due to activation of ATP-sensitive potassium current, IK-ATP , caused by reduced intracellular ATP).^{3,4}

Importantly, the effects of ischemia on the EP properties of myocardial cells are heterogeneous. Shortening of the action potential duration and reduction of upstroke velocity and amplitude are more pronounced within the central zone of ischemia and subepicardium than within the border zone and subendocardium. On the other hand, the surrounding normal myocardium can have an increase in conduction velocity (secondary to increased catecholamines) and decrease in refractoriness. This heterogeneity of action potential duration and dispersion of refractoriness provide a substrate for an injury current to flow between the ischemic and the nonischemic cells located at the border zone. In addition, myocardial ischemia causes disruption of gap junctions, leading to cellular uncoupling, with consequent slow and anisotropic conduction, and unidirectional conduction block, providing a substrate for reentry.^{3,4,6}

High levels of catecholamines, endothelin-1 activation, increased lysophosphatidylcholine (a phospholipid that accumulates in ischemic myocardium), mechanical stretch (induced by the viable myocardium surrounding the infarct zone), electrolyte abnormalities (particularly hypokalemia and hypomagnesemia), preexisting myocardial abnormalities (e.g., prior myocardial infarction [MI], hypertrophy, depressed ejection fraction), and genetic predisposition (likely mediated by mutations or polymorphism in genes encoding ion channels), can all significantly modify the EP properties of the substrate and contribute to arrhythmogenesis. Prolonged and severe acute ischemia and delayed or unsuccessful revascularization increase the risk of ventricular arrhythmias during an acute ischemic event.⁴

Experimental studies demonstrated that arrhythmia mechanisms undergo dynamic changes in the early minutes and hours after onset of myocardial ischemia. Two temporally distinct phases of ventricular arrhythmia develop in response to ischemic injury: phase 1 is the reversible phase of acute MI, whereas phase 2 is the infarct evolution phase (eFigs. 22.1 and 22.2).⁴

Phase 1: Acute Phase of Myocardial Ischemia

Phase 1, occurring during the first 2 to 30 minutes, is reversible if perfusion is restored within 15 minutes of coronary occlusion. It is estimated that 30% to 50% of sudden cardiac deaths (SCDs) during acute MI occur during phase 1 of ischemic injury, with VF occurring without or with a short interval of preceding symptoms.^{3,4}

Phase 1 is divided in 2 subphases: phase 1A (2 to 10 minutes) and phase 1B (10 to 30 minutes). Ventricular arrhythmias occurring within

the first 10 minutes following the onset of myocardial ischemia (phase 1A) are predominantly related to reentry within the ischemic myocardium caused by heterogeneity of conduction and refractoriness in normal and ischemic tissue. Phase 1A arrhythmias typically manifest as bursts of VT that rarely degenerate into VF.

On the other hand, ventricular arrhythmias occurring between 10 and 30 minutes following the onset of ischemia (phase 1B) seem to be mediated by abnormal automaticity, and possibly reentry, though the exact mechanism(s) remains uncertain. Phase 1B appears more arrhythmogenic than phase 1A, and arrhythmias in this phase more frequently evolve into VF.^{3,4}

Phase 2: Subacute Phase of Myocardial Ischemia

Persistent myocardial ischemia beyond the first 30 minutes leads to irreversible myocardial necrosis (Phase 2, infarct evolution phase), which extends between 1.5 and 48 hours after the onset of ischemia. Nonetheless, subendocardial Purkinje fibers are more resistant to ischemia and may survive, but with altered EP properties predisposing to arrhythmia generation. Reduced resting membrane potentials, Ca^{2+} overload, and heterogeneity of conduction and refractoriness at the infarct border zone, all can lead to focal (abnormal automaticity and triggered activity) and reentrant arrhythmias.^{3,4}

Of note, there is a period of low arrhythmogenesis lasting for 30 to 60 minutes between phases 1 and 2. There is no explanation for this phenomenon.

Mechanisms of Ventricular Arrhythmias Associated With Healed Infarction

Most post-MI sustained monomorphic ventricular tachycardias (SMVTs) are caused by macroreentry involving the region of the ventricular scar. Left ventricular (LV) remodeling begins almost immediately after acute MI. Experimental studies suggest that the EP substrate for monomorphic VT gradually forms in the subacute phase (in the first week) following acute MI and once established, appears to remain stable into the chronic phase. EP and electroanatomical characteristics demonstrated no difference between induced VT during the subacute and chronic phases, with comparable sites of earliest presystolic activation. These sites are located predominantly in the border zone adjacent to dense injury areas in both phases.^{3,4,7}

Persistent coronary occlusion typically leads to a central core of dense transmural scar in the territory supplied by the occluded artery, surrounded by a thin rim (border zone) where fibrotic tissue and viable myocardial fibers are intermixed. Conversely, early reperfusion (achieved by thrombolytics or coronary intervention) can lead to a more complex substrate, with nontransmural myocardial necrosis (primary subendocardial necrosis and variable epicardial sparing depending on the duration of coronary occlusion) and heterogeneous (and even patchy) scarring with multiple channels of viable myocardium embedded within the scar region, and complex border zones. The scar and fibrosis resulting from MI are distinctly different from nonischemic etiologies. Compared with post-MI VT, the scar in dilated cardiomyopathy (DCM) tends to be smaller and less confluent, with less endocardial involvement and less transmural involvement. Whereas ischemia produces a predictable wedge-shaped wavefront of necrosis progressing from subendocardium to epicardium (and scar areas larger endocardially than epicardially), usually confined to a specific coronary vascular territory, scars in nonischemic DCM have been shown to have a predilection for the midmyocardium and epicardium. In contrast to the dense post-MI scar with isolated surviving myocardial bundles, scarring in nonischemic DCM is patchy with fewer fixed boundaries and protected channels or isthmuses, which can alter the extent of local conduction slowing.^{8,9}

Generally, the reentrant circuit arises in areas of a dense fibrotic scar interspersed with bundles of viable myocytes with poor intercellular coupling (due to altered gap junctions), producing a zigzag course of activation along a pathway lengthened by branching and merging bundles of surviving myocytes, leading to nonuniform anisotropic conduction (see Fig. 3.18). Heterogeneity in tissue composition and autonomic innervation in these regions can create areas of slow conduction and block, which promote reentry.

Buried in the arrhythmogenic substrate is the common central pathway (critical isthmus), which is a narrow path of tissue with abnormal conduction properties, causing slowing of impulse propagation and allowing reentry to occur. The isthmus itself can be surrounded by dead ends or branches that do not participate in the common pathway of the main reentrant circuit (i.e., bystander channels). The critical isthmus is typically protected by boundaries formed of both fixed and functional conduction block. Fixed conduction barriers are anatomically determined by the heterogeneous scar geometry or a valvular annulus. Development of functional conduction block is a prerequisite for initiation of VT in most cases, forming at least one border of the diastolic pathway. Evidence indicates that formation of functional block leading to reentry is associated with a large dispersion in refractory periods over short anatomical distances.¹⁰

Depolarization of the small mass of tissue within the isthmus is usually not detectable on the surface ECG and constitutes the electrical diastole between QRS complexes during VT. The wavefront leaves the isthmus at the exit site and propagates out to depolarize the remainder of the ventricles, producing the QRS complex. After leaving the exit of the isthmus, the reentrant wavefront can return to the entrance of the isthmus through an outer loop or an inner loop (see Fig. 5.16). An outer loop is a broad sheet of myocardium along the outer border of the infarct. The reentrant wavefront propagates through the outer loop while at the same time activating the rest of the myocardium, corresponding to electrical systole (QRS complex) on the surface ECG. Reentrant circuits can have one or more outer loops. An inner loop is a conduction pathway within scars, communicating with the common central pathway (critical isthmus) forming a circuit. The inner loop can serve as an integral part of the reentrant circuit or function as a bystander pathway. The dominant loop is the circuit loop outside the common central pathway with the shortest conduction time. If conduction through the inner loop is slower than conduction from the exit to entrance sites (through the outer loop), the inner loop will serve as a bystander, and the outer loop will be the dominant loop. If conduction through the inner loop is faster than conduction through the outer loop, it will form an integral component of the reentrant circuit and is designated as the dominant inner loop. Bystander loops can serve as a potential component of a new reentrant circuit if the dominant loop is ablated.^{5,10} This may manifest as sudden slowing of the VT rate without changing QRS morphology during ablation of the dominant nonisthmus loop.

Studies using electroanatomic substrate mapping found that ischemic cardiomyopathy patients without clinical SMVT had markedly smaller endocardial low-voltage areas, fewer scar-related electrograms (i.e., fractionated, isolated, and very late potentials, which represent electrically viable sites within the scar), and fewer putative conducting channels compared with patients with spontaneous SMVT, despite equally severe LV dysfunction as well as similar infarct age and distribution. These differences in the myocardial EP substrate can play an important role in VT arrhythmogenesis in the chronic post-MI context. Both the extent of the scar areas (electrogram voltage less than 0.5 mV) and the presence of numerous channels within this zone seem to be critical to the development of VT. Although the border zone region of the scar (electrogram voltage, 0.5 to 1.5 mV) did not differ in area

between the two groups, this zone also had a significantly higher prevalence of putative conducting channels in the SMVT patients. This suggests a fundamentally different scar composition (more “arrhythmogenic”) in the SMVT patients. As noted, inhomogeneous scarring with varying degrees of subendocardial myocardial fiber preservation within dense zones of fibrosis leads to slowed conduction, nonuniform anisotropy, and the potential for channels within the scar zone—conditions necessary for the development of reentry.¹¹

It is common for patients with post-MI VT to have more than one VT morphology. Even in patients presenting with a single SMVT, multiple distinct uniform VTs can be induced in the EP laboratory, especially in patients receiving antiarrhythmic therapy. The induction of multiple VT morphologies during an ablation procedure suggests that the arrhythmogenic substrate can support multiple reentrant circuits or different exit sites from a single circuit. Distinct VT morphologies (as defined by the 12-lead ECG and tachycardia cycle length [TCL]) often share a common isthmus but differ in propagation direction or location across the isthmus perimeter during reentry, but can also arise from distinct, usually adjacent, circuits.

A focal mechanism of VT (abnormal automaticity or triggered activity) has been implicated in the setting of acute ischemia. Focal VT can also occur in the absence of an acute ischemic event in patients with chronic ischemic heart disease. In one study, a focal mechanism was present in up to 9% of VTs that were induced in patients with ischemic heart disease during EP study for radiofrequency (RF) ablation.¹²

Infrequently, SMVT in the setting of chronic coronary artery disease (CAD) is related to a nonischemic arrhythmogenic substrate rather than a healed infarct. CAD can coexist with nonischemic cardiomyopathy, in which setting, arrhythmogenic substrate is inconsistent with the distribution of CAD, with VT morphologies originating in the periannular basal ventricular segments and frequent epicardial VT exits.¹³

EPIDEMIOLOGY AND NATURAL HISTORY

Coronary heart disease is the most frequent cause of clinically documented VT and VF (76% to 82% of patients). The incidence of ventricular arrhythmias in the periinfarct period and long-term post MI seems to have decreased over the past decades, likely due to the contemporary coronary revascularization strategies and pharmacological therapy, which have reduced 1-year mortality rates to less than 5%. Sustained VT and VF continue to occur in almost 6% of patients in the very early phase of acute MI, and they remain a major cause of death in the first 30 days after MI, particularly in those with LV dysfunction or heart failure.^{3,4,14,15}

Among almost 41,000 patients with ST-elevation MI treated with thrombolysis in the GUSTO-1 trial, 3.5% developed VT alone and 2.7% developed both VT and VF. In general, the incidence of sustained VT/VF complicating non-ST-elevation acute coronary syndrome (non-ST-elevation MI and unstable angina) has been lower; a pooled analysis of four major trials of more than 26,000 patients with non-ST-elevation acute coronary syndrome, 2.1% developed sustained ventricular arrhythmias. More contemporary estimates suggest a lower incidence (1.5%) of sustained VT/VF in this patient population. In a study examining all patients undergoing percutaneous intervention for acute coronary syndromes (ranging from unstable angina to ST-elevation MI) in the New York State registry, just over 5% of patients experienced sustained VT/VF.^{3,4,16}

In general, in the setting of acute ST-elevation MI, sustained ventricular arrhythmias are most frequent within 24 to 48 hours after the onset of ischemia. In contrast, these events do not appear to be confined predominantly to the first 48 hours after non-ST-elevation acute coronary events.¹⁶

Premature Ventricular Complexes

Premature ventricular complexes (PVCs) are seen in most cases of acute MI. Early PVCs (within the first 48 hours) do not appear to affect the prognosis. In contrast, repetitive complex PVCs (ventricular bigeminy, couplets, or multiform PVCs) occurring beyond 48 hours after acute MI can be associated with increased arrhythmic risk, particularly in patients with larger infarctions and impaired LV function.

Accelerated Idioventricular Rhythm

Accelerated idioventricular rhythm occurs in up to 50% of patients with acute MI, predominantly occurring in the first 12 hours after admission for acute MI. Although more common in patients with successful reperfusion therapy, accelerated idioventricular rhythm is neither a sensitive nor a very specific marker for successful reperfusion.

Reperfusion Arrhythmias

Ventricular arrhythmias upon reperfusion typically manifest as bursts of PVCs with long coupling intervals and accelerated idioventricular rhythms occurring at the moment of reperfusion, and are hemodynamically well tolerated. These arrhythmias originate within the reperfusion zone and likely reflect myocellular reperfusion injury. Reperfusion injury produces a second peak of myocardial necrosis, which depends on the duration of the preceding ischemia. Alteration of the EP substrate and, in particular, intracellular Ca^{2+} overload combined with increased catecholamines, likely play a central role in reperfusion arrhythmias. Abnormal automaticity is the likely mechanism.

In conjunction with thrombolytic therapy, reperfusion ventricular arrhythmias were considered as a noninvasive marker of successful infarct artery recanalization; however, current evidence suggests that those arrhythmias are neither specific nor sensitive. In the more contemporary era of primary percutaneous coronary intervention (PCI), the presence of ventricular arrhythmia bursts timed closely to reperfusion appears to predict larger infarct size in patients presenting with ST-segment elevation MI and treated with primary PCI resulting in brisk epicardial flow restoration (TIMI 3 flow) and rapid and complete ST-segment resolution.^{17,18}

Nonsustained Ventricular Tachycardia

Nonsustained VT is observed in 1% to 7% of acute MI patients. Nonsustained VT occurring early (within the first 2 to 3 hours) following acute MI does not appear to predict poor prognosis. Arrhythmic episodes occurring later (after the first 24 hours, and particularly after the first week), in the course of acute MI portend a worse prognosis. Beyond the periinfarct period, nonsustained VT is common in ischemic heart disease, recorded in 30% to 80% of patients during long-term ambulatory monitoring, or detected by cardiac implanted devices.^{1,19}

Polymorphic Ventricular Tachycardia

Polymorphic VT, which occurs in 0.3% to 2% of patients, is usually due to abnormal automaticity or triggered activity associated with ischemia or reperfusion. In the setting of coronary disease, polymorphic VT is generally considered a marker of ongoing ischemia and is often suppressed by antiischemic interventions. Unlike monomorphic VT, polymorphic VT is rarely seen in patients with healed MI in the absence of acute myocardial ischemia.

Ventricular Fibrillation

VF occurs in 3.7% of all acute ST-elevation MIs in the first 48 hours, and this is likely an underestimation because prehospital events are not included. When all VF events, before and after 48 hours, were included, VF was found to occur in 6.7% of ST-elevation MI patients and in

1.3% of non-ST-elevation MI patients. The majority of arrhythmic episodes occur early (within the first 48 hours) in the course of acute MI.

Primary VF (i.e., VF that occurs during the first 48 hours of an uncomplicated MI, without recurrent ischemia or heart failure), is associated with an up to fivefold increase in hospital mortality (greater than 50% due to LV failure or cardiogenic shock) but appears to have little effect on long-term mortality in patients who survived to hospital discharge.²⁰ Conversely, *nonprimary VF* (i.e., VF that occurs beyond the first 48 hours following MI or in the setting of recurrent ischemia or heart failure) is associated with marked increases in both 30-day mortality and 6-month mortality. The temporal cutoff between “early” and “late” arrhythmias at 48 hours following MI, however, is arbitrary to some extent; data to suggest that this should be at 24 hours or even earlier exist.¹⁴

Several factors appear to be associated with an increased risk of early VF during the periinfarction period, including ST-elevation MI, larger infarct size, inferoposterior MI, periinfarction angina, incomplete revascularization, hypokalemia, hypotension, male gender, younger age, and history of smoking.¹⁴

Sudden Cardiac Death

SCD accounts for up to 15% of total mortality in industrialized countries and claims the lives of more than 200,000 to 400,000 people per year in the United States (precise number not known and impacted by how estimates are obtained). Approximately 50% of deaths in patients with prior MI occur suddenly and unexpectedly. Ventricular arrhythmias are responsible for most of these deaths in stable ambulatory populations. Most SCD victims have known heart disease—most frequently CAD or prior MI.

Cardiac arrest is the initial manifestation of heart disease in approximately 50% of cases. Such patients are more likely to have single-vessel coronary disease and normal or mildly abnormal LV systolic function than cardiac arrest victims with prior MI. Although heart failure increases risk for both sudden and nonsudden death, a history of heart failure is present in only approximately 10% of cardiac arrest victims.

Acute MI is a common precipitant of out-of-hospital cardiac arrest, especially in older patients. About 40% of out-of-hospital cardiac arrest survivors develop overt signs of an MI (e.g., ST-segment elevation, Q waves, or elevated cardiac enzymes), and 50% are found to have an acutely occluded coronary vessel on coronary angiography.²⁰

The risk for arrhythmic and total mortality is highest in the first month after an acute MI and stays high during the first 6 months after acute MI. After the first year post MI, there appears to be a relatively quiescent period of relatively low rates of SCD, followed by a second peak 4 to 10 years after acute MI. The later occurrence of SCD likely results from delayed ventricular remodeling resulting in the creation or activation of reentrant VT circuits on the infarct border and from heart failure developing late after MI.

Although cardiac arrest and SCD in post-MI patients are predominantly caused by VT or VF, several studies in patients with cardiac arrest have shown that VF as the causative rhythm appears to be decreasing, being replaced by pulseless electrical activity and asystole. The cause of this change is unknown, but it may reflect patients with sicker hearts who are living longer due to better therapy. Hearts with advanced disease may be more likely to develop pulseless electrical activity and asystole than VF.

Sustained Monomorphic Ventricular Tachycardia

“Early” SMVT within the first 24 to 48 hours of acute MI is uncommon, and occurs in about 2% to 3% of ST-elevation MI patients and in less than 1% of non-ST-elevation MI patients. Although early SMVT is

associated with an increase in in-hospital mortality, studies showed that mortality at 1 year (among 21- to 30-day survivors) is not increased, suggesting that the arrhythmogenic mechanisms can be transient in early post-MI SMVT. Nevertheless, it is important to understand that data are limited regarding the long-term prognostic significance of SMVT in the early post-MI setting because most studies combined VT and VF or sustained and nonsustained VT without specifying the results for each arrhythmia. Many investigators consider SMVT, even when occurring in the early hours following MI, to be an indicator of the presence of an already established permanent substrate (developing necrosis or preexisting scar) and, hence, an indicator of high long-term risk for arrhythmic events.

On the other hand, the typical patient with SMVT occurring during the subacute and healing phases, beginning more than 48 hours after an acute MI, has had a large, often complicated infarct with a reduced left ventricular ejection fraction (LVEF), and such VT is a predictor of a worse prognosis. SMVT within 3 months of an MI is associated with a 2-year mortality rate of 40% to 50%, with most deaths being sudden. Predictors of increased mortality in these patients include anterior wall MI, frequent episodes of sustained or nonsustained VT, heart failure, and multivessel coronary disease, particularly in individuals with residual ischemia.

Early reperfusion of infarct-related arteries results in less aneurysm formation, smaller scars, and less extensive EP abnormalities, although a significant risk of late VT (often with rapid TCLs) persists. In patients with ST-elevation MI treated with primary PCI, delayed reperfusion (greater than 5 hours after MI) was associated with a sixfold increase in the odds of inducible SMVT by programmed electrical stimulation (performed 6 to 10 days post MI) as well as an increased risk of spontaneous ventricular arrhythmias and SCD (after a mean follow-up of 28 ± 13 months) compared with early reperfusion (≤ 3 hours), independent of LVEF. It was estimated that each 1-hour delay in reperfusion conferred a 10.4% increase in the odds of inducible VT.

Most episodes of post-MI SMVT occur during the chronic phase. Among all patients presenting with SMVT in the setting of significant structural heart disease, ischemic heart disease is the most frequent etiology, comprising 54% to 59% of patients who receive an implantable cardioverter-defibrillator (ICD) or who are referred for catheter ablation.¹

VT occurs in 1% to 2% of patients late after MI, but the time interval from MI to first episode of VT is highly variable. The first episode can be seen within the first year post MI, but the median time of occurrence is about 3 years, and SMVT can occur as late as 10 to 15 years after an MI. Late SMVT often reflects significant LV dysfunction and the presence of a ventricular aneurysm or scarring. Late arrhythmias can also result from new cardiac events. The annual mortality rate for SMVT that occurs after the first 3 months following acute MI is approximately 5% to 15%. Predictors of life-threatening ventricular arrhythmias include residual ischemia in the setting of damaged myocardium, LVEF less than 40%, and electrical instability, including inducible or spontaneous VT, particularly in those who present with cardiac arrest.

Recent evidence suggests that coronary revascularization before or shortly after ICD placement in high-risk post-MI patients with LV dysfunction and wide QRS duration can potentially reduce the risk for life-threatening ventricular arrhythmias and appropriate ICD shocks.

The relationship between SMVT and VF is uncertain, and it is not clear how often VF is triggered by SMVT rather than occurring *de novo*. SMVT can simply be the company kept by VF in a number of patients or, in the appropriate setting such as recurrent ischemia, a rapid VT can develop a wavefront that becomes fractionated, leading to VF.

CLINICAL PRESENTATION

Clinical presentation of ventricular arrhythmias in patients with CAD is variable. In the setting of acute ischemia, sustained ventricular arrhythmias can manifest as palpitations or worsening angina, but more often present with syncope and cardiac arrest. In chronic ischemic heart disease, VT results in a wide spectrum of clinical presentations, ranging from mild symptoms (palpitations) to symptoms of hypoperfusion (lightheadedness, altered mental status, presyncope, and syncope), exacerbation of heart failure and angina, and cardiovascular collapse. Patients with ICDs may experience ICD shocks triggered by the arrhythmia. Incessant VT, even at relatively slow rates, can lead to hemodynamic deterioration and heart failure. Hemodynamic consequences associated with VT are related to ventricular rate, duration of VT, presence and extent of LV dysfunction, ventricular activation sequence (i.e., ventricular dyssynchrony), and loss of atrioventricular (AV) synchrony.

INITIAL EVALUATION

Evaluation of Type and Burden of Ventricular Arrhythmias

Identifying and quantifying the types and burden of sustained and nonsustained VT and PVCs are necessary. In addition to 12-lead ECG, ambulatory cardiac monitoring (Holter or event monitoring) or implantable loop recorders may be required to document the type, burden, and clinical impact of the arrhythmia. In patients with ICDs, stored device data such as electrogram morphology and TCL can be used to identify the clinical VT.

Evaluation of the Triggers of Ventricular Arrhythmias

Initial testing in patients with post-MI VT should evaluate for reversible causes of the arrhythmia. These include electrolyte imbalances, acute ischemia, heart failure, hypoxia, hypotension, drug effects, and anemia.

Evaluation of Myocardial Ischemia

Although recurrent SMVT is rarely due to acute myocardial ischemia in patients with known CAD, diagnostic evaluation for acute or persistent ischemia is warranted to improve patient outcome, especially if the severity of CAD has not been previously established or prior episodes of VT caused hemodynamic compromise. This may include echocardiographic examination, exercise testing, and cardiac catheterization. In patients with reversible myocardial ischemia, coronary revascularization may be warranted, and can potentially reduce the risk of life-threatening ventricular arrhythmias. However, if the severity of coronary disease has been recently defined and symptoms and hemodynamic tolerance of VT do not suggest significant ischemia, further evaluation may not be required.

Role of Electrophysiological Testing

Invasive EP testing should be considered in post-MI patients presenting with unexplained syncope or sustained palpitations, and those with wide complex tachycardia of uncertain mechanism. In addition, EP testing can be used for risk stratification late after MI in patients with ischemic cardiomyopathy and nonsustained VT (see later). However, EP testing is not recommended in patients with documented sustained VT unless catheter ablation is planned.¹

Programmed stimulation induces VT in over 90% of patients with a history of VT. Although the rate and QRS morphology of the induced VT can differ from that observed during spontaneous tachycardia, the induction of VT signifies the presence of a fixed anatomical substrate associated with an increased likelihood of future spontaneous events.

RISK STRATIFICATION

There are more than 50 million North American adults with CAD and more than 7 million have had an MI. However, only a fraction of these patients will suffer a cardiac arrest. Therefore noninvasive risk assessment after MI is required to identify patients at risk of SCD.

Various tests assessing the extent of myocardial damage and scarring, myocardial conduction disorders, dispersion of repolarization, and autonomic imbalance have been proposed to identify patients at high risk of SCD who are likely to benefit from prophylactic ICD therapy. Some of these techniques potentially identify the underlying substrate (e.g., myocardial scar, intramyocardial conduction abnormalities) or triggers (e.g., autonomic imbalance, nonsustained VT) of malignant ventricular arrhythmias. However, most of these techniques have not been validated in independent populations and, although they can predict higher risk of total mortality, their ability to predict arrhythmic death is uncertain (i.e., limited specificity). In addition, most conventional risk stratifiers of SCD have a relatively low positive predictive value that would preclude their wide application as guidelines for ICD implantation in patients known to be at risk for SCD.²¹

To date, only two approaches have been proven useful in guiding prophylactic ICD therapy in post-MI patients: the presence of significant LV dysfunction alone or in combination with the inducibility of sustained VT/VF during programmed electrical stimulation beyond the early phase after MI. It should be recognized, however, that the development of SCD in post-MI patients is multifactorial, and multiple events need to coincide for a cardiac arrest to ensue; therefore no one risk stratification test alone will be sufficient for all patients. Rather, combining multiple tests in screening for the different potential mechanisms of SCD may be necessary. Furthermore, because progression of ischemic heart disease can result in the evolution of new mechanisms of SCD in individual patients, repetition of risk stratification tests at certain intervals may be required. It would seem reasonable (in the absence of data) to retest every 2 years in apparently stable patients to detect potential changes in substrate, regardless of which tests appear to have the highest yield.

Ventricular Arrhythmias

In general, on the basis of large thrombolytic trials, the occurrence of ventricular arrhythmias and cardiac arrest in the early course (within the first 24 to 48 hours) of an uncomplicated acute MI is associated with increased in-hospital and 30-day mortality, but has not been considered a marker of long-term mortality beyond hospital discharge. Early ventricular arrhythmias likely represent a transient, reversible arrhythmogenic event caused by acute ischemia and reperfusion rather than a permanent arrhythmogenic substrate; hence, they do not predict an increased risk for recurrent arrhythmic events in patients who are successfully revascularized. Nonetheless, the long-term prognostic significance of SMVT in the early hours post MI remains uncertain, as most studies combined VT and VF or sustained and nonsustained VT without specifying the results for each arrhythmia. Many investigators consider SMVT, even when occurring in the early hours following MI, to be an indicator of the presence of an already established permanent substrate (developing necrosis or preexisting scar) and, hence, an indicator of high long-term risk for arrhythmic events.¹⁵

On the other hand, multiple studies confirm that the occurrence of sustained ventricular arrhythmias (VT and VF) late (greater than 48 hours following MI) or in the context of complicated MI is associated with significantly worse long-term prognosis and high risk of SCD, even after successful revascularization. The temporal cutoff between “early” and “late,” however, remains uncertain. Many investigators prefer a 24-hour (rather than 48-hour) cutoff. Furthermore, some more con-

temporary studies found that both early and late sustained VT/VF were associated with a markedly increased risk of all-cause death at 30 days and 1 year after discharge despite revascularization.^{3,4,14–16}

Repetitive complex PVCs (ventricular bigeminy, couplets, or multiform PVCs) occurring beyond 48 hours after acute MI can be associated with increased arrhythmic risk, particularly in patients with larger MIs and impaired LV function. In a recent report evaluating ventricular ectopy on Holter recordings obtained 6 weeks after acute MI in patients with LVEF of 40% or less, frequent PVCs (≥ 10 per hour), prevalence of repeating forms of PVCs, and low coupling interval variability were potentially useful risk markers of fatal or near-fatal arrhythmias after MI.²² However, the utility of these risk markers in guiding ICD implantation is limited.

The occurrence of nonsustained VT in the subacute and chronic phases post MI has been found to predict an increased risk of cardiovascular death. Nonsustained VT has been used for risk stratification but only in conjunction with moderate to severe LV dysfunction (LVEF $\leq 40\%$) and inducible VT at EP study. Nonetheless, the current guidelines do not recommend surveillance cardiac monitoring beyond 24 to 48 hours of hospitalization after an acute coronary event.¹⁹

Syncope

Patients with syncope (that is thought to be due to ventricular tachyarrhythmia) in the setting of structural heart disease (including LV systolic dysfunction or prior MI) have an increased incidence of SCD and overall mortality. It is recommended that these patients undergo ambulatory cardiac monitoring or invasive EP testing. If sustained VT is detected on cardiac monitoring or is inducible at EP study, an arrhythmic cause of syncope should be considered, and ICD implantation is recommended.¹⁵

Left Ventricular Ejection Fraction

Multiple studies evaluating survival of patients with prior MI established a clear relationship between reduced LVEF and increased mortality (Table 22.1; eFig. 22.3).¹⁵ However, these trials were designed to evaluate the usefulness of ICD in high-risk groups, defined mainly by reduced LVEF, and not to evaluate different variables, including LVEF, as risk stratifiers. In essence, these studies show that a reduced LVEF is associated with an increased SCD risk and that ICD therapy improves survival, but they do not establish LVEF as the optimal risk stratification variable for arrhythmic mortality.²¹

LVEF behaves as a continuous variable, with gradually increasing mortality risk until the LVEF declines to 40% and then markedly increasing risk for values less than 40%. Nevertheless, the exact mechanisms involved in the strong correlation between decreased LV systolic function and increased incidence of SCD are not clearly defined. LVEF is a global measure of heart function and is only loosely correlated with the amount of myocardial scar.²³

Although low LVEF identifies one patient population at relatively increased risk for SCD, there are clear limitations to LVEF as the ideal risk stratification test for deciding whether to implant an ICD for primary prevention of SCD. LV systolic dysfunction lacks specificity. There is no evidence of any direct mechanistic link between low LVEF and mechanisms responsible for ventricular tachyarrhythmias and no study has demonstrated that reduced LVEF is specifically related to SCD. In fact, in studies that enrolled all patients after MI, patients with LVEF less than 30% to 35% account for no more than 50% of sudden cardiac arrest victims. Thus, although LVEF is a good marker of risk for *total* mortality, it does not provide insight into how patients are likely to die (sudden vs. nonsudden). Furthermore, patients with low LVEF are not uniform with regard to other prognostic markers, and not all are at high risk for SCD.²¹

eFig. 22.3 Survival Curves for the Implantable Cardioverter-Defibrillator (ICD)-Only Primary Prevention Trials in Patients With Cardiomyopathy Due to Coronary Artery Disease (CAD) or Acute Myocardial Infarction (MI). All curves represent mortality/survival. CABG-Patch, Coronary artery bypass graft-patch; DINAMIT, defibrillator in acute myocardial infarction trial; EPG, electrophysiologically guided; IRIS, immediate risk stratification improves survival study; MADIT, multicenter automatic defibrillator trial; MUSTT, multicenter unsustained tachycardia trial; SCD-HeFT, sudden cardiac death in heart failure trial. (From Kusumoto FM, Calkins H, Boehmer J, et al. HRS/ACC/AHA expert consensus statement on the use of implantable cardioverter-defibrillator therapy in patients who are not included or not well represented in clinical trials. *J Am Coll Cardiol.* 2014;64:1143–1177.)

Another limitation of LVEF is its poor sensitivity. Although most studies have focused on patients with markedly reduced LVEF, this group currently accounts for only 10% to 15% of MI survivors, and most contemporarily managed post-MI patients who suffer a cardiac arrest have better-preserved LV systolic function (i.e., LVEF $\geq 35\%$).

It is also recognized that methods of LVEF determination lack precision. Different imaging modalities can produce significantly different LVEF values, and the accuracy of techniques varies among laboratories and institutions, and there is evidence that prognosis, and hence risk, depends on the method by which the LVEF is measured. It is therefore

recommended to use the LVEF determination that clinicians believe is the most clinically accurate and appropriate in their institution.²⁴

Invasive Electrophysiological Testing

Inducibility of VT/VF during invasive EP testing identifies patients at risk of spontaneous ventricular tachyarrhythmia and, hence, can enhance the predictive accuracy of reduced LVEF for post-MI patients with high mortality risk. Programmed ventricular stimulation is probably the most effective stratification technique for identification of post-MI patients at high risk for development of monomorphic VT, but the sensitivity is inadequate to predict SCD, especially in patients with severe LV systolic dysfunction.²¹

The first MADIT study demonstrated that those patients with inducible VT/VF and LVEF of 35% or less late after MI are likely to benefit from prophylactic ICD therapy. Moreover, the absolute mortality reduction in MADIT I (26.2% over 27 months) was substantially greater than what was found in either MADIT II or SCD-HeFT. Similar results were found in MUSTT. However, secondary analysis from MUSTT revealed that despite the significant difference in outcome between inducible patients enrolled in the trial and noninducible patients enrolled in a registry, EP inducibility was of limited value because the 5-year mortality rate in inducible patients was 48% compared with 44% in noninducible patients. Later, data from MADIT II showed that there is no need for additional risk stratifiers (including EP testing) when LVEF is so low. In more than 80% of patients randomized to the ICD arm of MADIT II, invasive EP testing with an attempt to induce tachyarrhythmias was performed at the time of ICD placement. VT inducibility, observed in 40% of studied patients, was not effective in identifying patients with cardiac events defined as VT, VF, or death. These observations from both MUSTT and MADIT II subanalyses suggest that in patients with substantially depressed LV function, EP inducibility should not be considered a useful predictor of outcome. It is possible, however, that inducibility might have much better predictive value in post-MI patients with LVEF greater than 30% or greater than 35%.

Furthermore, using inducible VT/VF to guide prophylactic ICD therapy is limited by low sensitivity. Post-MI patients with LVEF of 35% or less and no inducible VT/VF still appear to have a substantial (greater than 25%) risk of serious events over the near term. Furthermore, there are no data to support the use of invasive EP testing in

post-MI patients with LVEF values greater than 40% or in the early post-MI period. In fact, the BEST-ICD trial found that inducible VT/VF early after MI does not predict benefit from ICD therapy. In contrast, the CARISMA study found that inducible VT identified 6 weeks following an acute MI was a strong predictor of future life-threatening arrhythmias. In addition, EP testing is invasive and not practical for broad application as a screening tool.

Nonetheless, EP testing can be valuable when used in patients in whom the risk of sustained arrhythmias and SCD is intermediate, and the potential benefit of ICD therapy uncertain. Current guidelines recommend prophylactic ICD therapy in post-MI patients with nonsustained VT and LVEF less than 40% if sustained VT/VF is inducible at EP study.

Measures of Cardiac Repolarization

Microvolt-level T wave alternans (TWA) has emerged as a promising noninvasive marker of risk for SCD. TWA, measured on the surface ECG, detects subtle beat-to-beat oscillations in cardiac repolarization and has been linked to cellular mechanisms of arrhythmogenesis. Initial clinical studies of TWA demonstrated a high negative predictive value ($\geq 95\%$). In addition, an abnormal TWA was associated with significantly increased mortality risk as well as risk of arrhythmic events, although the positive predictive values were far more variable, depending on the characteristics of the study populations and pretest probability. Although those studies suggested that TWA could potentially provide prognostically useful information beyond the LVEF and help guide selection of appropriate patients for prophylactic ICD therapy, more recently, several large multicenter studies of TWA failed to support these findings. In fact, the latter studies strongly suggested that a negative TWA result should not be used to withhold ICD therapy among patients who meet other standard criteria.²⁵

Other noninvasive measures of dispersion of repolarization, including QT dispersion, QT variability, and QT dynamics, have had similar mixed predictive results in studies with limited clinical applicability.²³

Measures of Autonomic Imbalance

Methods to assess the autonomic nervous system, which has been thought to be a modulator between triggers of ventricular tachyarrhythmias and the underlying substrate (including heart rate variability, baroreflex sensitivity, heart rate turbulence, and deceleration capacity) have been

evaluated for SCD risk stratification. Multiple studies have correlated relative excess of sympathetic tone (or deficient parasympathetic tone) with increased mortality in post-MI patients as well as increased propensity for VF during acute ischemia. Although the majority of studies showed no significant difference in relative risk for SCD versus total mortality, a recent meta-analysis found that heart rate turbulence was a powerful predictor of both cardiac death and arrhythmic events in post-acute-MI patients with LVEF greater than 30%, and its performance was improved in combination with TWA. Nevertheless, these measures need further validation to support their use in guiding prophylactic ICD therapy.^{23,26,27}

Measures of Myocardial Conduction Disorders

Increased QRS duration on a surface ECG has been associated with a higher risk of death after MI and appears to reflect greater LV dysfunction, but association with SCD has not been proven. Similarly, the presence of late potentials on signal-averaged ECG failed to identify patients likely to benefit from ICD therapy. Because of the lack of discrimination in the mode of death, these noninvasive markers of risk have not had widespread adoption.

More recently, fragmentation of the QRS complex on the 12-lead surface ECG (filter range, 0.15 to 100 Hz; AC filter, 60 Hz, 25 mm/s, 10 mm/mV), which likely signifies inhomogeneous ventricular activation due to myocardial scar or ischemia in patients with CAD, has been found to potentially predict increased risk of appropriate ICD therapies in patients who received an ICD for primary and secondary prevention.²³ In a recent meta-analysis, fragmented QRS was found to be an indicator of all-cause mortality and SCD risk. The risk was greater in patients with LVEF of 35% or less and in those with QRS duration exceeding 120 milliseconds. However, in the absence of a prospective study of ICD implantation, randomized on the basis of fragmented QRS, it is not clear how the tool should be applied in clinical practice.^{28,29}

Genetic Testing

There is compelling evidence that a genetic mechanism may increase patient susceptibility to SCD following MI, and genetic assessment may play a role in the future. However, there is presently no evidence for using genetic testing to identify post-MI patients at risk.

Cardiac Magnetic Resonance Imaging

Characteristics of myocardial scar architecture and tissue heterogeneity in the periinfarct zone, as defined by contrast-enhanced cardiovascular magnetic resonance (CMR), can potentially identify a proarrhythmic substrate, and appear to be strong predictors of ventricular arrhythmias and appropriate ICD therapies. In patients with ischemic cardiomyopathy, nontransmural (rather than transmural) hyperenhanced areas were found to predict a higher risk of sustained VT. Current evidence, however, does not support the use of CMR for SCD prognostication. Large prospective trials are still required to evaluate the reliability of these techniques for risk stratification.^{23,30–32}

Risk Stratification Early Postinfarction

The risk of SCD is greatest in the first month after MI and appears to decline in the first year after MI. Nevertheless, both prospective and retrospective studies of prophylactic ICD therapy have failed to show a reduction in all-cause mortality in early post-MI patients. The reasons for the lack of benefit of early ICD implantation after MI are unclear. The reduction in the rate of death due to arrhythmia associated with ICD therapy was offset by an increase in the rate of death from nonarrhythmic cardiac causes (e.g., LV rupture, acute mitral regurgitation) in the ICD groups (see Table 22.1; see eFig. 22.3). This discrepancy not only highlights the limitations of current risk stratification techniques,

but also reflects relative differences in the risk factors for SCD at different time points after MI and the fact that nonarrhythmic death accounts for an appreciable percentage of deaths during that time period. In addition, some portion of the post-MI population will eventually recover LV function, rendering them at lower risk of SCD.

Heart rate and creatinine clearance measured at baseline are strongly associated with SCD during the in-hospital period, whereas recurrent cardiovascular events (including heart failure, MI, and rehospitalization) and a baseline LVEF of 40% or less are more strongly associated with the occurrence of SCD after discharge.

Although the cumulative incidence of SCD is greatest in post-MI patients with an LVEF of 30% or less, the incidence of SCD is higher in patients with an LVEF greater than 40% in the first 30 days after MI when compared with patients with an LVEF of 30% or less after 90 days. The strength of the association between LVEF and survival free from SCD appears to be greatest in long-term follow-up (greater than 6 months). Currently, there is no strategy (invasive or noninvasive) that can reliably predict the risk for SCD or guide empiric ICD implantation soon after an MI. Data suggest it is best to wait 2 to 3 months after acute MI before performing risk stratification.

Some evidence suggests a potential benefit of EP testing in risk stratification in patients with ST-elevation MI and LVEF less than 40% treated with primary PCI. Inducible SMVT by programmed electrical stimulation performed 6 to 10 days post MI was associated with an increased risk of spontaneous VT/VF and SCD (after a mean follow-up of 28 ± 13 months). However, further evaluation in randomized clinical trials is required before adoption of this approach.

PRINCIPLES OF MANAGEMENT

Pharmacological Therapy

Acute Therapy

When ventricular arrhythmias are precipitated by acute ischemia, immediate reperfusion is critical. In addition, beta-blockers should be started, electrolyte abnormalities (hypomagnesemia and hypokalemia) should be corrected, treatment of decompensated heart failure should be optimized, and proarrhythmic medications should be discontinued.^{4,14}

For PVCs and nonsustained VT, antiarrhythmic drugs, aside from beta-blockers, are *not* recommended because this strategy does not improve either short- or long-term outcomes, and, with some drugs, may actually increase mortality. However, when the burden of PVCs or nonsustained VT is large despite beta-blocker therapy and significantly impact the clinical condition (worsening angina or heart failure), treatment with antiarrhythmic medications (amiodarone) may be useful. Most episodes of accelerated idioventricular rhythm are transient and benign, and do not require specific treatment.^{4,14}

For sustained ventricular arrhythmias, the degree of hemodynamic tolerance should dictate the initial therapeutic strategy. Treatment of VF and pulseless VT and should follow the Advanced Cardiac Life Support (ACLS) protocol. Electrical cardioversion is recommended for VTs causing severe symptoms of angina, heart failure decompensation, or hemodynamic deterioration. Whenever possible, a 12-lead ECG should be recorded before cardioversion. Recurrent polymorphic VT or VF can be an indicator of incomplete reperfusion or recurrence of acute ischemia, especially in the presence of ST segment or T wave changes during normal sinus rhythm (NSR). Therefore immediate coronary angiography and revascularization should be considered.^{1,4}

In patients with hemodynamically stable sustained VT, IV amiodarone is the drug of choice. IV procainamide and sotalol are alternatives. Lidocaine is less effective in the absence of acute ischemia; however, it can be considered in combination with procainamide or amiodarone if the latter drugs are ineffective alone.¹

In patients with drug-refractory electrical storm, neuraxial modulation (thoracic epidural anesthesia, left or bilateral cardiac sympathetic denervation) may significantly reduce arrhythmia burden. Deep sedation and mechanical ventilation can be useful in the management of these patients. Mechanical hemodynamic support (LV assist devices or extracorporeal life support) should be considered for hemodynamic stabilization.^{1,14,33–35} Once reversible factors are rectified and hemodynamic status is optimized as possible, catheter ablation should be considered early in the course of treatment for refractory patients. New approaches, such as renal artery denervation, are being studied.^{14,36}

Importantly, in patients with acute ischemia and no ventricular arrhythmias, prophylactic treatment with antiarrhythmic drugs has not proven beneficial and may even be harmful and is not therefore recommended.¹⁴

Chronic Therapy

In patients with ventricular arrhythmias, antiarrhythmic medication may be considered as adjunctive therapy in ICD recipients who experience frequent symptoms or device discharges triggered by ventricular arrhythmias. Antiarrhythmic drug therapy can also be considered for patients with high burden of PVCs or nonsustained VT that are refractory to beta-blockers and are causing significant symptoms, worsening cardiomyopathy, or interfering with cardiac resynchronization therapy.¹

It is important to understand that, with the exception of beta-blocker therapy, no antiarrhythmic medication has been demonstrated to reduce the mortality of patients with SMVT. The significant reduction of VT episodes with antiarrhythmic drug therapy does not appear to translate into a mortality benefit. These observations suggest that recurrent VT in ICD patients might be only a marker of advanced disease that cannot be modified by prevention of recurrent VT. In addition, antiarrhythmic drugs are of modest efficacy and have important side effects, with a potential for increase in all-cause mortality with amiodarone. Therefore the goal of antiarrhythmic drugs in VT patients is to improve quality of life in symptomatic patients or those with frequent VT leading to ICD shocks.³⁷

There are three main indications for antiarrhythmic drug therapy along with an ICD: (1) to reduce the frequency of ventricular arrhythmias in patients with unacceptably frequent ICD therapies; (2) to reduce the rate of VT so that it is better tolerated hemodynamically and more amenable to pace termination or low-energy cardioversion; and (3) to suppress other arrhythmias (e.g., sinus tachycardia, atrial fibrillation [AF], nonsustained VT) that cause symptoms or interfere with ICD function or cause inappropriate discharges.¹

When ICD patients need drugs because of frequent shocks, the weight of evidence supports optimizing beta-blocker therapy. When long-term antiarrhythmic therapy is required, amiodarone and sotalol are the most commonly used drugs. Sotalol is less effective than amiodarone, but given its more favorable adverse effect profile than amiodarone, it may be a better first-line antiarrhythmic medication in appropriate patients. However, sotalol is generally avoided in patients with a severely reduced LVEF due to its negative inotropic effects and the risk of torsades de pointes.

For refractory VT, escalating doses of amiodarone (300 or 400 mg/day) or adding a class I (mexiletine) or class III (dofetilide) agent to amiodarone therapy may be considered. It may be appropriate to attempt gradual withdrawal of antiarrhythmic medications in patients who remain free of arrhythmic events over a reasonable period of follow-up (12 to 18 months).^{38,39} For patients who cannot tolerate amiodarone or sotalol, dofetilide has been suggested as an alternative. Azimilide can be effective with fewer side effects (except torsades de pointes), but is not approved by the US Food and Drug Administration

or European authorities, and experience is limited. No comparative data for amiodarone and azimilide are available. Class IC medications (flecainide and propafenone) are not recommended in patients with prior MI.³⁷

Although some reports suggested the early use of antiarrhythmic drugs (after the first episode of VT or after a single ICD shock), this approach is likely to overtreat a large group of patients who will never have an ICD intervention but are exposed to drug side effects; or the drug may elicit an ICD intervention due to proarrhythmia. At this point, the decision as to when to start adjuvant antiarrhythmic drug therapy in patients who receive an ICD for secondary prevention should be individualized, with the expectation that well-designed therapy can reduce ICD shocks and improve quality of life.

The influence of ischemia in the genesis of SMVT in patients with chronic stable CAD remains controversial. Data suggest that coronary revascularization alone is unlikely to significantly reduce the risk of recurrence of VT in post-MI patients with SMVT in the absence of an acute coronary syndrome. On the contrary, revascularization might be beneficial in patients presenting with VF, polymorphic VT, or exercise-induced arrhythmias associated with ischemia.^{39,40}

Prophylactic antiarrhythmic drug therapy has no proven beneficial effects, and can be harmful in CAD patients, even those deemed to be at high risk of SCD.¹⁴ Similarly, antiarrhythmic drugs are not recommended in patients with asymptomatic PVCs or nonsustained VT for the purpose of arrhythmia suppression.

Implantable Cardioverter-Defibrillator Secondary Prevention

ICD therapy has a proven mortality benefit among patients with structural heart disease and a history of VT or VF, with a 7% absolute reduction and a 25% relative reduction in all-cause mortality (as compared with amiodarone therapy), due entirely to a 50% reduction in arrhythmic death.^{24,39,41}

Implantation of an ICD is recommended for secondary prevention in patients with prior cardiac arrest or sustained VT, even when systolic function is normal, and even in patients undergoing successful catheter ablation of the VT or responding to antiarrhythmic therapy, because the latter two approaches do not sufficiently reduce residual risk of SCD (Table 22.2; Fig. 22.2). Also, ICD implantation is recommended in patients with syncope and inducible SMVT even if they do not otherwise meet criteria for primary prevention. Importantly, in patients with incessant VT or VF, an ICD should not be implanted until sufficient arrhythmia is achieved to prevent repeated ICD shocks.^{1,39}

Although one report has questioned the benefit from an ICD compared with pharmacological therapy in patients with VT and LVEF exceeding 40%, the guidelines did not stratify recommendations based on the LVEF. This seems appropriate for two reasons: the prognostic importance of the LVEF was based on subset analysis and, given the current ease of ICD implantation, the potential adverse consequences of choosing a possibly less effective therapy are too great.

Sustained VT or VF occurring within the first 24 to 48 hours of an uncomplicated acute MI are usually considered to be a result of a transient, reversible arrhythmogenic event caused by acute ischemia rather than a permanent arrhythmogenic substrate; hence, they are thought to be relatively benign and do not predict an increased risk for recurrent arrhythmic events in patients who are successfully revascularized. Early ICD implantation is not recommended in those patients unless coronary revascularization is not possible and there is evidence of significant preexisting LV dysfunction.¹⁴ On the other hand, ICD implantation is recommended for all patients who develop sustained VT or VF beyond the first 48 hours following acute MI or in the context of a complicated MI, which are considered indicators of

TABLE 22.2 AHA/ACC/HRS Recommendations for Prevention of Sudden Cardiac Death in Patients With Ischemic Heart Disease

Secondary Prevention	
• In patients with ischemic heart disease, who either survive SCA due to VT/VF or experience hemodynamically unstable VT or stable VT not due to reversible causes, an ICD is recommended if meaningful survival greater than 1 year is expected.	Class I
• In patients with ischemic heart disease and unexplained syncope who have inducible sustained monomorphic VT on EP study, an ICD is recommended if meaningful survival of greater than 1 year is expected.	Class I
Primary Prevention	
• In patients with LVEF of 35% or less that is due to ischemic heart disease who are at least 40 days post MI and at least 90 days postrevascularization, and with NYHA class II or III HF despite GDMT, an ICD is recommended if meaningful survival of greater than 1 year is expected.	Class I
• In patients with LVEF of 30% or less that is due to ischemic heart disease who are at least 40 days post MI and at least 90 days postrevascularization, and with NYHA class I HF despite GDMT, an ICD is recommended if meaningful survival of greater than 1 year is expected.	Class I
• In patients with NSVT due to prior MI, LVEF of 40% or less and inducible sustained VT or VF at EP study, an ICD is recommended if meaningful survival of greater than 1 year is expected.	Class I
• In nonhospitalized patients with NYHA class IV symptoms who are candidates for cardiac transplantation or an LVAD, an ICD is reasonable if meaningful survival of greater than 1 year is expected.	Class IIa
• An ICD is not indicated for NYHA class IV patients with medication-refractory HF who are not also candidates for cardiac transplantation, an LVAD, or a CRT defibrillator that incorporates both pacing and defibrillation capabilities.	Class III

[Epub ahead of print]

worse long-term prognosis and high risk of SCD, even after successful revascularization. Early ICD implantation (or the temporary use of a wearable cardioverter-defibrillator) is usually recommended in those patients. However, it is worth noting that the temporal cutoff between “early” and “late” is not clear. Many investigators prefer a 24-hour (rather than 48-hour) cutoff.^{24,42}

Importantly, prolonged episodes of sustained monomorphic VT or VF may be associated with a rise of cardiac enzymes related to myocardial supply-demand mismatch rather than a primary coronary event. Therefore, in patients with CAD who present with sustained VT or VF and modest elevations of cardiac enzymes, it should not be assumed that a new MI was the cause of the VT or VF. If clinical evaluation for ischemia does not support the occurrence of a new MI, these patients should be treated similarly to patients who have sustained VT and no documented rise in cardiac enzymes, including ICD implantation for secondary prevention.²⁴

Although ICDs improve overall survival, they do not eliminate the substrate responsible for sustained arrhythmias and therefore do not prevent arrhythmias. Furthermore, ICD shocks, both appropriate and inappropriate, are associated with increased mortality and reduced quality of life. To reduce the risk of these events, ICD detection criteria and therapies should be programmed to minimize inappropriate shocks, prevent shocks for potentially self-terminating VTs, and favor anti-tachycardia pacing therapies when feasible.⁴³ Long VT detection intervals prior to the delivery of ICD therapies and rapid VF detection rates reduce shocks and improve mortality in patients receiving an ICD for primary prophylaxis. The value of programming a long VT detection time in patients with a history of sustained VT or VF is less certain.¹ Furthermore, although device programming can reduce the frequency of ICD shocks, it does not reduce the risk of VT recurrence or eliminate the symptoms associated with the arrhythmia, such as palpitations, dizziness, and syncope.³⁷

Primary Prevention

Current guidelines recommend prophylactic ICD implantation in patients with prior MI and reduced LVEF (less than 35%) who are on optimal medical management (see Table 22.2; Fig. 22.3). These recommendations are based on the fundamental relationship that exists between reduced LVEF and cardiovascular mortality and the findings of MADIT II and SCD-HeFT. Both MADIT II and SCD-HeFT clearly demonstrated a mortality benefit from prophylactic ICD therapy in patients with a history of MI and severely reduced LVEF ($\leq 30\%$ and $\leq 35\%$, respectively). However, the absolute mortality reduction in these trials was modest: 5.6% over 27 months in MADIT II and 7.3% over 60 months in SCD-HeFT. Fewer than one in five ICD recipients in MADIT II and SCD-HeFT received appropriate ICD therapies over average follow-up periods of 20 and 60 months, respectively. Because appropriate ICD therapies overestimate the mortality benefit of ICD therapy by at least twofold, fewer than 1 in 10 patients who receive a prophylactic ICD for an LVEF of 35% or less post MI are likely to receive a survival benefit in the near term. In two meta-analyses of these trials, ICD therapy in high-risk CAD patients resulted in a net risk reduction for total mortality of 20% to 30%.^{24,39,41,44}

EP testing appears most useful as an adjunct study in patients having equivocal results after noninvasive testing and in whom the potential benefit of ICD therapy is uncertain. Examples include patients with remote MI, nonsustained VT, and an LVEF between 30% and 40%, as suggested by the most recent guidelines, or in combination with other clinical risk factors or symptoms suggestive of VTs including palpitations, presyncope, and syncope. Patients with CAD who are found to have inducible monomorphic VT during programmed stimulation should be treated for the prevention of SCD. The mode of stimulation (burst pacing, single, or double VESs vs. triple VESs) of sustained VT does not influence prognosis and should not influence treatment decisions.

Fig. 22.2 AHA/ACC/HRS Recommendations for Secondary Prevention of Sudden Cardiac Death (SCD) in Patients With Ischemic Heart Disease (IHD). ^aExclude reversible causes. ^bHistory consistent with an arrhythmic etiology for syncope. ^cICD candidacy as determined by functional status, life expectancy, or patient preference. (From Al-Khatib, SM, Stevenson WG, Ackerman MJ, et al. 2017 AHA/ACC/HRS guideline for management of patients with ventricular arrhythmias and the prevention of sudden cardiac death: a report of the American College of Cardiology/American Heart Association Task Force on Clinical Practice Guidelines and the Heart Rhythm Society. *Heart Rhythm*. 2017 Oct 26. [Epub ahead of print])

In the acute to subacute period after MI, the arrhythmia substrate is dynamic. LV function can improve in up to 70% of patients. Although the risk of SCD is highest in the first month after MI, there is currently no reliable risk stratification strategy that can guide early prophylactic ICD implantation. In fact, primary prevention trials with ICD have failed to show a reduction in all-cause mortality (despite a decrease in arrhythmic mortality) in early post-MI patients identified on the basis of the current risk stratifiers. SCD in this period may occur from not only arrhythmic, but also nonarrhythmic (mechanical) causes, limiting ICD benefits. Accordingly, the current published guidelines recommend avoiding ICD implantations in the early post-MI phase. Therefore, in the early post-MI period, medical therapy and coronary revascularization, when feasible, should be optimized. The LVEF should then be measured at least 40 days after the MI and, if the LVEF remains at 35% or less, the patient should be considered for ICD implantation. Whether the 40-day waiting period still applies in patients with acute MI who have known LV dysfunction and who have previously satisfied criteria for implantation of a primary prevention ICD is still controversial. Because those patients have an increased rate of nonarrhythmic mortality that is unlikely to be significantly impacted by early ICD implantation, some investigators recommend implementing the 40-day waiting period in these patients.^{15,24,42}

It is important to understand, however, that the mere presence of elevated cardiac enzymes does not establish a diagnosis of acute MI. If

clinical evaluation for ischemia does not support the occurrence of a new MI, early implantation of an ICD is recommended in patients who otherwise would be candidates for implantation on the basis of primary prevention or secondary prevention criteria. The requirement to delay ICD implantation for 40 days after presentation is not applicable if a clear diagnosis of acute MI is not established. This mandatory waiting period should not be imposed on patients who would otherwise qualify for an ICD for either primary or secondary prevention.^{15,24}

Similarly, the waiting period may not be mandated in patients who, within 40 days of an MI, require a nonelective permanent pacemaker implantation or present with syncope that is thought to be due to ventricular tachyarrhythmia (by clinical history, documented nonsustained ventricular tachycardia [NSVT], or EP study), who would also meet primary prevention criteria for implantation of an ICD, and recovery of LV function is uncertain or not expected. Early ICD implantation with appropriately selected pacing capabilities is recommended in these patients.¹⁵

In addition, improvement of LVEF of 5% to 6% or more can be observed in 15% to 65% of patients following coronary revascularization. Therefore LVEF should be reevaluated 6 to 12 weeks after coronary revascularization to assess potential indications for primary prevention ICD implantation. As noted previously, the waiting period may not be mandatory for patients in whom recovery of LV function is uncertain or not expected and either require a nonelective permanent pacemaker implantation or present with syncope that is thought to be due to ventricular tachyarrhythmia (by clinical history, documented NSVT, or EP study).^{14,15}

Wearable cardioverter-defibrillators effectively terminate VT and VF and are a potential therapeutic option to bridge patients from hospital discharge until follow-up evaluation of LV function to assess the value of ICD for primary prevention of SCD. The wearable external defibrillator vest can provide protection from SCD during the early period after MI until arrhythmic risk may be reduced after improvement in LVEF or until ICD implantation can be performed for those with persistently reduced LVEF.³ In one report, the risk of VT/VF was highest in the first month of wearable cardioverter-defibrillator use, with a median time until first treatment of 9 days, and 1.4% of patients were resuscitated by the external defibrillator in the early weeks post MI. Of treated patients, 75% received therapy in the first month of use, and 96% in the first 3 months of use.^{45,46} However, whether wearable external defibrillators improve total mortality is uncertain. No randomized study has validated the role of wearable cardioverter-defibrillators in preventing early SCD compared to optimal medical therapy alone. A wearable cardioverter-defibrillator would not be expected to offer a mortality benefit where an ICD does not except by avoiding early deaths related to ICD implantation (estimated at only 0.2%). Total mortality rate is expected to remain high (based on the previous ICD trial results) because both ICDs and wearable external defibrillators will favorably impact arrhythmic causes of death, but will not treat nonarrhythmic causes of mortality.^{47,48}

Catheter Ablation

Catheter ablation of post-MI VT is generally indicated as a *palliative* and *adjunctive* therapy in post-MI patients with ICD who experience frequent recurrences of VT or ICD therapies. Recurrences of VT/VF causing frequent ICD therapies (including ICD shocks) are relatively common; approximately 20% to 35% of ICD recipients for primary prevention and up to 45% of those who receive an ICD for secondary prevention will receive an appropriate shock within 3 years of implantation.

Although ICD shocks for rapid VT or VF reduces the risk of SCD by approximately 60%, the occurrence of shocks can have deleterious consequences. ICD shocks are associated with progressive heart failure

Fig. 22.3 AHA/ACC/HRS Recommendations for Primary Prevention of SCD in Patients With Ischemic Heart Disease. ^aScenarios exist for early ICD placement in select circumstances such as patients with a pacing indication or syncope. ^bAdvanced HF therapy includes CRT, cardiac transplant, and left ventricular assist device. (From Al-Khatib, SM, Stevenson WG, Ackerman MJ, et al. 2017 AHA/ACC/HRS guideline for management of patients with ventricular arrhythmias and the prevention of sudden cardiac death: a report of the American College of Cardiology/American Heart Association Task Force on Clinical Practice Guidelines and the Heart Rhythm Society. *Heart Rhythm*. 2017 Oct 26. [Epub ahead of print])

symptoms, a significant decline in psychosocial quality of life, and a two- to fivefold increase in nonarrhythmic mortality, despite termination of the acute arrhythmic event. The incidence of appropriate shocks can be reduced by using antitachycardia pacing in the VT or VF detection zones, or with up-titration of effective medical therapies. If optimization of pharmacological therapies and device programming fails to suppress appropriate ICD shocks for VT, or when ventricular arrhythmias precipitate significant symptoms, such as angina, presyncope, syncope, or worsening heart failure, catheter ablation is recommended.^{14,49,50}

Compared to antiarrhythmic drug therapy, catheter ablation is significantly more effective in reducing the risk of VT recurrences in patients with ischemic cardiomyopathy, and has emerged to become a standard of care to prevent medically refractory ICD shocks. Successful VT ablation can minimize long-term exposure to antiarrhythmic drugs or substantially reduce their dose requirement, which can potentially improve long-term outcomes.^{50,51} However, a reduction in overall mortality has yet to be demonstrated.^{1,37}

Catheter ablation reduces VT recurrences and thereby ICD interventions by more than 75% in patients after multiple ICD shocks.⁵² However, most patients with post-MI VT have multiple types of monomorphic VTs, and elimination of all VTs often is not feasible, and because the recurrence of an ablated VT or the onset of a new VT can be fatal, RF ablation is rarely used as the sole therapy for VT. Instead, VT ablation is typically used for patients with CAD as an adjunct to an ICD. In this patient population, the incidence of ablation procedure-related death ranges from 0% to 3%, and the incidence of major complications ranges from 3.6% to 10%.¹

Catheter ablation is necessary and can be life saving in patients with electrical storm and incessant VT without any apparent correctable cause and despite adequate medical treatment. Repeated ICD shocks within a short time interval, known as an ICD “storm,” occur in 10% to 25% of patients. Accumulated evidence suggests that acute suppression of VT in an electrical storm can be achieved in up to 90% of patients. However, arrhythmic recurrences are frequent during follow-up. In the setting of incessant VT, catheter ablation is preferred over antiarrhythmic drug therapy. Catheter ablation may also be considered for patients with recurrent polymorphic VT or VF when those arrhythmias are triggered by PVCs of consistent QRS morphology. In this setting, ablation targets the arrhythmia trigger rather than the substrate.^{1,4,14}

The optimal time of catheter ablation in ICD patients (after multiple ICD interventions or before any ICD intervention) remains unclear. Current guidelines recommend considering catheter ablation for VT that recurs despite antiarrhythmic drug therapy or when antiarrhythmic drugs are not tolerated or desired (Box 22.1). In clinical practice, VT ablation is often not considered until pharmacological options have been exhausted, often after the patient has suffered substantial morbidity from recurrent episodes of VT and ICD shocks. However, recent studies suggest that catheter ablation should generally be considered early in the course treatment of post-MI VT, before escalating medication therapy, or even before initiating antiarrhythmic drug therapy in select patients. In fact, small randomized studies of treatment after the first VT episode in post-MI patients have demonstrated significantly reduced VT recurrences following ablation compared with conventional medical therapy. Interestingly, in this patient population the ablation-related mortality

BOX 22.1 Expert Consensus Recommendations on Catheter Ablation of Ventricular Tachycardia in Patients With Structural Heart Disease

Catheter Ablation Is Recommended for:

- Symptomatic SMVT, including VT terminated by an ICD, that recurs despite antiarrhythmic drug therapy or when antiarrhythmic drugs are not tolerated or not desired.
- Incessant SMVT or VT storm not due to a transient reversible cause.
- Frequent PVCs, nonsustained or sustained VT that is presumed to cause ventricular dysfunction.
- Bundle branch reentrant or interfascicular VTs.
- Recurrent sustained polymorphic VT and VF that is refractory to antiarrhythmic therapy when there is a suspected trigger that can be targeted for ablation.

Catheter Ablation Is Reasonable for:

- One or more episodes of SMVT despite therapy with one or more class I or III antiarrhythmic drugs.
- Patients with ischemic heart disease and ICD shocks for SMVT or symptomatic SMVT that is recurrent, or hemodynamically tolerated, even if they have not failed antiarrhythmic drug therapy.

Ventricular Tachycardia Catheter Ablation Is Contraindicated for:

- Patients with a mobile ventricular thrombus (epicardial ablation may be considered).
- Asymptomatic PVCs and/or nonsustained VT that are not suspected of causing or contributing to ventricular dysfunction.
- VT due to transient, reversible causes, such as acute ischemia, hyperkalemia, or drug-induced torsade de pointes.

ICD, Implantable cardioverter-defibrillator; PVCs, premature ventricular complexes; SMVT, sustained monomorphic ventricular tachycardia; VT, ventricular tachycardia; VF, ventricular fibrillation.

Modified from Al-Khatib SM, Stevenson WG, Ackerman MJ, et al. 2017 AHA/ACC/HRS guideline for management of patients with ventricular arrhythmias and the prevention of sudden cardiac death. *Heart Rhythm*. 2017 Oct 26. [Epub ahead of print]; Aliot EM, Stevenson WG, Almendral-Garrote JM, et al. EHRA/HRS expert consensus on catheter ablation of ventricular arrhythmias: developed in a partnership with the European Heart Rhythm Association (EHRA), a Registered Branch of the European Society of Cardiology (ESC), and the Heart Rhythm Society (HRS); in collaboration with the American College of Cardiology (ACC) and the American Heart Association (AHA). *Heart Rhythm*. 2009;6:886–933.

rate was 0%, and major complications occurred in 3.8% to 4.7%.^{53,54} In contrast, acute and long-term ablation success is more limited when VT ablation is performed in patients with previous MI selected after failure of prior antiarrhythmic drug therapy. Whether earlier ablation can alter the prognosis of post-MI VT and improve survival compared with comprehensive medical therapy over extended follow-up remains uncertain.^{39,55–57}

Catheter ablation also should be considered for patients with frequent PVCs or nonsustained or sustained VT that is presumed to cause ventricular dysfunction.^{14,49}

Alternative Interventional Treatment

Several interventional approaches, such as transcatheter ethanol ablation, surgical cryoablation, or percutaneous catheter ablation facilitated

by a surgically created epicardial window, can be considered for selected patients with recurrent or incessant VT in whom antiarrhythmic drug therapy and percutaneous endocardial and epicardial catheter ablation have failed or are not feasible (e.g., due to presence of pericardial adhesion or mechanical aortic and mitral valves, or proximity to coronary arteries). However, experience with these approaches is limited, and they are considered last-resort options.^{58,59}

Transcatheter ethanol ablation can be of value for intramural circuits that are refractory to endocardial-epicardial ablation techniques. This technique requires subselective cannulation of the coronary arterial branches supplying the target region. Before ethanol injection, the appropriate target can be confirmed by infusion of iced saline through the arterial lumen. Alcohol injection is performed only if iced saline successfully terminates the VT or renders it noninducible by programmed electrical stimulation.⁵⁸

An epicardial window can allow access to epicardial substrates when percutaneous epicardial access is not feasible. Surgical creation of a subxiphoid pericardial window and manual dissection with lysis of pericardial adhesions can allow catheter mapping and ablation. Surgical treatment of ventricular arrhythmias is rarely required today, but remains a viable therapeutic option for VT refractory to conventional therapies, especially patients requiring surgical coronary revascularization or aneurysm resection and LV reconstruction for refractory heart failure, or known LV thrombus.⁵⁸

ELECTROCARDIOGRAPHIC FEATURES

In general, QRS patterns are less accurate in localizing the “site of origin” of reentrant VTs in patients with prior MI and wall motion abnormalities than they are for focal VTs in patients with normal hearts. Nonetheless, the ECG is capable of regionalizing the VT to areas smaller than 15 to 20 cm², even in the most abnormal hearts.

The site of origin of VT is the source of electrical activity producing the VT QRS. Although this is a discrete site of impulse formation in automatic and triggered (i.e., focal) rhythms, during reentrant VT it represents the exit site from the diastolic pathway (isthmus) to the myocardium giving rise to the QRS. The pattern of ventricular activation, and hence the resultant QRS morphology, depends on how the wavefront propagates from the site of origin to the remainder of the heart; this can be totally different during VT than during pacing from the same site in NSR. It is also important to recognize that the 12-lead ECG provides information about the VT exit site from the scar border and not about the site to be targeted by ablation. Ablation of post-MI reentrant VTs targets the critical isthmus of the reentrant circuit, which can be some distance (1 to 3 cm) removed from the exit site indicated by the surface ECG. Ablation of the exit site typically fails in eliminating the tachycardia.⁶⁰

A sophisticated algorithm has been developed using eight different patterns of R wave progression in the precordium in addition to the relationship with prior anterior or inferior MI, axis deviation, and BBB pattern. This algorithm has a predictive accuracy of more than 70% for a specific QRS morphology to identify a particular endocardial region of 10 cm² or less (Fig. 22.4).⁶¹ A second algorithm that utilizes the BBB pattern on the 12-lead surface ECG and polarity in the limb leads for VT localization was found to predict the LV VT exit site region in 71% of clinical VTs without prior knowledge of infarct location (Figs. 22.5 and 22.6).⁶² More recently, an automated computerized algorithm was shown to improve the utility of the 12-lead ECG for localizing the VT exit site.^{60,63}

Electrocardiographic Clues to the Underlying Substrate

VTs arising from normal myocardium typically have rapid initial forces, whereas slurring of the initial forces is frequently seen when the VT

Fig. 22.4 Algorithm Correlating Region of Origin to 12-Lead Electrocardiogram of Ventricular Tachycardia (VT), Derived from the Retrospective Analysis. (A) Anterior infarct-associated VTs. (B) Inferior infarct-associated VTs. The first branch point is bundle branch block (BBB) configuration, followed by QRS axis and R wave progression. When possible, a specific region of origin is indicated. The number of VTs in each group is indicated in parentheses. A vertical line ending in an asterisk indicates inadequate numbers of VTs for analysis; a vertical line terminating in a horizontal bar indicates adequate numbers for analysis, but no specific patterns. (C) Precordial R wave progression patterns. Eight different patterns are listed, with the number of examples in parentheses. Typical R wave patterns for V₁ through V₆ are shown. I, Inferior; L, left; LBBB, left bundle branch block; R, right; RBBB, right bundle branch block; S, superior. (From Miller JM, Marchlinski FE, Buxton AE, Josephson ME. Relationship between the 12-lead electrocardiogram during ventricular tachycardia and endocardial site of origin in patients with coronary artery disease. *Circulation*. 1988;77:759–766.)

Fig. 22.5 Algorithm Correlating 12-Lead Electrocardiogram (ECG) Morphology of Right Bundle Branch Block (RBBB) Ventricular Tachycardia (VT) With Exit Site Region, Derived From Retrospective Analysis. (A) VT with negative (neg) polarity in the inferior leads. (B) VT with positive (pos) polarity in the inferior leads. A vertical line ending a horizontal bar indicates that no VT with this ECG pattern was identified. Exit sites with a positive predictive value of at least 70% are marked by asterisks. The numbers of VTs for each ECG pattern and exit site region identified in retrospective analysis are shown in parentheses. AA, Anteroapical; AB, anteroapical; AM, midanterior; PA, posteroapical; PB, posterobasal; PM, midposterior. (From Segal OR, Chow AWW, Wong T, et al. A novel algorithm for determining endocardial VT exit site from 12-lead surface ECG characteristics in human, infarct-related ventricular tachycardia. *J Cardiovasc Electrophysiol*. 2007;18:161–168.)

arises from an area of scar or from the epicardium. In addition, VTs originating from very diseased hearts usually have lower amplitude complexes than those arising in normal hearts, and the presence of notching and fractionation of the QRS can be a sign of scar tissue with resultant disrupted wavefront propagation.

Although QS complexes can be seen in a variety of disorders, the presence of qR, QR, or Qr complexes in related leads is highly suggestive of the presence of an infarct. Sometimes it is easier to recognize the presence of MI during VT than during NSR (i.e., LBBB in NSR masking an infarct).

Electrocardiographic Localization of Postinfarction Ventricular Tachycardia

QRS Duration

QRS duration is affected by the proximity of the VT origin to the septum. Post-MI VTs almost always arise in the LV or interventricular

Fig. 22.6 Algorithm Correlating 12-Lead Electrocardiogram (ECG) Morphology of Left Bundle Branch Block (LBBB) Ventricular Tachycardia (VT) With Exit Site Region, Derived From Retrospective Analysis. (A) VT with negative (*neg*) polarity in the inferior leads. (B) VT with positive (*pos*) polarity in the inferior leads. A vertical line ending with a horizontal bar indicates that no VTs with this ECG pattern were identified. SA, Anteroseptal; SB, basal septum; SM, midseptum. Exit sites with a positive predictive value of at least 70% are marked by asterisks. Numbers of VTs for each ECG pattern and exit site region identified in retrospective analysis are shown in parentheses. (From Segal OR, Chow AW, Wong T, et al. A novel algorithm for determining endocardial VT exit site from 12-lead surface ECG characteristics in human, infarct-related ventricular tachycardia. *J Cardiovasc Electrophysiol*. 2007;18:161–168.)

septum. Septal VTs generally have QRS durations that are narrower than free-wall VTs because of more nearly simultaneous activation of RV and LV from a septal source, and because of earlier entry into the His-Purkinje system (HPS), which more rapidly activates the latter portion of the QRS complex. In addition, QRS width during VT is affected by the amount of myocardial disease, and is wider with poor overall ventricular conduction.⁵

QRS Axis

A right superior QRS axis suggests apical septal or apical lateral sites of origin, often demonstrating QS in leads I, II, and III and QS or rS in leads V₅ and V₆. A right inferior axis suggests a high basal origin (high LV septum, or high lateral LV). A left inferior axis is occasionally associated with VTs arising from the top of the LV septum. Sometimes, the QRS axis is inappropriate for the exit site. This almost always occurs with large apical infarcts. Typically, discrepan-

cies occur in VTs with LBBB or RBBB with a right or left superior axis. Such discrepancies can be related to abnormalities of conduction out of the area of the reentrant circuit toward the rest of the myocardium.

Bundle Branch Block Pattern

Post-MI VTs with RBBB patterns always arise in the LV, and VTs with LBBB patterns almost always arise in or adjacent to the LV septum. Therefore LBBB patterns, which all cluster on or adjacent to the septum, have a higher predictive accuracy (regardless of the presence of anterior vs. inferior MI) than RBBB patterns, which could be septal or located on the free wall. Most VTs with RBBB patterns associated with inferior MI are clustered in a small region, but are more widely disparate with anterior MI (Figs. 22.7–22.9).⁵

Precordial Concordance

VTs with positive concordance in all precordial leads arise only at the base of the heart (left ventricular outflow tract, along the mitral or aortic valves, or in the basal septum), whereas a negative concordance is observed only in VTs originating near the apical septum, most commonly seen with anteroseptal MI.

Presence of QS Complexes

The presence of a QS complex in any lead suggests that the wavefront is propagating away from that site. Therefore QS complexes in the inferior leads suggest that the activation is originating in the inferior wall, QS complexes in leads V₂ to V₄ suggest anterior wall origin, QS complexes in leads V₃ to V₅ suggest an apical location, and QS complexes in leads V₅ and V₆ suggest a lateral wall exit. The presence of Q waves in leads I, V₁, V₂, and V₆ is seen in VTs with an RBBB pattern originating near the apex, but not those originating in the inferobasal parts of the LV. R waves in leads I, V₁, V₂, and V₆ are specific for VTs with an RBBB or LBBB pattern of posterior origin. In addition, the presence of Q waves in leads I and V₆ in VTs with an LBBB pattern is seen with apical septal locations, whereas the presence of R waves in leads I and V₆ is associated with inferobasal septal locations.⁵

Inferior Myocardial Infarction Ventricular Tachycardias

With inferior MI, most VTs have basal exit sites and thus have relatively preserved precordial R waves (that usually are present in leads V₂ to V₄ with the persistence of an r or R wave through lead V₆). However, more extensive inferior MIs can result in apical exits (Fig. 22.10).⁵

VT with LBBB morphology. VTs with LBBB (especially when left axis deviation is present) have a characteristic location at the inferobasal septum (see Fig. 22.8). As the VT axis shifts to a more normal axis, the exit site moves higher up along the septum. Rarely, inferior MI VTs can have exit sites as high as the aortic valve along the septum. Very rarely, the VT can only be ablated from the RV.⁵

VT with RBBB morphology. In VTs with RBBB, the R waves can persist across the precordium (positive concordance). When the VT originates near the posterior basal septum and when it arises more laterally (or posteriorly), there can be a decrease in the R wave amplitude across the precordium because the infarct can extend to the posterolateral areas (see Fig. 22.7). Left axis deviation is seen in inferior MI VTs when the exit site is near the septum. As the VT exit moves from the midline toward the lateral (i.e., posterior) wall, the QRS axis becomes directed more rightward or superior.⁵

The mitral isthmus (between the mitral annulus and inferior infarct scar) contains a critical region of slow conduction in some patients with VT following inferior MI, providing a vulnerable and anatomically localized target for catheter ablation. This critical zone of slow conduction is activated parallel to the mitral annulus in either direction, resulting in two distinct QRS configurations not seen in VTs arising from other

Fig. 22.7 Surface Electrocardiogram of Sustained Monomorphic Ventricular Tachycardia With Right Bundle Branch Block (RBBB) Pattern. *Left panel*, Ventricular tachycardia (VT) with RBBB pattern and normal axis in a patient with prior anterior myocardial infarction (MI). The site of origin was mapped to the midanterior left ventricular (LV) wall. Note the qR pattern in leads V₁ to V₃, consistent with anterior infarct. *Middle panel*, VT with RBBB pattern and left superior axis in a patient with prior inferior MI. The site of origin was mapped to the posterobasal LV free wall. *Right panel*, VT with RBBB pattern and left superior axis in a patient with prior inferior MI. The site of origin was mapped to the midinferior LV wall.

Fig. 22.8 Surface Electrocardiogram of Sustained Monomorphic Ventricular Tachycardia With Left Bundle Branch Block (LBBB) Pattern. *Left panel*, Ventricular tachycardia (VT) with LBBB pattern and right inferior axis in a patient with prior anterior myocardial infarction (MI). The site of origin was mapped to the midanterior left ventricular (LV) septum. *Middle panel*, VT with LBBB pattern and left superior axis in a patient with prior inferior MI. The site of origin was mapped to the inferobasal LV septum. *Right panel*, VT with LBBB pattern and left inferior axis in a patient with prior anterior MI. The site of origin was mapped to the anteroapical LV septum.

Fig. 22.9 Electrocardiographic Location of Ventricular Tachycardia (VT) Origin. (A) Location should be assessed based on three axes: septal/lateral, superior/inferior, and basal/apical. (B) Examples of VTs from different locations arising from scars of anterior or inferior myocardial infarction (MI). Although complete electrocardiographic assessment requires analysis of all three axes, only some representative leads essential for the diagnosis in each case are shown in the colored squares. LAO, Left anterior oblique; RAO, right anterior oblique. (From Benito B, Josephson ME. Ventricular tachycardia in coronary artery disease. *Rev Española Cardiol. [English ed.]*. 2012;65:939–955.)

sites: LBBB pattern (rS in lead V₁, R in lead V₆) with left superior axis, and RBBB pattern (R in lead V₁, QS in lead V₆) and right superior axis.⁵

Anterior Myocardial Infarction Ventricular Tachycardias

Anterior MIs are usually associated with more extensive myocardial damage. Therefore the accuracy of the ECG in localizing the origin of VTs associated with anterior MI is less than in those with inferior MI.⁵

VT with LBBB morphology. VTs with an LBBB pattern and left axis deviation usually originate from the inferoapical septum, but occasionally there is a discrepancy, with the exit site being more superior than expected for the QRS axis. LBBB morphology VTs with left superior axis usually exit from the apical septum. However, LBBB VTs associated with large anteroseptal MIs can present with QS complexes across the precordium (i.e., negative precordial concordance), and they are always associated with a Q wave in leads I and aVL. If an R wave is seen in lead V₁ along with the Q wave in lead aVL, the location of the exit site is more posterior on the septum, closer to the middle third (see Fig. 22.8). VTs with LBBB and right inferior axis generally exit from the superior midseptal aspect of the anterior scar, but occasionally can exit just off the septum (see Fig. 22.10).⁵

VT with RBBB morphology. RBBB VTs originating from the LV apex usually have a right and superior axis. Lead V₁ usually has a qR or, occasionally, a monophasic R wave, but there is almost always a QS or QR complex in leads V₂, V₃, and/or V₄. More commonly, when there are QS complexes in leads I, II, and III, there are also QS complexes across the precordium from lead V₂ through V₆.

VTs with RBBB and right inferior axis can exit superiorly on the septum but also can exit from the superolateral regions of the scar

across the apex on the free wall. In both cases, there is a negative deflection in leads aVR and aVL, and the QS ratio in aVR and aVL can help distinguish these entities. Generally, VTs with LBBB or RBBB patterns and a marked inferior right axis arise superiorly on what is usually the edge of an anterior aneurysm.⁵

The most difficult VTs to localize are VTs with RBBB and right superior axis associated with anterior MI. QS complexes in the lateral leads (V₄ to V₆) reflect an origin near the apex, regardless of whether it is septal or lateral. It is almost impossible to distinguish VTs arising from the apical septum and the apical free wall based on the ECG alone. It is only when the VT location moves more posterolaterally that a difference can be appreciated as the R wave in lead aVR becomes dominant over the R wave in lead aVL. This is usually associated with a large apical aneurysm, but occasionally can also be seen with a posterolateral MI.⁵

High Posterolateral Myocardial Infarction Ventricular Tachycardias

VTs associated with high posterior MI (left circumflex artery territory) are characterized by a prominent R wave in leads V₁ to V₄ and right inferior axis.

Epicardial Ventricular Tachycardias

Epicardial VT exits are uncommon in post-MI VT because of the subendocardial nature of the underlying substrate. With all other factors being equal, an epicardial origin of ventricular activation widens the initial part of the QRS complex (pseudo-delta wave). When the initial activation starts in the endocardium, rapid depolarization of the ventricles occurs along the specialized conducting system, resulting in a

Fig. 22.11 Electrocardiogram of Post-Myocardial Infarction Ventricular Tachycardia That Required Epicardial Ablation. Note delayed QRS upstroke in V_2 and delayed S wave downstroke (pseudo-delta wave) and long RS interval in V_3 and V_4 .

relatively narrower QRS on the surface ECG and the absence of a pseudo-delta wave. In contrast, when the initial ventricular activation occurs in the epicardium, the intramyocardial conduction delay produces a slurred initial part of the QRS complex.⁵

Several ECG findings suggest an epicardial origin of the LV VT with an RBBB pattern, and all generally rely on the late engagement of rapidly conducting His-Purkinje fibers by tachycardia circuit exits on the epicardium, including the presence of a pseudo-delta wave, very wide QRS complex (duration ≥ 200 milliseconds), long R wave peak time in lead V_2 , and shortest RS complex duration in any precordial lead longer than 120 milliseconds (Fig. 22.11). However, the proposed 12-lead ECG features for differentiation of epicardial versus endocardial VT exit sites were assessed in patients without MI, and their utility for localization of post-MI VTs has not been validated. ECG criteria for identifying an epicardial origin of VT appear to be region and substrate specific. In fact, in a more recent study, these ECG characteristics failed to reliably identify post-MI VTs requiring epicardial ablation. Slow initial forces can be present during tachycardia at the MI scar region and, hence, not specific for epicardial origins. Furthermore, the presence of typical Q waves in the VT ECGs of patients with previous MI precludes the use of morphological ECG criteria, and when present in the precordial leads, Q waves can interfere with the measurement of all interval criteria. It is also important to note that the VT 12-lead ECG provides information about the VT exit site from the scar border, which is generally not the ablation target. In post-MI VT, the critical isthmus constitutes the target for ablation; this isthmus can be complex, and can have an endocardial and epicardial trajectory permitting successful ablation from the endocardium (especially in the presence of wall thinning) even in a VT with an epicardial exit. Therefore endocardial mapping should be the first approach to catheter ablation for VTs in patients with ischemic heart disease, even when the surface ECG suggests an epicardial origin of the tachycardia.^{5,60,64,65}

ELECTROPHYSIOLOGICAL TESTING

Induction of Tachycardia

Recommended Stimulation Protocols

For evaluation of ventricular arrhythmias, multipolar catheters are typically positioned in the high RA, the HB position, and the RV apex. Recording the His potential during VT is important to differentiate BBR VT from myocardial VT. The most commonly used stimulation protocol applies pacing output at twice the diastolic threshold current

and a pulse width of 1 to 2 milliseconds. Single VESs during NSR and at pacing drive cycle lengths (CLs) of 600 and 400 milliseconds are delivered, first from the RV apex and then from the right ventricular outflow tract (RVOT). The prematurity of extrastimuli is increased until refractoriness or induction of sustained VT is achieved. Long-short cycle sequences may be tested. If these measures fail to induce VT, double and then triple VESs are used in the same manner. Because a VES with a very short coupling interval is more likely to induce VF as opposed to monomorphic VT, it may be reasonable to limit the prematurity of the VESs to a minimum of 180 milliseconds when studying patients for whom only inducible SMVT would be considered a positive endpoint. If VT still cannot be induced, rapid ventricular pacing is started at a CL of 400 milliseconds, gradually decreasing the pacing cycle length (PCL) until 1:1 ventricular capture is lost or a PCL of 220 milliseconds is reached. Repeating the protocol at other pacing drive CLs, at other RV or LV stimulation sites, or after administration of isoproterenol or procainamide is then attempted.⁶⁶

An alternative stimulation protocol uses a shorter pacing drive CL (350 milliseconds) and a reverse order of the pacing drive CL (i.e., starting the stimulation protocol at 350, then 400, and then 600 milliseconds). This *accelerated protocol* has been shown in one report to reduce the number of protocol steps and duration of time required to induce monomorphic VT by an average of more than 50% and improves the specificity of programmed electrical stimulation without impairing the yield of monomorphic VT.⁶⁷

Another proposed stimulation protocol exclusively uses four VESs; at no point are one, two, or three VESs used. At each basic drive train PCL, programmed electrical stimulation is initiated with coupling intervals of 290, 280, 270, and 260 milliseconds for the first through fourth VES. The coupling intervals of the VESs are then shortened simultaneously in 10-millisecond steps until S_2 (the first VES) falls during the refractory period or a 200-millisecond coupling interval is reached. If S_2 is refractory at 290 milliseconds, all extrastimuli are lengthened by 30 milliseconds, and programmed electrical stimulation is then initiated. This *six-step protocol* was tested in a single report and was shown to improve the specificity and efficiency of programmed electrical stimulation without compromising the yield of inducibility of monomorphic VT in patients with CAD.⁶⁸

Number of VESs. The sensitivity of programmed electrical stimulation to initiate SMVT increases with increasing the number of VESs used, but at the expense of decreasing specificity. The use of three VESs seems optimal because it offers the highest sensitivity associated with

an acceptable specificity. More aggressive stimulation is likely to produce nonspecific responses, usually polymorphic VT or VF.

In the majority of patients with CAD undergoing EP testing for risk stratification for SCD, triple VESs are typically required for VT induction. Sustained VT induced with triple VESs is usually faster and more likely to result in hemodynamic compromise. Despite these differences, long-term prognosis does not appear to be affected by the mode of induction. In a recent report, there was no difference in the incidence of arrhythmic death or all-cause mortality at 2 years between patients induced with burst pacing, one or two VESs, and those induced with three VESs.

When SMVT is studied, the use of four VESs may be considered. However, when a patient resuscitated from cardiac arrest is studied, four VESs should not be used because the likelihood of inducing a nonspecific response (polymorphic VT/VF) is far higher than that of inducing SMVT (10:1). Of note, triple VESs are required to induce SMVT in 20% to 40% of patients presenting with SMVT and in 40% to 60% of patients presenting with cardiac arrest.

Pacing drive CL. The use of at least two pacing drive CLs (typically 600 and 400 milliseconds) can enhance the sensitivity of induction of SMVT in patients presenting with sustained VT of any morphology or those with cardiac arrest. VES at shorter or longer drive CLs or even in NSR can be necessary to initiate VT in some patients. Abrupt changes in CL can also facilitate VT induction. The CL used can also influence the number and prematurity of VESs required to initiate VT. Rapid ventricular pacing has a low yield in VT initiation.

In a minority of patients with prior SMVT or cardiac arrest, VT can be initiated only with VES during NSR. On the other hand, most VTs that can be induced during NSR can also be induced during ventricular pacing or VESs delivered after a pacing drive.

Site of ventricular stimulation. In contrast to automatic or triggered-activity VT, in which the stimulation site has no effect on VT inducibility, reentrant VT can demonstrate absolute or relative site specificity for initiation. In most cases, development of functional unidirectional block is a prerequisite for initiation of macroreentrant VT; however, during VES, functional block may not always develop despite short coupling intervals, suggesting that formation of functional block is dependent on the direction of activation following stimulation. Therefore the use of at least two sites of stimulation enhances the ability to induce VT.

If triple VESs are delivered only from the RV apex, 10% to 20% of patients will require the use of a second RV or LV pacing site for initiation of SMVT (less than 5% require an LV site). If double VESs are used, 20% to 30% will require a second pacing site (10% require an LV site). Because the number of VESs required for initiation can differ depending on the site of stimulation, which occurs in approximately 20% of patients with SMVT, the site that allows the use of the fewest number of VESs is preferred to avoid nonspecific responses. Thus it is preferable to stimulate from both the RV apex and the RVOT at each drive CL and with the number of VESs before proceeding to more aggressive stimulation.

If stimulation from the RV apex and RVOT fails to initiate VT, stimulation from the LV may be used. However, the yield is low (2% to 5%) for patients with SMVT and somewhat higher in patients with cardiac arrest.

Atrial extrastimulation (AES) can initiate VT in approximately 5% of patients with SMVT. Usually, those VTs can also be initiated by VES, are usually slower, and are reproducibly initiated over a broad zone of VES coupling intervals. Initiation with AES is more common in patients without CAD.

Pacing current output. Increasing the current (more than twice the diastolic threshold current or pulse width more than 2 milliseconds)

produces only a small increase in sensitivity of initiating SMVT, but this is outweighed by a significant decrease in specificity and increase in the incidence of VF. The use of currents more than 5 mA is not recommended.

Isoproterenol administration. Isoproterenol has a low yield in facilitating induction in patients with CAD and SMVT and is more useful in initiation of exercise-related VTs or triggered-activity OT VTs.

Reproducibility of Ventricular Tachycardia Initiation

More than 90% of patients with clinical SMVT will have inducible VT, regardless of the underlying pathology, with the exception of exercise-induced VT. Patients with cardiac arrest or nonsustained VT have a lower incidence of inducibility; inducibility is higher in patients with CAD.

SMVT can be reproducibly initiated from day to day and year to year, especially in patients with CAD. However, the exact mode of initiation is not necessarily reproducible. Once SMVT is initiated, it is easier to reinstate by repeating the same stimulation protocol that was initially successful, either longitudinally (by repeating the entire protocol) or horizontally (by repeating each coupling interval).

Although reproducibility of sustained VT can be variable when comparing induction during the initial month post MI with subsequent months, induction of any sustained VT in the more chronic phase of MI is highly reproducible over both short-term and extended time intervals. However, a change in the number of extrastimuli required for VT reinduction is reported in 30% to 70% of patients, and is more common as the time interval between studies increases. Similar inconsistencies are reported in the exact QRS morphology and TCL of induced VTs during repeated testing. These data confirm that the substrate for chronic post-MI inducible VT per se can be highly stable for up to several years in the absence of major changes in clinical status. However, the mode of induction and VT characteristics demonstrate substantial variability; therefore it is improbable that such features would predict long-term outcome.

Endpoints of Programmed Electrical Stimulation

Induction of clinical SMVT. Induction of SMVT is very specific (especially with a VES coupling interval of more than 240 milliseconds), and only occurs in patients with spontaneous VT, cardiac arrest, or an arrhythmogenic substrate. In patients who had spontaneous VT prior to the EP study, the endpoint of programmed electrical stimulation should be induction of the clinical arrhythmia or the presumed arrhythmia. Clinical VT is defined as an inducible SMVT that matches the 12-lead ECG QRS morphology and approximate CL of the patient's documented, spontaneously occurring SMVT. Nonclinical VTs are defined as inducible SMVTs that were not previously known to have occurred spontaneously.

Induction of multiple SMVTs. The majority (85%) of patients with post-MI VT have more than one inducible VT morphology. Even in patients presenting with a single clinical SMVT, multiple distinct uniform VTs may be induced in the EP laboratory, especially during antiarrhythmic therapy. Multiple VT morphologies are defined as two or more inducible VTs having at least one of the following: (1) contralateral BBB patterns; (2) a frontal plane axis of 30 degrees or more divergent; (3) marked differences in individual ECG leads recorded from the same electrode locations; (4) a precordial transition zone in one or more leads or a different dominant deflection in more than one precordial lead; and (5) a different TCL (more than 100 milliseconds for VTs with a similar morphology). A change in VT morphology need not reflect a change in a reentrant circuit or site of impulse formation but may merely reflect a change in the overall pattern of ventricular activation. In some cases, pacing can reverse the direction of wavefront

propagation within the same reentrant loop. The majority of multiple morphologically distinct SMVTs arise from the same region of the heart (i.e., have closely located exit sites or shared components of an isthmus or diastolic pathway).

Multiple uniform VTs inducible in the EP laboratory are of clinical significance because the distinction between clinical and nonclinical is often uncertain. Clinically, the ECG of spontaneous VTs terminated by an ICD or emergency medical technician is often not available. Even when available, differences in ECG lead placement, patient position, and antiarrhythmic drugs can influence the similarity between two episodes of VT that arise from the same circuit. In addition, the presence of multiple VT morphologies might have been overlooked because of the lack of 12-lead ECGs obtained during multiple spontaneous episodes on a variety of different antiarrhythmic agents. The use of single-lead rhythm strips to record VT has been a major misleading factor suggesting that there is only one VT. The minimum number of ECG leads required to discern differences between different VT origins or circuits is not clear. The TCL alone is influenced by antiarrhythmic drugs and can be similar for different VTs or may be different for VTs originating from the same region and, therefore, is unreliable as a sole indicator of clinical VT. Of note, inducible VTs never seen spontaneously in the preablation state can occur spontaneously following ablation of the clinical VT.

Therefore the term *clinical VT* should be reserved for induced VTs that are known to have the same 12-lead ECG QRS morphology and approximate TCL as a spontaneous VT. Other VTs should be designated as either *presumptive clinical* or *previously undocumented* VT morphology.

Induction of polymorphic VT or VF. When EP testing is performed in patients presenting with SMVT, polymorphic VT and VF must be considered as nonspecific responses. Both sustained and nonsustained polymorphic VT and VF can be induced, even in normal subjects. In general, induction of VF requires multiple VESs delivered at shorter coupling intervals (usually less than 180 milliseconds) than induction of SMVT.

On the other hand, induction of polymorphic VT or VF in a patient who presents with cardiac arrest can have a different implication. Because cardiac arrest can be initiated by a polymorphic VT, the induction of polymorphic VT in this patient population can be significant. Therefore, although doubt will always exist, reproducible polymorphic VT induction is treated as a possible indicator of the clinical arrhythmia. Features that suggest that a polymorphic VT can be mechanistically meaningful are reproducible initiation of the same polymorphic VT template, especially from different stimulation sites; inducibility with relatively mild stimulation (single or double VESs); and transformation of the polymorphic VT to SMVT by procainamide.

Of note, the induction of any arrhythmia (SMVT, polymorphic VT, or VF) in the setting of a recent MI (less than 1 month) may not have clinical significance.

Induction of very fast VT. The induction of VT with a TCL longer than 230 milliseconds is predictive of recurrent ventricular arrhythmia in high-risk patients, such as those with prior MI and reduced LVEF ($\leq 40\%$), ischemic cardiomyopathy presenting with syncope, resuscitated cardiac arrest, or asymptomatic nonsustained VT. In up to 20% of patients undergoing EP testing, VT with a TCL ranging from 200 to 250 milliseconds can be inducible. Although a limited number of studies have closely and specifically examined long-term outcomes of this group of patients, and although previous large ICD trials, such as MADIT and MUSTT, excluded such patients if this arrhythmia was induced by more than two VESs, there is a growing body of evidence that an inducible fast VT is of sufficient clinical importance that it should no longer be considered a nonspecific finding of EP testing because it poses a

significant risk of spontaneous ventricular arrhythmia or SCD over long-term follow-up. This risk appears equivalent to that of patients with inducible VT with a TCL between 250 and 320 milliseconds, and markedly worse than that of patients who are noninducible or have inducible VF. These findings seem to be consistent regardless of the mode of induction of VT (with 2, 3, or 4 VESs), or measured LVEF ($\leq 30\%$ or between 31% and 40%).⁶⁸

Tachycardia Features

His Bundle Activation

No visible His potential during VT. The His potential may not be observed during VT in many patients, likely because the retrograde His potential is masked by ventricular activation or because of suboptimal catheter position. A proper HB catheter position can be verified by observation of the immediate appearance of the His potential on termination of the VT, the disappearance of the His potential on initiation of VT, or the sudden appearance of the His potential when spontaneous or induced supraventricular beats capture the HB (with or without ventricular capture) during VT. In addition, when complete ventricular–His bundle (VH) block is present, dissociated His potentials will be observed (an extremely rare phenomenon).

Visible His potential during VT. His potentials can be recorded during VT in approximately 80% of patients. When the His potential is visible during VT, it is often difficult to determine whether the recorded His potential is anterograde or retrograde, and whether an apparent His potential is actually a right bundle branch (RB) potential. Recording the RB or left bundle branch (LB) potentials to demonstrate that their activation precedes HB activation during VT, and HB pacing producing a longer His bundle–ventricular (HV) interval than the one noted during VT, usually helps clarify the situation.

In post-MI VT, the relative timing of the retrograde His potential in the QRS depends on how quickly the HPS is engaged and how slowly the impulse reaches the ventricle to produce the QRS. Thus depending on the relative conduction time up the HPS versus through the slowly conducting muscle to give rise to the QRS, the His potential can occur before, during, or after the QRS. The His potential can occasionally occur before ventricular activation (with an HV interval during VT shorter than that during NSR; eFig. 22.4) and can also occur just after the onset of ventricular activation (eFig. 22.5). The occurrence of an HV interval (i.e., with the His potential preceding the QRS onset) shorter than that during NSR (in the absence of preexcitation) or a VH interval (i.e., with the His potential following the QRS onset) implies the presence of retrograde HB activation.

Engagement of the HPS, when present, can allow for more rapid activation of the myocardium, which in turn results in a narrower QRS. Some have suggested that the site of origin of such VTs is within the HPS (i.e., fascicular VTs), although proof that such VTs originate from the fascicles and differ from other forms of VT is often lacking. The retrograde His potential appears to reflect passive activation of the HPS, rather than involvement of the HPS in the reentrant circuit. This concept is supported by several observations. HB deflections can appear intermittently (typically in a 2:1 or 3:2 fashion, and occasionally in a Wenckebach periodicity), and changes in the VH interval can occur without changes in the TCL (eFig. 22.6). In fact, marked changes in the TCL can be present with no changes in the VH interval. Furthermore, AES or atrial pacing can result in anterograde capture of the HB in the presence or absence of ventricular capture or fusion beats. Such an event, linking atrial activation to the HB deflection, proves that HB deflections are caused by anterograde activation and are unrelated to maintenance of the VT in the vast majority of cases.

For wide complex tachycardias with the His potential preceding the QRS, an HV interval that is shorter during tachycardia than during

eFig. 22.4 Ventricular Tachycardia With Short Constant His Bundle (HB)–Ventricular Interval, Consistent With Early Retrograde Activation of the HB. *RVA*, Right ventricular apex.

eFig. 22.5 Ventricular Tachycardia With a Constant Ventricular–His bundle Interval, Consistent With Retrograde Activation of the His Bundle (HB). HB activation is recorded by the ablation catheter (*ABL*) positioned in the left ventricular outflow tract.

eFig. 22.6 Ventricular Tachycardia (VT) With Variable Relationship Between Ventricular and His Bundle (HB) Activation. HB catheter position is verified by observation of His potentials during normal sinus rhythm at left. His potentials are observed intermittently during VT, with variable relationship to the QRS complexes, suggesting that the His–Purkinje system is not an essential part of the VT circuit. *His_{dist}*, Distal His bundle; *His_{prox}*, proximal His bundle.

NSR suggests VT or preexcited supraventricular tachycardia (SVT), whereas an HV interval during tachycardia that is equal to or longer than that during NSR suggests SVT with aberrancy (see Fig. 20.9) or BBR VT (see Fig. 26.3). A changing AH interval or failure to observe anterograde His potential during VT with AV dissociation suggests the presence of retrograde conduction with concealment in the AVN.

The mere presence of a His potential before the QRS with a normal HV interval is not absolutely reliable evidence that the tachycardia is an SVT. The HV interval during VT is usually less than that during NSR; hence, if infranodal conduction delay is present during NSR, the VT can exist in the presence of an apparently normal HV interval (i.e., 35 to 55 milliseconds), but will be less than that during NSR. In post-MI VT, because ventricular activation is occurring in diastole (albeit slow enough not to be apparent on the surface ECG), the HPS could be activated during this time, giving rise to a short or possibly normal HV interval during the VT. The time to conduct retrogradely to the HB can theoretically be less than the time required to exit from the VT circuit and produce the onset of the QRS, thereby producing an HV interval. Such VTs, which are rare, have a relatively narrow QRS. BBR VT can also give rise to an HV interval that is longer than that during NSR.

Right Ventricular Apical Local Activation Time

In the setting of apical MI, VT with an RBBB pattern is common, but QRS morphologies of lateral versus septal apical locations significantly overlap, with variable early R wave progression and a similar frontal plane axis. Assessing the activation time to a fixed reference endocardial recording at the RV apex can help regionalize a septal versus lateral origin for such VTs. For RBBB-type VT in the setting of an apical infarct, the QRS-to-RV apical activation time is consistently less than 100 milliseconds for an LV septal apical origin and more than 125 milliseconds for a lateral apical origin. The same values for the QRS-to-RV apical activation time will also help identify a septal versus lateral wall origin in the setting of prior nonapical infarcts.

Relationship of Ventricular Stimulus to the Onset of Ventricular Tachycardia

Conduction delay is required for the initiation of reentrant rhythms; thus an inverse relationship between the coupling interval of the VES initiating the VT or the pacing train CL and the interval from the VES to the first VT complex favors reentry. In contrast, a linear relationship of the PCL or VES coupling interval to the interval to the first VT complex and initial CL of the VT favors triggered activity. In reentrant VT, the initial CL reflects conduction through the VT circuit, which in the absence of exit block should demonstrate the same or longer CL as the remaining VT cycles, depending on whether any conduction delay is produced in the circuit on initiation.

Diagnostic Maneuvers During Tachycardia

The response of VT to programmed stimulation can be studied only for SMVT. Nonsustained VT is too short and unpredictable in duration to allow reliable evaluation. Polymorphic VT is invariably associated with rapid hemodynamic collapse. Also, SMVT must be well tolerated and must have a stable TCL to evaluate the response to stimulation. Fast, unstable SMVT can usually be slowed by antiarrhythmic drugs (e.g., procainamide) to permit evaluation by programmed stimulation.

Ventricular Extrastimulation During Tachycardia

Initially, a single VES is delivered at a coupling interval 10 to 20 milliseconds shorter than the TCL. The coupling interval is then gradually decreased by 5- to 10-millisecond decrements, until the local effective refractory period (ERP) is reached. The RV apex is used as the initial site of stimulation. Stimulation from other sites (RVOT and LV) can

also be used to gain information regarding the site specificity of a given response. The return CL is analyzed to evaluate whether the VES has influenced the VT in terms of resetting, ability and pattern of termination, and site specificity for stimulation affecting the VT.

If resetting or termination of VT is not observed with single VESs, stimulation is repeated using double VESs. The first VES is delivered at a coupling interval 20 milliseconds greater than the longest coupling interval at which a single VES resets the VT, or 20 milliseconds above the local ERP if a single VES fails to interact with the VT. The second VES is delivered at a coupling interval equal to the TCL, and then this coupling interval is progressively decreased in 5- to 10-millisecond decrements until the local ERP is reached. The use of double VESs allows comparable coupling intervals to reach the circuit at a greater relative degree of prematurity and ability to influence the VT than if the same coupling interval were used for a single VES. By this methodology, only a single VES interacts with the circuit; if the two VESs are delivered such that each VES interacts with the site of impulse formation, interpretation of the response would then be difficult. Thus the first VES is delivered so that it will not interact with the circuit but will help the second VES to do so.

The response of VT to VES is evaluated for manifest or concealed perpetuation, resetting with or without fusion, and termination.

Manifest perpetuation. Manifest perpetuation is said to be present when the VES fails to influence the VT, resulting in a full compensatory pause surrounding the VES. Factors influencing the ability of the VES to interact with the VT include the TCL, local ventricular ERP at the stimulation site, and distance between the stimulation site and VT circuit. The TCL and duration of the excitable gap are the most important factors; the faster the VT (especially with TCLs less than 300 milliseconds) and the shorter the duration of the reentrant circuit excitable gap, the more difficult it is for the VES to enter the VT circuit. Local ERP at the stimulation site and at the site of impulse formation can also limit the prematurity with which the VES can be introduced. Furthermore, the farther the stimulation site is from the VT circuit, the more difficult it is for the VES to reach the circuit with adequate prematurity.

Failure of a VES to affect the VT circuit helps demonstrate the extent of the ventricular myocardium that is *not* required for the VT. Thus the ability to capture significant portions of the ventricle by the VES without affecting the VT suggests that those captured areas are not required for the VT circuit. Similarly, intermittent capture of the HPS during VT suggests that it also is not necessary to maintain the VT, regardless of where the His potential is located relative to the QRS during the VT. In an analogous fashion, atrial captures (occurring spontaneously or in response to atrial stimulation) may occur without influencing the VT. The demonstration that neither the proximal HPS nor the majority of the ventricles are required to sustain the VT suggests that the VT circuit must occupy a relatively small and electrocardiographically silent area of the heart.

Concealed perpetuation. Concealed perpetuation implies that the VES not only fails to influence the VT circuit, but is also followed by a pause that exceeds the TCL or that is occasionally interrupted by a sinus capture before the next VT beat. Such pauses are a form of functional exit block because the VT impulse is unable to exit the circuit and depolarize the ventricles that have just been activated by the VES (eFig. 22.7).

Resetting. Resetting is the interaction of a premature wavefront with a tachycardia, resulting in either advancement (acceleration) or delay of the subsequent tachycardia beat (eFig. 22.8). The first return VT complexes should have the same morphology and CL as the VT before the VES, regardless of whether a single or multiple extrastimuli are used.

eFig. 22.7 Concealed Perpetuation in Ventricular Tachycardia (VT). For reentrant slow VT (cycle length, 690 msec), a single ventricular extrastimulus (VES) is introduced (S) that seems to terminate the VT; a conducted sinus complex (*) follows and then VT recurs. However, inspection of the distal ablation (Abl1-2) electrogram shows that VT never actually terminated because the mid-diastolic electrogram continues unperturbed by the VES. RVA, Right ventricular apex.

eFig. 22.8 Resetting of Ventricular Tachycardia (VT). A single ventricular extrastimulus from the right ventricular outflow tract (RVOT) captures the ventricle during VT and causes the subsequent QRS to occur earlier than anticipated (dashed line), indicating resetting.

The introduction of a single VES (S_2) during VT yields a return cycle (S_2V_3) if the VT is not terminated. If S_2 does not affect the VT circuit, the coupling interval (V_1-S_2) plus the return cycle (S_2V_3) will be equal to twice the VT cycle ($2 \times V_1V_1$); that is, a fully compensatory pause will occur (see Fig. 3.13). Resetting of VT occurs when a less than fully compensatory pause occurs (by at least 20 milliseconds). In this situation, $[V_1S_2 + S_2V_3]$ will be less than $[2 \times V_1V_1]$, as measured from the surface ECG. TCL oscillation should be taken into account when the return cycle is evaluated. To account for any TCL oscillation, at least a 20-millisecond shortening of the return cycle is required to demonstrate resetting. When more than a single VES is used, the relative prematurity should be corrected by subtracting the coupling interval(s) from the spontaneous tachycardia cycles when the VESs are delivered.^{69,70}

To reset a reentrant VT, the stimulated wavefront must reach the reentrant circuit, encounter excitable tissue within the circuit (i.e., enter the excitable gap of the reentrant circuit), collide in the antidromic (retrograde) direction with the previous tachycardia beat, and continue in the orthodromic (anterograde) direction to exit at an earlier than expected time and perpetuate the tachycardia (see Fig. 3.14). If the VES encounters a fully excitable tissue, which commonly occurs in reentrant tachycardias with large excitable gaps, the tachycardia is advanced (i.e., made to occur earlier) by the extent to which the stimulated wavefront arrives at the entrance site prematurely. If the tissue is partially excitable, which can occur in reentrant tachycardias with small or partially excitable gaps, or even in circuits with large excitable gaps when the VES is very premature, the stimulated wavefront will encounter some conduction delay in the orthodromic direction within the circuit. As a consequence, the degree of advancement of the next tachycardia beat will depend on both the degree of prematurity of the VES and the degree of slowing of its conduction within the circuit. Therefore the reset tachycardia beat can be early, on time, or later than expected.^{69,70}

Effect of number of VESs. When refractoriness of the intervening tissue between the pacing site and the reentrant circuit limits the ability of an extrastimulus to reach the reentrant circuit with adequate prematurity, the use of double extrastimuli can be helpful. The first extrastimulus, although not resetting the tachycardia, does shorten the local refractory period at the pacing site and reverse the activation sequence in part of the intervening tissue, allowing the second extrastimulus to access and interact with the reentrant circuit with a greater degree of prematurity at comparable coupling intervals. Approximately 60% of VTs can be reset with a single VES and 85% with double VESs using RV pacing. All VTs reset by a single VES can also be reset by double VESs. Double VESs produce resetting over a longer range of coupling intervals and should therefore be used to characterize the excitable gap of the VT more fully. The resetting zone is approximately 70 milliseconds for most VTs, but is usually longer in those VTs reset by both single and double VESs than those requiring double VESs. Resetting zones in response to single VESs usually occupy 10% to 20% of the VT cycle. This is increased to approximately 25% in response to double VESs, but occasionally can exceed 30%, even in response to a single VES. VTs with LBBB morphology are less likely to require double VESs for resetting than VTs with RBBB morphology, regardless of the frontal plane axis, because VTs with LBBB arise in or adjacent to the septum, closer to the RV stimulation site.^{69,71}

Effect of site of stimulation. Resetting does not require that the pacing site be located within the reentrant circuit. The closer the pacing site is to the circuit, however, the less premature a single VES can be and reach the circuit without being extinguished by collision with a wave emerging from the circuit. The longest coupling interval for a VES to be able to reset a reentrant tachycardia depends on (1) the TCL; (2) the duration of the excitable gap of the tachycardia; (3) refractori-

ness at the pacing site; and (4) the conduction time from the pacing site to the reentrant circuit. Neither local ventricular ERP nor local activation time influences the number of VESs required for resetting. Approximately 10% to 20% of VTs demonstrate site specificity in response to VES. Using double VESs reduces this site specificity. Approximately 70% of VTs can be reset with a single VES delivered to the RV apex or RVOT. Resetting of VT by a single VES can always be achieved from some site in the LV, even when resetting cannot be achieved from RV sites.

Return cycle. The return cycle is the time interval from the resetting VES to the next excitation of the pacing site by the new orthodromic VT wavefront. This corresponds to the time required for the stimulated impulse to reach the circuit, conduct through the circuit, exit the circuit, and travel back to the pacing site. The noncompensatory pause following the VES and the return cycle are typically measured at the pacing site; however, they can also be measured to the onset of the QRS complex on the surface ECG. Conduction time between the pacing site and the VT circuit may or may not be equal to that from the VT circuit to the pacing site. Differences in the VT circuit entrance and exit can result in differences in conduction time to and from the pacing site. These differences depend on the site of stimulation and VT site of origin. In VTs reset by both single and double VESs, the shortest return cycle seen by both methods is usually the same. If the return cycle is measured from the VES producing resetting to the onset of the first return VT QRS complex on the surface ECG, the shortest return cycle will be less than the TCL in more than 40% of VTs. Because stimulation is usually performed from the RV, conduction time into the VT circuit is incorporated into that measurement. If one considers conduction time between the pacing site and the circuit to be equal to that from the circuit to the pacing site (i.e., local activation time) and subtracts this value from the return cycle as measured to the surface ECG QRS, the resultant value for the return cycle is less than the TCL in 80% of VTs.

Resetting response curves. Flat or mixed (i.e., flat, and then increasing) response curves characterize reentrant VTs. A flat curve is noted in approximately two-thirds of VTs, suggesting that a fully excitable gap is present. It also signifies anatomically separate entrance and exit sites of the circuit (see Fig. 3.15). In approximately 40% of VTs, the types of resetting curves can vary, depending on the site of ventricular stimulation. VESs from different pacing sites likely engage different sites in the VT circuit that are in different states of excitability or refractoriness and, therefore, result in different conduction velocities and resetting patterns.

Resetting with fusion. The ability to reset a tachycardia after it has begun activating the myocardium (i.e., resetting with fusion) excludes focal mechanisms (automatic, triggered activity, and microreentry) and is diagnostic of macroreentry. Resetting with ECG fusion requires wide separation (in time and/or distance) of entry and exit sites of the VT circuit, with the stimulus wavefront preferentially engaging the entrance. For resetting with fusion to occur, the VES wavefront has to reach the entrance of the reentrant circuit before it reaches the exit, and, at the same time, allow for the VT wavefront to exit the reentrant circuit, while the VT wavefront is unable to reach the entrance of the circuit before the paced wavefront (Fig. 22.12).

Fusion of the stimulated impulse can be observed on the surface ECG and/or intracardiac recordings if the stimulated impulse is intermediate in morphology between a fully paced complex and the tachycardia complex. The ability to recognize surface ECG fusion requires a significant mass of myocardium to be depolarized by both the VES and VT. If presystolic activity in the reentrant circuit is present before delivery of the VES that resets the VT, this must be considered to represent local fusion. Thus a VES delivered after the onset of the tachycardia QRS on the surface ECG that enters and resets the VT circuit will always

Fig. 22.12 Schematic Representation of the Relationship of the Return Cycle During Resetting of Ventricular Tachycardia (VT) to the Absence or Presence of Surface Electrocardiogram (ECG) Fusion. (A) Stylized VT circuit, with direction of propagation as shown; electrogram is from a remote site. (B) Single ventricular extrastimulus (VES) is introduced during VT at a coupling interval of 250 milliseconds. *Left panel*, The VES occurs early enough that the circuit's exit site is captured; thus there is no fusion. Meanwhile, the paced wavefront (*blue arrows*) enters the entrance of the diastolic corridor before the approaching wavefront of the prior VT cycle (*red arrow*), allowing resetting. *Right panel*, Resetting is demonstrated in that the first VT cycle after the VES occurs at less than twice the tachycardia cycle length (TCL). (C) A slightly later VES is introduced, with a paced wavefront (*blue arrows*) approaching the diastolic pathway's exit after the VT wavefront (*red arrows*) has already left; this results in ECG fusion. Meanwhile, as before, the paced wavefront arrives at the entrance site before the VT wavefront, allowing resetting. The right panel again shows fusion. *Asterisks*, Pacing site; *CI*, coupling interval; *EGM*, intracardiac electrogram.

demonstrate local fusion. Resetting with local fusion and a totally paced surface QRS complex suggests that the reentrant circuit is physically small.

The farther the stimulation site is from the reentrant circuit, the less likely that resetting with ECG fusion will occur. In this setting, the VES should be delivered at a shorter coupling interval to enable

the paced wavefront to reach the VT circuit with sufficient prematurity; hence, the stimulated impulse is more likely to capture both the exit and entrance sites and therefore have a purely paced QRS morphology without fusion.⁶⁹

Resetting with surface ECG QRS fusion during RV stimulation is observed in 60% of VTs, 40% of which are usually reset with a VES

delivered after the onset of the VT QRS. VTs reset with fusion have a higher incidence of flat resetting curves, longer resetting zones, and significantly shorter return cycles (measured from the stimulus to the onset of the VT QRS) than VTs not reset with fusion. The return cycle corrected to the TCL is shorter with VTs reset with fusion (0.89 vs. 1.12). In 80% of VTs reset with fusion, the return cycle is shorter than the TCL measured at the onset of the QRS (vs. only 4% of VTs reset without fusion). The return cycle minus local activation time is equal to the time for the wavefront to traverse the distance from the entrance to the exit of the circuit. This interval is less than the TCL in 100% of VTs reset with fusion. These findings are consistent with widely separate entrance and exit sites of the VT circuit.

Tachycardia termination. Termination of VT by a VES occurs when the VES collides with the preceding tachycardia impulse antidromically and blocks in the reentrant circuit orthodromically (see Fig. 3.14). This occurs when the VES enters the reentrant circuit early enough in the relative refractory period because it fails to propagate in the anterograde direction and encounters absolutely refractory tissue. In the retrograde direction, it confronts increasingly recovered tissue and is able to propagate until it collides with the circulating wavefront and terminates the arrhythmia.

Termination of VT by a single VES is uncommon. The closer the stimulation site to the circuit, the more prematurely a VES can engage the VT circuit because the refractoriness and conduction delay in intervening myocardial tissue are avoided. The success of termination, however, is directly related to the number of VESs used. Occasionally, when stimulation is performed at the critical isthmus of the VT circuit, termination can occur with a nonpropagated VES that fails to depolarize the bulk of the myocardium but is adequate to depolarize the isthmus and make it refractory to the incoming VT wavefront, resulting in termination of the VT (Fig. 22.13).

Ventricular Pacing During Tachycardia

Rapid ventricular pacing is performed during VT at a PCL 10 to 20 milliseconds shorter than the TCL. The PCL is then decreased in 10-millisecond decrements in a stepwise fashion until the VT is terminated. Pacing is stopped after each PCL and the response of VT to pacing is assessed. It is important to ensure that termination and reinitiation of the VT have not occurred during the pacing train, which would then affect the interpretation of the VT response.

It is critical to synchronize the initiation of pacing to the electrogram at the pacing site because absence of synchronization will lead

to a variable coupling interval of the first paced impulse to the VT. It is also important to perform overdrive ventricular pacing at each PCL for sufficiently long duration to allow the pacing drive to penetrate and affect the VT circuit. Pacing for a short period is a common mistake; it results in erroneous evaluation of the VT response. For VTs that are not stable enough to allow completion of an entire stimulation protocol, synchronized bursts of pacing at variable PCLs for a specified but variable number of beats, can usually be performed and can provide information about resetting or entrainment, overdrive suppression, and termination.

The response of VT to overdrive pacing is evaluated for overdrive suppression, acceleration, transformation into distinct uniform VT morphologies, entrainment, ability and pattern of termination, and site specificity for stimulation affecting the VT.

Overdrive suppression. Overdrive suppression analogous to that seen with automatic rhythms has not been observed in post-MI VTs, although prolonged return cycles can be seen at rapid pacing rates.

Tachycardia acceleration. Acceleration by overdrive pacing refers to sustained shortening of the TCL following cessation of pacing. Acceleration occurs in about 25% of VTs, and is more common with ventricular pacing than with VES (35% vs. 5%). However, overdrive acceleration of VT analogous to that seen in triggered rhythms (i.e., linear relation of PCL to early acceleration of the TCL) is uncommon in post-MI VT. Because rapid ventricular pacing is usually required to terminate faster VTs, these VTs have a higher incidence of acceleration (40% of VTs with TCL less than 300 milliseconds with rapid ventricular pacing). Approximately 50% of the accelerated VTs can be terminated with even faster ventricular pacing; the other 50% (which can be polymorphic VT or ventricular flutter) require electrical cardioversion.

Acceleration is classified according to the morphology of the accelerated tachycardia: VT morphology identical to or different from the original VT, or polymorphic VT. An accelerated VT with a QRS morphology identical to the original VT suggests that the accelerated VT is using the same exit of the original VT circuit. The most likely mechanism underlying this form of VT acceleration is an area of block that determines the size of the reentrant circuit, which is determined to some extent by refractoriness. Rapid pacing can shorten the refractoriness in a proximal region of the arc of block, which would in turn shorten the length of the reentrant pathway. If the distal component of the arc of block remains unchanged, acceleration of the VT will occur with the same exit site and hence the same QRS morphology.

Fig. 22.13 Ventricular Tachycardia (VT) Termination by a Nonpropagated Ventricular Extrastimulus (VES). VT is shown with the ablation electrode recording a small mid-diastolic potential (arrows). A single VES (S) is delivered during VT that does not appear to capture myocardium, yet terminates the tachycardia. *Abl_{dist}*, Distal ablation site; *Abl_{prox}*, proximal ablation site.

Alternatively, rapid pacing can remove block in a shorter potential pathway, creating a smaller circuit.

On the other hand, a VT morphology different from the original VT can be secondary to a change in the exit site from the same circuit, a reversal of the reentrant circuit, or the termination of the initial VT and initiation of a different VT. Polymorphic VT with or without degeneration to VF can occur because of the inability of the myocardium to respond to the short PCL with the development of changing activation wavefronts, leading to multiple reentrant wavelets that can degenerate into VF. There is no way to predict which type of acceleration will occur. However, in the presence of antiarrhythmic drugs, acceleration to different morphologically distinct VTs is common.

Tachycardia transformation. Transformation of the index VT into a second uniform VT with distinct morphology can occur in response to overdrive pacing. It is not uncommon for stimulation during one VT to induce another VT of different morphology and TCL, only to be changed to a third or fourth one by continued stimulation. The significance of all these multiple morphologically distinct VTs induced during overdrive pacing of the index VT is uncertain if they were never seen before spontaneously or induced by programmed stimulation during NSR. Usually, however, these VTs can also be induced by programmed electrical stimulation. Nevertheless, any VT (even if not seen before) that is uniform and has a TCL longer than 250 milliseconds should be regarded as clinically important. Those VTs may not have been observed previously because the original VT dominates because it is more readily inducible. Induction of rapid unstable VTs (TCL < 250 milliseconds) in patients who presented with only stable VT does not have prognostic value.

The ability to change from one VT to another with a different TCL using single or double VESs is infrequent during triggered rhythms (other than those because of digitalis), and is another observation that is most compatible with a reentrant mechanism.

Entrainment. Overdrive ventricular pacing at long PCLs (i.e., 10 to 30 milliseconds shorter than the TCL) can almost always entrain reentrant VTs. The slower the pacing rate and the farther the pacing site from the reentrant circuit, the longer the pacing drive required to penetrate and entrain the tachycardia.

Following the first beat of the pacing train that penetrates and resets the reentrant circuit, the subsequent stimuli will interact with the reset circuit, which has an abbreviated excitable gap. Depending on the degree that the excitable gap is preexcited by that first resetting stimulus, subsequent stimuli fall on fully or partially excitable tissue. Entrainment is said to be present when two consecutive extrastimuli conduct orthodromically through the circuit with the same conduction time while colliding antidromically with the preceding paced wavefront. During entrainment, the paced stimuli enter the reentrant circuit, block with the existing tachycardia wavefront in the antidromic direction, and conduct through the circuit in the orthodromic direction to produce the return cycle beat.

Entrainment criteria. The traditional definition of entrainment states that, during constant-rate pacing, entrainment of a reentrant tachycardia results in the activation of all myocardial tissue responsible for maintaining the tachycardia at the PCL, with the resumption of the same tachycardia morphology following cessation of pacing, with the first postpacing ECG tachycardia complex displaying no fusion but occurring at a return cycle equal to the PCL. Importantly, the mere acceleration of the tachycardia to the pacing rate and the subsequent resumption of the original tachycardia after cessation of pacing do not establish the presence of entrainment. Therefore several surface ECG and intracardiac electrogram criteria have been proposed for establishing the presence of entrainment (see Fig. 5.17 and Box 5.1).⁶⁹⁻⁷¹ These criteria are discussed in more detail in Chapter 5.

Entrainment with fusion. A stimulated impulse is said to be fused when its morphology is a hybrid between that of a fully paced QRS morphology (when pacing is performed at the identical site and rate but in the absence of tachycardia) and a tachycardia QRS morphology (in the absence of pacing) (Fig. 22.14; and see Figs. 5.17 and 5.19). The ability to demonstrate QRS fusion on the surface ECG requires a significant mass of myocardium to be depolarized by both the extrastimulus and the tachycardia. The farther the stimulation site is from the reentrant circuit, the less likely entrainment with ECG fusion will occur.⁷⁰

During entrainment of reentrant VT, varying degrees of QRS fusion at different pacing rates are caused by a progressive increase in the amount of myocardium activated by the antidromic paced wavefront at progressively shorter PCLs. Importantly, fusion remains fixed at each of the PCLs, but a different degree of fixed fusion is manifest at different PCLs (see Figs. 5.17 and 5.19).

Focal tachycardias (automatic, triggered activity, or microreentrant) cannot manifest fixed fusion during overdrive pacing (Fig. 22.15). It is important to note that overdrive pacing of tachycardia of any mechanism can result in a certain degree of fusion, especially when the PCL is only slightly shorter than the TCL. Such fusion, however, is unstable during the same pacing drive at a constant PCL because pacing stimuli fall on a progressively earlier portion of the tachycardia cycle and produce progressively less fusion and more fully paced morphology. Such a phenomenon (referred to as “variable fusion”) should be distinguished from the “constant fusion” and “progressive fusion” characteristics of entrainment, and sometimes this distinction requires pacing for long intervals to demonstrate variable degrees of fusion. Moreover, overdrive pacing frequently results in suppression (automatic) or acceleration (triggered activity) of focal tachycardias, rather than resumption of the original tachycardia with an unchanged TCL.^{69,71}

Entrainment with manifest fusion. Demonstration of the presence of manifest fusion during entrainment requires knowledge of the surface ECG morphology of the tachycardia and of pure pacing (at the same site and rate) in the absence of tachycardia. Manifest fusion is said to be present when the QRS morphology is a hybrid of the QRS morphology of the tachycardia and that observed during pure pacing (see Figs. 5.17 and 5.19).

Entrainment of reentrant VT commonly produces manifest fusion that is stable (fixed) during the pacing drive at a given PCL; repeated entrainment at PCLs progressively shorter than the TCL results in different degrees of QRS fusion, with the resultant QRS configuration looking more like a fully paced configuration (see Figs. 5.17 and 5.19). When entrainment is manifest, the last captured wave is entrained (occurring at the PCL) but does not demonstrate fusion.⁶⁹

Entrainment with inapparent fusion. Entrainment with inapparent fusion (also referred to as “local” or “intracardiac fusion”) is said to be present when a fully paced QRS morphology (with no surface ECG fusion) is observed during entrainment, even though the tachycardia wavefront does exit the reentrant circuit (i.e., orthodromic activation of the presystolic electrogram is present). In this setting, fusion is limited to a small area and does not produce surface ECG fusion, and only intracardiac (local) fusion can be recognized (see Fig. 5.20).

Local fusion can only occur when the presystolic electrogram is activated orthodromically. Collision with the last paced impulse must occur distal to the presystolic electrogram, either at the exit from the circuit or just outside the circuit. In such cases, the return cycle measured at this local electrogram will equal the PCL. Therefore a stimulus delivered after the onset of the surface ECG QRS during entrainment will always demonstrate local fusion. This is to be distinguished from entrainment with antidromic capture, whereby the return cycle, even when

Fig. 22.14 Fusion With Ventricular Pacing During Macroreentrant Postinfarction Ventricular Tachycardia (VT). VT with a right bundle branch block pattern and right superior axis is shown at left (cycle length [CL], 405 milliseconds, in blue shading). In the panels at right, pacing during VT over a range of CLs from the right ventricular (RV) apex (with a left bundle branch block pattern and left superior axis) is shown. Pure RV pacing during sinus rhythm at CL of 600 milliseconds is shown at far right (yellow shading). It is evident that while pacing during VT, QRS complexes at each paced CL are different from both VT and pure pacing, indicating contribution of both the VT and paced wavefronts to the QRS complexes (fusion, most evident in leads III, aVL, aVF, and V₁ and V₂). *Abl_{dist}*, Distal ablation site; *Abl_{prox}*, proximal ablation site; *His_{dist}*, distal His bundle; *RVA*, right ventricular apex.

measured at the site of the presystolic electrogram, exceeds the PCL (see later).

Entrainment with concealed fusion. Entrainment with concealed fusion (sometimes referred to as “concealed entrainment” or “exact entrainment”) is defined as entrainment with orthodromic capture and a surface ECG complex identical to that of the tachycardia (Fig. 22.16).⁶⁹ Entrainment with concealed fusion suggests that the pacing site is within a protected isthmus inside the reentrant circuit or outside but attached to the circuit (i.e., the pacing site can be in, attached to, or at the entrance to a protected isthmus that forms the diastolic pathway of the circuit). In this setting, transient entrainment is achieved when the stimulated wavefront propagating orthodromically resets the tachycardia, while the stimulated wavefront propagating antidromically

collides with the tachycardia wavefront in or near the reentry circuit and fails to exit the slow conduction zone. Only the tissue near the pacing site within the critical isthmus is antidromically activated; hence, there is no evidence of fusion. Compared with the intrinsic tachycardia, this antidromic capture can result in earlier intracardiac recordings from bipole sites located adjacent to the pacing region. The morphological appearance of the ECG, however, is the same during entrainment as during the tachycardia.

It should be emphasized that entrainment with concealed fusion can occur not only when pacing at the critical isthmus of the reentry circuit, but also during pacing at bystander pathways (such as a blind alley, alternate pathway, or inner loop) that are not critical to the maintenance of reentry. In the latter situation, activation propagates from

Fig. 22.15 Lack of Fusion With Ventricular Pacing During Focal Ventricular Tachycardia (VT). VT with a right bundle branch block pattern and left superior axis is shown at left in blue shading (cycle length [CL], 470 milliseconds). In the panels at right, pacing during VT over a range of CLs from the right ventricular outflow tract (RVOT, with a left bundle branch block pattern and right inferior axis) is shown. It is clear that while pacing during VT, all QRS complexes are identical, indicating no contribution of the VT to the QRS complexes (thus no fusion). *His_{dist}*, Distal His bundle; *His_{prox}*, proximal His bundle.

the main circuit loop but is constrained by block lines having the shape of a cul-de-sac; ablation at these sites does not terminate reentry.^{69,70,72}

Occasionally, one of the first few stimuli of a drive train intended to entrain VT terminates VT without propagation. Subsequent stimuli often result in QRS complexes that do not resemble VT, leading the operator to conclude that the site is far from the isthmus. Review of the first few stimuli of pacing may show that the site actually was very attractive for ablation (eFig. 22.9).

Entrainment with antidromic capture. When pacing is performed at a PCL significantly shorter than the TCL, the paced impulse can penetrate the circuit retrogradely (antidromically) to capture the presystolic electrogram (within the protected isthmus prior to the exit site). As a result, the tachycardia wavefront cannot exit from the reentrant circuit and, thus, cannot contribute to myocardial activation. Therefore the surface QRS during entrainment appears fully paced. When pacing is stopped, the impulse that conducts antidromically also conducts orthodromically to reset the reentrant circuit with orthodromic activation of the presystolic electrogram. When antidromic (retrograde) capture of the local presystolic electrogram occurs, the return cycle, even when measured at the site of the presystolic electrogram, will exceed the PCL by the difference in time between when the electrogram is activated retrogradely (i.e., preexcited antidromically) and when it would have been activated orthodromically (see Fig. 5.17).⁷⁰

Tachycardia termination. The ability to terminate SMVT by rapid ventricular pacing or VES is influenced most importantly by the TCL (about 50% of VTs with TCLs less than 300 milliseconds will require electrical cardioversion), but also by the local ERP at the pacing site,

conduction time from the stimulation site to the site of origin of the VT, duration of the excitable gap, and presence of antiarrhythmic agents.

Failure of rapid ventricular pacing or VES to terminate VT has several potential explanations: (1) the reentrant circuit being a protected focus; (2) inability of VES to access the reentrant circuit because of local myocardial refractoriness; (3) absence of an accessible excitable gap; (4) termination of VT followed by reinitiation by a subsequent pacing impulse in the same pacing drive; or (5) failure of conduction block to occur within the reentrant circuit, despite accelerating the VT to the faster pacing rate.

Factors influencing termination of VT can be modified. Refractoriness at the site of stimulation can be overcome by the use of multiple VESs or a higher pacing current. The distance and conduction time from the site of stimulation to the VT site can be modified by changing the site of stimulation. The TCL can be increased by antiarrhythmic agents, but the response is unpredictable. Nonetheless, two problems are frequently encountered in attempts to terminate VT—acceleration of the VT by overdrive pacing and the appearance of multiple distinct uniform VT morphologies.

When tachycardia termination occurs, it is usually abrupt (regardless of the mode of stimulation used), which distinguishes reentrant VTs from triggered VTs. In reentrant VTs, termination must occur when an impulse penetrates the circuit and blocks in both directions. Rapid ventricular pacing is the most efficacious way of VT termination, regardless of the TCL. Approximately 80% of VTs terminated by a single VES have a TCL longer than 400 milliseconds. All VTs terminated by single or double VESs can also be terminated by ventricular pacing.

eFig. 22.9 Nonpropagated Ventricular Tachycardia (VT) Termination During Attempted Entrainment. VT is shown with a diastolic potential (*blue arrow*); during attempted stimulation at this site during VT, the first several stimuli (*S*) have no effect but the fifth stimulus (*red arrow*) results in VT termination without propagation of the impulse (no subsequent QRS). Subsequent stimuli capture the site but result in a very different QRS configuration. *Abl_{dist}*, Distal ablation site; *Abl_{prox}*, proximal ablation site; *CS_{dist}*, distal coronary sinus; *CS_{prox}*, proximal coronary sinus; *His_{dist}*, distal His bundle; *His_{prox}*, proximal His bundle; *RVA*, right ventricular apex.

Fig. 22.16 Entrainment Mapping of Ventricular Tachycardia (VT).

(A) Entrainment of VT from a distant site. Diagrammatic representation of a figure-of-8 VT circuit at left, with an electrogram recorded at a site remote from critical circuit elements. At center, during entrainment pacing, the paced wavefront from this remote site (*) interacts with the circuit by colliding with a VT wavefront that has exited the diastolic corridor while also entering the diastolic corridor at the opposite end. This results in fusion (part of the ventricle depolarized by the VT wavefront, part by the paced wavefront). For as long as pacing continues, this fusion of ventricular activation remains stable. With cessation of pacing (*right figure*), the last paced wavefront enters the diastolic corridor as on other cycles, but there is no subsequent paced wavefront to collide with the wavefront that is exiting the corridor; thus the first return cycle complex is entrained, but not fused. The PPI measured at the site of pacing reflects the time it takes to make one complete revolution around the circuit plus any time required to get from the pacing site to the circuit and back from the circuit to the pacing site. (B) Entrainment of VT from a site within the circuit. The pacing site (*) is within the circuit but outside the diastolic corridor. As a result, the entrained QRS complex shows fusion and the PPI equals the TCL. (C) Entrainment of VT from a site within the critical isthmus. The pacing site (*) is within the circuit and inside the diastolic corridor, recording the mid-diastolic electrogram. As a result, the entrained QRS complex shows no fusion and the PPI equals the TCL. The S-QRS interval equals the electrogram-to-QRS interval during VT. This is the ideal ablation site. EGM, Intra-cardiac electrogram; PCL, pacing cycle length; PPI, postpacing interval; TCL, tachycardia cycle length.

Termination is less likely to occur when the VT cannot be reset with very premature VES (i.e., the VES coupling interval is more than 75% of the TCL).

A single VES delivered during entrainment of VT can facilitate termination of VT by allowing easier access to the excitable gap. Even when a single VES alone or overdrive pacing alone fails to terminate the VT, the combination of both can be successful. Overdrive pacing ensures stable resetting of the VT circuit, allowing a single VES to interact with the circuit much more prematurely than it could in the absence

of entrainment. Overdrive pacing also shortens the excitable gap of tissue in the reset circuit, making it possible for a single VES to terminate the VT. This technique avoids the need for multiple VESs, which can increase the heterogeneity of conduction and refractoriness in the intervening tissue and produce polymorphic VT, and the need for rapid pacing, which might induce acceleration of the VT. This method is especially helpful in VTs that were accelerated by rapid pacing and especially in those VTs for which antiarrhythmic agents have made the tachycardia more difficult to terminate.

Response to Antiarrhythmic Drugs

Class I agents are the most uniformly successful drugs for slowing or terminating SMVT. These drugs can also facilitate the induction of SMVT in patients in whom SMVT cannot be induced by the standard programmed electrical stimulation protocol and in patients with CAD and nonsustained VT. Occasionally, class I agents produce incessant SMVT in patients who, before therapy, only had paroxysmal events. This phenomenon, almost always associated with a slower VT and prolongation of conduction by the agent, would not be expected if the mechanism were triggered activity or abnormal automaticity. Adenosine, beta-blockers, and calcium channel blockers are ineffective for termination of post-MI VT.

Exclusion of Other Arrhythmia Mechanisms

Exclusion of Triggered-Activity Ventricular Tachycardia

Stimulation site specificity. The site of ventricular stimulation should have no effect on the initiation of triggered-activity VT as long as the impulse reaches the focus of the VT. Reentrant VT, on the other hand, can demonstrate absolute or relative site specificity for initiation.

Inducibility with programmed electrical stimulation. Ventricular stimulation can initiate triggered-activity VT in less than 65% of cases. Rapid ventricular pacing to initiate triggered VT should be more effective than VES. Multiple VESs during NSR or following a drive train of fewer than 8 to 10 beats usually fail to initiate triggered-activity VT. Most episodes of triggered-activity VT induced by ventricular stimulation are usually nonsustained. Induction of triggered-activity VT with atrial pacing is not uncommon. In contrast, VES is more effective than rapid pacing at initiating reentrant VT.

Reproducibility of initiation. Reproducibility of triggered-activity VT induction using all methods is less than 50%. Reproducibility is markedly affected by quiescence. Once a triggered rhythm is initiated, a period of quiescence is necessary to reinstate the rhythm. Thus the ability to initiate, terminate, and reinstate a sequence is uncommon, in contrast to reentrant VT.

Relationship of ventricular stimulus to the onset of VT. Typically, both the initial cycle of the triggered-activity VT (the return cycle) and the TCL following cessation of pacing bear a direct relationship to the PCL (and a direct relationship to the coupling interval of the VES, when used). Thus the shorter the initiating ventricular PCL, or the shorter the initiating VES coupling interval, the shorter the interval to the first VT beat and the shorter the initial TCL. Occasionally, with early VESs, a jump in the interval to the onset of the VT complex occurs, so that it is approximately twice the interval to the onset of the VT initiated by later coupled VESs. This is secondary to failure of the initial DAD to reach the threshold while the second DAD reaches the threshold. Thus, in triggered-activity VTs caused by DADs, the coupling interval of the initial VT complex shortens or suddenly increases in response to progressively premature VES. It would not be expected to demonstrate an inverse or gradually increasing relationship, in contrast to reentrant VT. Only with the addition of very early VESs or, occasionally, very rapid ventricular pacing (PCL < 300 milliseconds) can a sudden jump in the interval to the first VT complex be observed. Furthermore, ventricular PCLs longer or shorter than the critical CL window fail to induce triggered-activity VT. This critical window may shift with changing autonomic tone.

Effects of catecholamines. Inducibility of triggered-activity VT is facilitated by catecholamines, whereas in the setting of reentrant VT, isoproterenol facilitates VT induction in only 5% of cases. However, induction of triggered-activity VT can be inconsistent and is exquisitely sensitive to the immediate autonomic status of the patient. Therefore noninducibility during a single EP study is not enough evidence to attribute the arrhythmia to a nontriggered activity mechanism.

Response to antiarrhythmic drugs. Triggered-activity VTs respond favorably to calcium channel blockers and beta-blockers. Conversely, those drugs fail to terminate the vast majority of VTs associated with CAD.

Diastolic electrical activity. In reentrant VT, electrical activity occurs throughout the TCL. Thus, during diastole, conduction is extremely slow and in a small enough area that it is not recorded on the surface ECG. Demonstration that the VT initiation is dependent on a critical degree of slow conduction, manifested by fragmented electrograms spanning diastole, and that maintenance of the VT is associated with repetitive continuous activity is consistent with a reentrant mechanism.

Exclusion of Bundle Branch Reentrant Ventricular Tachycardia

His bundle–ventricular interval. BBR should be suspected when the His potential precedes ventricular activation and the HV interval during VT is longer than that during NSR. In other VTs, the His potential is usually recorded immediately before or after, or obscured within the local ventricular electrogram. Occasionally, the His potential can precede the onset of the QRS in post-MI VT; however, in contrast to BBR VT, the HV interval in those VTs is shorter than that during NSR.

Oscillation of TCL. Spontaneous or induced changes in the V-V intervals during BBR VT are dictated and preceded by similar changes in the H-H intervals. These changes can be demonstrated by ventricular stimulation during VT or can occur spontaneously following initiation. In other VTs, in contrast to BBR VT, the V-V interval variation usually dictates the subsequent H-H interval changes.

Activation sequence. In the common type of BBR VT (LBBB pattern), the activation wavefront travels retrogradely up the LB to the HB and then anterogradely down the RB, with subsequent ventricular activation. This sequence is reversed in BBR VT with an RBBB pattern. Unfortunately, RB and LB potentials are not routinely recorded, so that the typical activation sequences (LB-HB-RB-V or RB-HB-LB-V) are not available for analysis. Even if either sequence is present, the HPS (usually the LB) could be activated passively in the retrograde fashion to produce an HB-RB-V sequence during an intramyocardial VT with an LBBB pattern without reentry requiring the LB. In these cases, other diagnostic criteria for BBR VT should be used.

Exclusion of Supraventricular Tachycardia

SVT with aberrancy. If VT exhibits 1:1 ventriculoatrial (VA) conduction, it can mimic SVT with aberrancy. Surface QRS morphology usually helps distinguish SVT with typical RBBB or LBBB from VT.⁷³ Furthermore, in VT, the atrium is not part of the tachycardia circuit and can be dissociated by atrial pacing. Also, the HV interval in aberrantly conducted SVT is always equal to or longer than that during NSR, which is in contrast to intramyocardial VTs. In addition, tachycardia response to VES and atrial pacing can be useful for distinguishing SVT from VT, as discussed in detail in **Chapter 21**.

Preexcited SVT. Differentiation between VT and preexcited SVT (i.e., SVT with anterograde conduction over an AV BT) is particularly difficult on the surface ECG because ventricular activation begins outside the normal intraventricular conduction system in both tachycardias. As a result, many of the standard criteria cannot discriminate between preexcited SVT and VT. The HV interval is usually short or negative in both preexcited SVT and VT, and does not help in the differential diagnosis.

Because the atrium is not part of the VT circuit, the ability to dissociate the atrium (with rapid atrial pacing) without influencing the TCL (V-V interval) or QRS morphology suggests VT and excludes preexcited SVTs. Other pacing maneuvers used for differential diagnosis are discussed in **Chapter 21**.

MAPPING

Preprocedural Evaluation

Evaluation and treatment of potential ischemia and heart failure decompensation, which could contribute to instability during the ablation procedure, is necessary. Cardiac imaging studies may be used to identify the size and location of the infarct that potentially contains the arrhythmogenic substrate. These tests also help exclude the presence of LV thrombus, which can increase the risk of embolization during mapping. Patients with post-MI VT should also be evaluated for comorbidities that can alter the approach to mapping and ablation. In patients with suspected peripheral vascular disease and valvular heart disease, evaluation of the presence of severe disease is warranted, because it can affect the approach to LV access (atrial transseptal vs. retrograde transaortic vs. epicardial). In addition, assessment of the risks for sedation and anesthesia must be performed prior to the procedure because these patients are likely to require deep sedation or general anesthesia.

Optimization of Cardiac Function

Treatment of congestive heart failure and myocardial ischemia should be optimized. Coronary revascularization should be considered in patients with reversible ischemia because substantial ischemic burden can often be aggravated by the potential induction of prolonged periods of tachycardia or hemodynamically unstable arrhythmias during the ablation procedure. In patients with frequent or incessant VT, however, catheter ablation may be required on an urgent basis before the assessment for CAD in order to gain prompt control of the ventricular arrhythmia.

Evaluation for Intracardiac Thrombi

Assessment of LV intracavitary thrombi is an important part of the preprocedural workup. The presence of LV thrombi can increase the risk of thromboembolism due to catheter manipulation, and can also prevent endocardial access to “critical” portions of the arrhythmia circuit. The incidence of LV thrombus after acute MI has diminished in the era of PCI but has been reported in up to 5% to 15%, especially in patients with anterior MI, LVEF less than 35%, and apical dyskinesia or aneurysm. Contrast transthoracic echocardiography (TTE), transesophageal echocardiography (TEE), cardiac computed tomography, and CMR may be used to exclude the presence of intracardiac thrombi. Although CMR is the gold standard, contrast TTE is a readily available tool with reliable positive and negative predictive value (93% and 91%, respectively). A recent report found intracardiac echocardiography (ICE) to be superior to TTE for the detection of LV thrombi. Another advantage of ICE is that it enables intraprocedural visualization of thrombus margins and guide catheter placement in relation to the LV thrombus.⁷⁴

The risk of embolic episodes is high in the presence of soft, mobile, and protruding LV thrombi, and less for chronic, organized, mural thrombi. Assessment of thrombus chronicity can be challenging. Laminated appearance of the thrombus is highly suggestive of an organized thrombus; however, specific criteria indicating thrombus chronicity are lacking. Furthermore, it is often difficult to reliably exclude acute-on-chronic thrombus layering.⁷⁵ The presence of a *mobile* thrombus is an absolute contraindication to endocardial catheter ablation. Conversely, the presence of a laminated thrombus per se is not a perceived contraindication if the patient has been therapeutically anticoagulated with warfarin for at least 4 weeks prior to ablation; however, the thrombus is very likely to reside in an area where mapping would be important (scar/aneurysm) and thus catheter movement in this area is generally inadvisable.

Similarly, the presence of intraatrial clots should be excluded in patients with inadequately anticoagulated persistent AF to reduce the risk of thromboembolism in the event of AF termination following

electrical shocks for termination of unstable ventricular arrhythmias, or transseptal access to the LV.

Imaging the Arrhythmogenic Substrate

In patients with ventricular dysfunction, tissue heterogeneity with inexcitable myocardial fibrous scar and surviving myocardium provides a potential substrate for reentry circuits. Several noninvasive methodologies have been used to assess the substrate and identify patients at high risk for ventricular arrhythmias.

Ventriculography. Left ventriculography provides valuable information about LV function and ventricular thrombi. In addition, regions of wall motion abnormalities and aneurysms can be identified that likely harbor the VT substrate.

Echocardiography. TTE is routinely performed to evaluate LV systolic function, LVEF, and wall motion abnormalities that may contain the potential VT substrate. TTE also serves as a reliable tool to rule out ventricular thrombi before LV procedures. In addition, it helps to identify relatively infrequent cardiomyopathies associated with VT such as arrhythmogenic right ventricular cardiomyopathy and hypertrophic cardiomyopathy. Although echocardiography can provide anatomical and contractile parameters, it cannot provide relevant clinical information about transmural extent and intramycocardial location of the scar.

TEE can be used in patients with AF or atrial flutter (AFL) to detect thrombi within the left atrium (LA) and LA appendage to prevent thromboembolic events when a transseptal access to the LV or cardioversion is required. Severe atheroma in the aorta detected on TEE may encourage the operator to avoid the retrograde approach to the LV.

ICE applied from the right atrium (RA) and the right ventricle (RV) has been used for real-time imaging during VT ablation procedures. ICE provides both an anatomical and a functional assessment of the LV, allowing for real-time identification of wall motion abnormalities. ICE also allows for visualization of scarred tissue and thus may help to identify the VT substrate and facilitate mapping and ablation (see later).⁷⁶

Cardiac magnetic resonance. CMR is currently the noninvasive gold standard for quantification of cardiac anatomy and function, with a unique ability to differentiate and characterize tissues. CMR has been shown to detect myocardial fibrosis and necrosis and delineate regions of scar tissue potentially forming part of the arrhythmia substrate in patients with ischemic cardiomyopathy.^{30,31}

CMR is extremely valuable for assessing viable and nonviable myocardium in infarcted and poorly contracting myocardial areas, and enables the depiction of transmural and nontransmural infarctions with high spatial resolution and better accuracy than scintigraphic techniques (eFig. 22.10). Assessing the characteristics and distribution of myocardial scar by CMR can potentially help identify patients at high risk of VT. In patients with ischemic cardiomyopathy; the non-transmural hyperenhanced areas, but not the transmural hyperenhanced areas, were found to predict higher risk of sustained VT.

In addition, visualizing scar topography and transmural extent on delayed enhancement CMR helps focus mapping and ablation to the culprit regions and can potentially predict the approach required for successful VT ablation (endocardial vs. epicardial).^{77,78}

Furthermore, registration of preacquired CMR images with real-time electroanatomical mapping has successfully been used to facilitate and guide catheter navigation and ablation in the LV. Visualization of ventricular anatomy and obstacles to procedural success, for example, epicardial fat in the case of epicardial mapping approaches, and the possibility of navigation and ablation in the ventricular chambers have the potential to reduce procedure time, decrease the rate of complications, and increase success rates.

eFig. 22.10 Magnetic Resonance Scans of the Left Ventricle (LV) in a Patient With an Old Anterior Myocardial Infarction. Long axis (*at left*) and short axis (*at right*) views of the LV show a dense anteroapical scar (*arrowheads*), which can be visualized as a white thin area of the LV wall.

One potential disadvantage concerns the safety and quality of CMR imaging in patients with implanted cardiac devices. Nonetheless, recent studies have consistently demonstrated the feasibility and safety of CMR in patients with cardiac devices, and evolving technologies have further improved the CMR imaging compatibility of some devices. Importantly, the device hardware introduces significant artifacts, especially in the basal anterior free LV wall, which degrades the image quality and often limit interpretation of CMR in VT patients. However, the interventricular septum, and the LV lateral and inferior walls are mostly free of artifact in most patients. Recently, a wideband late gadolinium enhanced CMR technique has been reported to reduce hyperintense artifacts from the ICD generator.^{77,79}

Positron emission tomography. Currently, positron emission tomography (PET) is considered the gold standard for tissue viability assessment. In patients with scar-related VT, PET can accurately detect myocardial scar within the LV and provide additional tissue characterization by displaying metabolic and morphological information of the VT substrate. Its spatial resolution of 4 to 6 mm can delineate scar in any wall segment, with good correlation between areas of endocardial voltage less than 0.5 mV and PET-defined myocardial scar.⁸⁰

Because PET scans alone do not provide the necessary anatomical information required for integration with electroanatomic maps, computed tomography (CT) angiography scan is required to provide an anatomical skeleton onto which the physiological information acquired from the PET scan would be superimposed on its precise anatomical location. Fusion of multimodality imaging sets derived from PET/CT allows accurate, simultaneous display of LV anatomy and myocardial scar and can facilitate an image-guided approach to substrate-based VT ablations.⁸⁰

Cardiac CT. Contrast-enhanced cardiac CT enables a detailed and comprehensive evaluation of LV myocardium using multimodality imaging based on anatomical, dynamic, and perfusion parameters to identify abnormal substrate (myocardial scar and border zone) with high spatial (≤ 1 mm) and temporal resolution. Areas of CT hypoperfusion and ventricular wall thinning correlate best with areas of abnormal voltage (less than 1.5 mV) rather than scar alone (less than 0.5 mV). Perfusion imaging from CT can indicate scar transmural and intramyocardial scar location.^{78,81}

The ability of contrast-enhanced CT to characterize the transmural extent and intramyocardial location of scar tissue and to visualize surviving mid- and epicardial myocardium at sites of endocardial scar can potentially help identify areas involved in myocardial reentry representing appropriate ablation targets and help to overcome one of the significant limitations of endocardial voltage mapping. In addition, the presence of an epicardial VT substrate can facilitate planning of VT ablations, such as for a combined endocardial and epicardial approach. When compared with contrast-enhanced CMR, absolute sizes of early hypoperfused and late hyperenhanced regions were similar on contrast-enhanced CT and contrast-enhanced CMR.

In addition, the three-dimensional (3-D) CT-defined image of abnormal myocardium can be accurately extracted and embedded in clinical mapping systems displaying areas of abnormal anatomical, dynamic, and perfusion parameters for substrate-guided VT ablations.

Left Ventricular Access

The LV is generally accessed through the retrograde transaortic approach, usually via a femoral arterial access. An atrial transseptal approach can also be used, although accessing the entire LV is then more difficult. Both transseptal and retrograde approaches can be used concomitantly, so when a particular region of the LV cannot be mapped using one approach, it can be mapped using the other approach. Anticoagulation (with IV heparin) is started once the LV is accessed (or, more commonly,

before) to maintain the activated clotting time (ACT) between 250 and 350 seconds. Certain electrode arrays with high thrombogenicity may require an ACT of at least 300 seconds.

The presence of severe arterial disease, severe aortic stenosis, or mechanical aortic prosthesis prohibits the retrograde transaortic access to the LV. On the other hand, the presence of mechanical mitral valve precludes an atrial access to the LV. In addition, the presence of a *mobile* thrombus is an absolute contraindication to endocardial catheter ablation, and the epicardial approach should be considered.

Hemodynamic Support

Post-MI VT is often associated with hemodynamic instability that precludes detailed entrainment and activation mapping techniques. Furthermore, repetitive inductions of short periods of unstable VT, or even prolonged episodes of otherwise hemodynamically tolerated arrhythmia, can have a detrimental cumulative effect and expose patients to progressive hemodynamic compromise, myocardial ischemia, and exacerbation of heart and renal failure, affecting patient morbidity and clinical outcomes.⁸²

In some patients undergoing VT ablation, particularly those with severely depressed LVEF or preexisting significant heart failure, and in those in whom the induced VT is only marginally tolerated, circulatory support can be achieved with an IV infusion of dopamine, dobutamine, or phenylephrine; intraaortic balloon counterpulsation; extracorporeal membrane oxygenation (ECMO); or LV assist devices (Impella microcirculatory axial blood flow pump, Abiomed, Danvers, MA; and TandemHeart, Cardiac Assist, Pittsburgh, PA, United States). In addition, IV procainamide (infused with a maximal loading dose of 15 mg/kg at a rate of 50 mg/min, followed by a continuous infusion at a maximal rate of 0.11 mg/kg per minute) can help slow and stabilize the VT rate.⁸²⁻⁸⁴

Although intraaortic balloon pumps augment diastolic pressure and diminish afterload during periods of sinus rhythm, they do not provide a significant level of hemodynamic support during VT. Intraaortic balloon pumps require synchronization with the cardiac cycle, which is not feasible during fast ventricular arrhythmias. Conversely, temporary percutaneous LV assist devices are generally capable of providing greater hemodynamic stability and maintaining cardiac output and vital organ perfusion in the setting of unstable VT.⁸⁴ ECMO can be of particular advantage when the use of percutaneous LV assist devices is limited by the presence of mechanical aortic valves or LV thrombosis.⁸⁵

In addition to the potential benefit in reducing the risk of acute heart failure after the procedure, the improved hemodynamic support provided by percutaneous LV assist devices can permit sustaining VT for longer durations and, hence, allow more detailed entrainment and activation mapping during VT, ultimately yielding a greater number of VT terminations with ablation. Even in the setting of hemodynamically stable VT, mechanical hemodynamic support can help reduce intracardiac filling pressures, ventricular wall stress, and myocardial oxygen consumption, which can potentially reduce the risk of cardiac stunning due to multiple VT inductions for mapping and during ablation.

Percutaneous LV assist devices have been used as a “rescue” intervention in patients who develop periprocedural acute hemodynamic decompensation or when mapping and ablation of hemodynamically unstable VT is needed. More recently, several centers have reported potential benefits of the preemptive use of mechanical hemodynamic support in high-risk patients undergoing VT ablation. Predictors of periprocedural acute hemodynamic decompensation include advanced age, ischemic cardiomyopathy, severely reduced LVEF, presentation with VT storm, New York Heart Association (NYHA) functional class III/IV, chronic obstructive pulmonary disease, diabetes, and the use of

general anesthesia.⁸⁶ However, in recent studies, this did not necessarily translate into improved short-term procedural success or greater long-term freedom from VT. Furthermore, several potential risks of using those devices should be considered, including complications related to vascular access and thromboembolism. Therefore these devices are used selectively, and their potential risks should be balanced against the expected added value for the mapping and ablation strategy utilized in the individual patient. Although some interference from these devices with electroanatomic mapping may be observed, it is generally not detrimental to ablation success.^{54,84,87}

Importantly, the volume status and fluid balance should be closely monitored during the ablation procedure, especially when utilizing open-irrigated ablation catheters. In some patients, administration of diuretics and utilization of decreased irrigation rates or closed-irrigation ablation catheters need to be considered. When the transeptal approach is utilized for LV access, monitoring LA pressure can help assess volume status.

Electroanatomic Mapping

The main goal of VT mapping is the identification of the site of origin of the VT. The site of origin of the tachycardia is the source of electrical activity producing the QRS. Although this is a discrete site of impulse formation in focal rhythms, during macroreentrant VT it represents the exit site from the diastolic pathway (i.e., from the critical isthmus of the reentrant circuit) to the myocardium giving rise to the QRS complex. During macroreentrant VT, the critical isthmus is typically formed by a corridor of conductive myocardial tissue bounded by non-conductive tissues (barriers) through which the depolarization wavefront must propagate to perpetuate the tachycardia. These barriers can be anatomical (e.g., scar areas, mitral annulus) or functional (present only during tachycardia, but not in sinus rhythm) obstacles (Fig. 22.17).

Activation and entrainment mapping are used to identify the critical isthmus of the VT and guide ablation. When multiple VTs are inducible, it is recommended that all mappable VTs be completely mapped and targeted. However, some recommend targeting only the clinical VT, especially in very ill patients in whom the goal is to decrease the frequency of ICD shocks and improve the quality of life. It is important to have a 12-lead ECG of the clinical VTs available, if possible, for review at the time of the EP procedure. This information can be used to focus on the exit region suggested by the VT morphology to help limit the extent of detailed mapping, particularly when the clinical VT is hemodynamically unstable. In patients with ICDs, VT is usually terminated promptly and a 12-lead ECG is often not available. Nonetheless,

comparing the TCL and ICD electrogram morphology during spontaneous and induced VTs can be helpful, particularly when trying to limit ablation and target only the presumptive clinical VT.

However, mapping of VT circuits and identification of critical isthmuses are often challenging, and require reproducibly inducible SMVT that is hemodynamically stable. The abnormal area of scarring, where the isthmus is located, is often large and contains false isthmuses (bystanders) that confuse mapping. Although in the majority of cases a portion of the VT isthmus is located in the subendocardium, where it can be ablated, in some cases the isthmuses or even the entire circuits are deep in the myocardium or even in the epicardium and cannot be identified or ablated from the endocardium. In addition, multiple potential reentry circuits are frequently present, giving rise to multiple different monomorphic VTs in a single patient. Ablation in one area may abolish more than one VT or leave VT circuits in other locations intact.

Substrate mapping has evolved as an adjunct to activation and entrainment mapping to help identify potential circuit isthmuses during NSR, which can then be targeted by entrainment and activation mapping techniques during VT. Substrate mapping becomes the main strategy to guide ablation when SMVT is not reproducibly inducible or not hemodynamically tolerated. This approach reduces or eliminates the need for mapping during prolonged periods of VT.

Using conventional mapping techniques, it is difficult to conceive the 3-D orientation of cardiac structures because these techniques use a limited number of recording electrodes guided by fluoroscopy. Although catheters using multiple electrodes to acquire data points are available, the exact location of an acquired unit of EP data is difficult to ascertain because of inaccurate delineation of the location of anatomical structures. The inability to associate the intracardiac electrogram accurately with a specific endocardial site also limits the reliability with which the roving catheter tip can be placed at a site that was previously mapped. This results in limitations when the creation of long linear lesions is required to modify the substrate, and when multiple isthmuses, or channels, are present. This inability to identify, for example, the site of a previous ablation increases the risk of repeated ablation of areas already dealt with and the likelihood that new sites can be missed.

Therefore electroanatomic mapping using CARTO (Biosense Webster, Diamond Bar, CA, United States), ESI-NavX (St. Jude Medical, St. Paul, MN, United States), or Rhythmia (Boston Scientific, Cambridge, MA, United States) is generally utilized for mapping and ablation of post-MI VT. Electroanatomic mapping can help in the precise description of VT reentrant circuits, sequence of ventricular activation during the VT, rapid visualization of the activation wavefront, and identification of a

Fig. 22.17 Electroanatomic Activation and Voltage Mapping of Postinfarction Ventricular Tachycardia (VT). A series of electroanatomic (Rhythmia) activation and voltage maps of VT originating from the anteroapical region of the left ventricle (LV). Top panel, window of interest includes the QRS complex template (*left, white*) with overlay of the acquired QRS complex (*yellow*), and continuous recording during VT (*top right*). Panels A through D each include: (1) recorded local electrogram (*left*) with timing annotation; (2) activation map (*middle*) with leading propagation wavefront in red and tail in purple and roving electrode icon denoting the anatomical location of annotated local electrogram; (3) voltage map (*right*) and identical location of the roving electrode icon as that in the corresponding activation map. Red on the voltage map indicates local electrogram amplitudes of <0.1 mV; purple indicates electrogram amplitudes >0.4 mV. (A) The activation wavefront arrives at the lateral aspect of the anteroapical scar, where local electrogram occurs at the end of the QRS complex. The arrow shows the likely path of wavefront propagation during diastole. (B) The wavefront is propagating transversely through the scar; the local recording exhibits mid-diastolic fractionated electrogram, likely corresponding to the diastolic pathway of the reentry circuit. (C) The wavefront continues propagating toward the septal aspect of the scar, and the corresponding local activation time is late diastolic. (D) The propagating wavefront arrives at the septal scar border, where the local activation timing is presystolic, likely denoting the exit site. *Lat*, Lateral LV wall; *Sep*, septal LV wall.

slow-conducting pathway. These systems also help navigation of the ablation catheter, planning of ablation lines, and cataloging sites of interest (e.g., sites with favorable entrainment or pace mapping findings), which can then be revisited with precision. In addition, the use of electroanatomic mapping systems is essential for substrate-based approaches to mapping and ablation of post-MI VT.

A quadripolar mapping-ablation catheter is typically utilized for point-by-point mapping. Poles 1 to 3 (distal) and 2 to 4 (proximal) of the ablation catheter are used for recording, and poles 1 to 3 are used for stimulation. High-density mapping can be facilitated by the use of a 20-pole catheter (PentaRay, Biosense-Webster) or mini-basket catheter (Orion, Boston Scientific).^{88–90}

Activation Mapping

In post-MI VT, the goal of activation mapping is to seek sites with continuous activity spanning diastole or with an isolated mid-diastolic potential, presumably representing the diastolic pathway (critical isthmus) of the reentrant circuit. Unlike focal tachycardias, a presystolic electrogram preceding the tachycardia complex by 10 to 40 milliseconds is not adequate in defining the ablation target of a macroreentrant tachycardia.

Activation mapping of post-MI VT has several prerequisites, including inducibility of VT at the time of EP testing, hemodynamic stability of the VT (which usually requires a relatively slow VT rate), and stability of the VT reentry circuit (i.e., stable VT morphology and TCL). If the tachycardia is not stable (morphologically or hemodynamically), mapping can still be performed in some cases by starting and stopping the VT after data acquisition at each site, assuming reinitiation of the same VT. In addition, poorly tolerated rapid VTs can sometimes be slowed by antiarrhythmic drugs to allow for mapping. Generally, antiarrhythmic drugs do not alter the sequence of activation, despite slowing of the VT and widening of the QRS and, although the electrogram at the site of origin can widen, its relationship to the onset of the QRS remains unchanged. Furthermore, as discussed previously, the use of IV vasopressors and external hemodynamic support devices can potentially provide hemodynamic support and allow mapping of otherwise unstable VT.^{82–84} The use of 20-pole catheter (PentaRay; 2–6–2 mm interelectrode spacing, 1 mm electrodes), the mini-basket catheter (Orion), and noncontact mapping can also provide large amounts of activation mapping data during nonsustained or unstable VT.

Technique of Activation Mapping

During electroanatomic activation mapping, the electrical reference is generally chosen as a morphologically stable and regular electrogram obtained from an endocardial (e.g., RV apical electrogram) or surface lead (e.g., surface ECG lead with a QRS complex during VT demonstrating a sharp apex and a strong positive or negative deflection). The width of the window of interest is adjusted to approximate, usually 20 milliseconds less than, the TCL. The middle of the window of interest is selected to coincide with the electrical reference or with mid-diastole on the ECG.

Point-by-point activation mapping or high-density multielectrode or mini-basket catheter mapping is performed by moving the mapping catheter over the endocardium of the region of interest to sample local electrogram morphology and activation timing. Initially, one should seek the general region of the origin of the tachycardia as indicated by the surface ECG and preablation imaging studies localizing the infarct region that possibly harbors the arrhythmogenic substrate (see Fig. 22.17).

Typically, bipolar electrogram recordings are used for activation mapping as they provide an improved signal-to-noise ratio and more clearly defined high-frequency components. Unipolar recordings in

scar areas, on the other hand, have very low amplitudes with a poor signal-to-noise ratio and distant electrical activity can be difficult to separate from local electrograms. This is especially true when recording from areas of prior MI, where the QS potentials are ubiquitous, and it is often impossible to select a rapid negative dV/dt when the entire QS potential is of low amplitude and/or slowly inscribed. Therefore unipolar electrograms are typically filtered at comparable settings to those of bipolar electrograms (30 to 300 Hz or more) when scar-related VT is studied. Filtering gives reasonably clean signals; however, the signal is often of very low amplitude. Therefore bipolar recordings are preferred for activation mapping; filtered unipolar electrograms can be used to help ensure that the tip electrode, which is the ablation electrode, is responsible for the early component of the bipolar electrograms.

The local activation time for each endocardial position under the mapping catheter is calculated as the interval between the electrical reference and the onset of the high-frequency bipolar electrogram as it leaves the baseline. Infarct regions are sought first and more data points are acquired around these areas, as identified by low-amplitude potentials, with diastolic electrograms, or double potentials. In regions of myocardial scar, electrode catheters often record multiple potentials separated in time, some of which are far-field potentials that are caused by depolarization of adjacent myocardium. Therefore it is important to carefully interrogate the recorded electrogram and assign activation timing only to the local electrogram. Assignment of an incorrect time of activation that can render activation sequence maps misleading.

The resulting reentrant circuit is considered to be the spatially shortest route of unidirectional activation encompassing a full range of mapped activation times (greater than 90% of the TCL) and returning to the site of earliest activation (see Fig. 22.17). Contact is critical when standard quadripolar catheters are used. The degree of contact can be assessed by pacing threshold or impedance measurements at the recording electrode pair. Use of ICE and contact force catheters can also help ensure adequate catheter contact.⁹¹

Continuous Activity

Theoretically, if reentry is the mechanism of VT, electrical activity should occur throughout the VT cycle. Thus, during diastole, conduction should be extremely slow and in a small enough area that it is not recorded on the surface ECG. Demonstration that VT initiation is dependent on a critical degree of slow conduction, manifested by fragmented electrograms spanning diastole, and that maintenance of the VT is associated with repetitive continuous activity, would be compatible with reentry.

In post-MI VT, continuous activity, when observed, invariably occurs at sites that demonstrate markedly abnormal electrograms during NSR (Fig. 22.18). However, continuous diastolic activity can be recorded in only 5% to 10% of post-MI VTs with detailed mapping using standard equipment. The ability to record continuous activity depends on the spatial and geometric arrangement of the involved tissue, the position of the catheter, and the interelectrode distance. Thus continuous diastolic activity is likely to be recorded only if a bipolar pair records a short isthmus. If a longer isthmus is recorded (i.e., the isthmus is larger than the recording area of the catheter or the catheter is not covering it completely), a nonholodiastolic electrogram will be recorded. In such VTs, when nonholodiastolic electrical activity is recorded at the isthmus, repositioning of the catheter to other sites can allow recording of the bridging of diastole (electrical activity in these adjacent sites spans diastole) (Fig. 22.19). Failure to record continuous activity is not surprising because catheter and intraoperative VT mapping suggest that most post-MI VTs incorporate a diastolic pathway 1 to 3 cm long and a few millimeters to 1 cm wide, with a circuit area probably larger than 4 cm².

Fig. 22.18 Continuous Diastolic Electrical Activity During Reentrant Ventricular Tachycardia (VT). VT is shown with almost continuous electrical activity in the distal ablation recording. During sinus rhythm (*right*), the electrogram is very fragmented and outlasts the surface QRS complex. *NSR*, Normal sinus rhythm.

Fig. 22.19 Bridging of Diastole During Reentrant Ventricular Tachycardia (VT). Shown is the compilation of numerous mapping sites around the left ventricular apical region during VT; diastole is shaded, showing progression of activation from early to mid to late diastole.

Not all areas from which diastolic activity is recorded are necessarily part of the reentrant circuit. Such sites can represent late activation and may not be related to the VT critical isthmus. Analysis of the response of these electrograms to spontaneous or induced changes in TCL is critical in deciding their relationship to the VT circuit. Electrical signals that come and go throughout diastole should not be considered

continuous. For continuous activity to be consistent with reentry, the following must be demonstrated: (1) VT initiation is dependent on continuous activity (i.e., broadening of electrograms that span diastole); (2) VT maintenance is dependent on continuous activity, so that termination of continuous activity, either spontaneously or following stimulation, without affecting the VT would exclude such continuous

activity as requisite for sustaining the VT; (3) the recorded continuous diastolic activity is not just a broad electrogram whose duration equals the diastolic interval, which can be verified by analyzing the local electrogram while pacing during sinus rhythm at a PCL comparable to the TCL—if pacing produces continuous diastolic activity in the absence of VT, the continuous electrogram has no mechanistic significance; (4) motion artifact should be excluded (this is easiest because such electrograms are recorded only in infarcted areas and never from moving, contractile normal areas); (5) the continuous activity should be recorded from a circumscribed area; and (6) if possible, ablation of the area from which continuous activity is recorded will terminate the VT.

Mid-Diastolic Activity

An isolated mid-diastolic potential is defined as a low-amplitude, high-frequency diastolic potential separated from the preceding and subsequent ventricular electrograms by an isoelectric segment (see Fig. 22.17; eFig. 22.11). It is likely that isolated mid-diastolic potentials that cannot be dissociated from the VT are generated in segments of the zone of slow conduction or critical isthmus, which are integral components of the reentry circuit. The earliest presystolic electrogram closest to mid-diastole is the most commonly observed indicator of an isthmus site in a VT circuit; however, continuous diastolic activity or bridging of diastole at adjacent sites or mapping a discrete diastolic pathway would be most consistent with a reentrant circuit (see Fig. 22.18).

In post-MI reentrant VT, the earliest presystolic electrogram is invariably abnormal and frequently fractionated or split, regardless of the QRS morphology of the VT or the location of the isthmus. Thus a normal presystolic bipolar electrogram (amplitude greater than 3 mV, duration less than 70 milliseconds) should prompt further search for earlier activity. The earliest electrogram in post-MI VT not infrequently has diastolic and systolic components separated by an isoelectric component, representing activation of different pieces of tissue separated by a barrier of scar (see eFig. 22.11). Detailed mapping will usually reveal more than one site of diastolic activity. It is therefore essential to demonstrate that the diastolic site recorded is in fact the earliest site. This can be done by demonstrating that sites surrounding the assumed earliest site are activated later than the index site, even though they may be diastolic in timing. If, after very detailed mapping, the earliest recorded site is not at least 50 milliseconds presystolic, this suggests that either the map is inadequate (most common) or the VT isthmus is deeper than the subendocardium, in the midmyocardium, or even incorporating the subepicardium.

It is important to recognize that mid-diastolic sites can also be part of a larger area of abnormal slow conduction unrelated to the VT circuit (i.e., a dead-end pathway), and can be recorded from a bystander site attached to the isthmus. Therefore, regardless of where in diastole the presystolic electrogram occurs (early, mid, or late), its appearance on initiation of VT and diastolic timing, although necessary, does not confirm its relevance to the VT mechanism. One must always confirm that the electrogram cannot be dissociated from the VT and is required for VT maintenance (see eFig. 5.2). This can be verified by demonstrating that the electrogram (regardless of its position in diastole) maintains a fixed relationship to the subsequent QRS (and not the preceding QRS) during induced or spontaneous changes in the TCL.

In general, local activation at post-MI VT exit sites precedes the onset of the surface QRS complex by 40 to 80 milliseconds (see Fig. 22.17). Sites with local activation occurring at less than 20 milliseconds before the QRS are considered “post-exit” sites. At sites with presystolic potentials, the time interval between the recorded near-field diastolic and far-field systolic potentials can help confirm whether those sites with presystolic potentials truly represent the exit of the VT circuit versus being merely bystander sites. Short intervals (approximately 25

milliseconds) are suggestive of an exit site, whereas longer intervals are more compatible with either a bystander site or a more proximal location within the isthmus.⁹²

Limitations of Activation Mapping

Standard transcatheter endocardial mapping as performed in the EP laboratory is limited by the number, size, and types of electrodes that can be placed within the heart. Because these methods cover only a small portion of the endocardial surface, time-consuming point-by-point maneuvering of the catheter is required to trace the origin of an arrhythmic event and its activation sequence in the neighboring areas.

The success of roving point mapping is predicated on the sequential beat-by-beat stability of the activation sequence being mapped and the ability of the patient to tolerate the sustained arrhythmia. Therefore it can be difficult to perform activation mapping in the setting of poorly inducible VT at the time of EP testing, hemodynamically unstable VT, and unstable VT morphology.

Although activation mapping is adequate for defining the site of origin of focal tachycardias, it is deficient by itself in defining the critical isthmus of macroreentrant tachycardias. Adjunctive mapping modalities (e.g., entrainment mapping, pace mapping) are required for this.

Entrainment Mapping

Focal ablation of multiple sites defined as being in the reentrant circuit may not result in elimination of VT; that instead requires ablation of an isthmus bordered by barriers on either side, which is critical to the reentrant circuit. Because the circuit incorporates sites outside this critical isthmus, ablation of these external sites will not eliminate VT. Entrainment mapping during reentrant VT is used to verify whether a site recording diastolic activity (regardless of where in diastole it occurs, its position, and appearance on initiation of VT) is functionally involved in the VT circuit, which helps in focusing ablation efforts in areas likely to eliminate VT (see Fig. 22.16).

Technique of Entrainment Mapping

Entrainment mapping is directed to sites identified by other mapping modalities, such as activation and pace mapping, as potentially related to the reentrant circuit. These include areas of slow conduction (manifest as fractionated electrograms), sites with mid-diastolic electrograms, or those displaying long delays between the pacing stimulus and the captured surface ECG complex.

Entrainment mapping can be reliably carried out only if one can record and stimulate from the same area (e.g., for 2-5-2-mm spacing catheters, record from the second and fourth poles and stimulate from the first and third poles). Pacing is usually started at a PCL just shorter (10 to 30 milliseconds) than the TCL. Pacing should be continued for a long enough duration to allow for entrainment; short pacing trains are usually not helpful.

After cessation of each pacing drive, the presence of entrainment should be verified, employing the entrainment criteria discussed previously (see Figs. 5.17 and 5.19). The mere acceleration of the tachycardia to the pacing rate and then resumption of the original tachycardia after cessation of pacing does not establish the presence of entrainment, and evaluation of the postpacing interval (PPI) or other criteria is meaningless when the presence of true entrainment has not been verified. Moreover, it is important to verify the absence of termination and reinitiation of the tachycardia during the same pacing train.^{69,70}

Once the presence of entrainment is verified, several criteria can be used to indicate the relation of the pacing site to the reentrant circuit. The first entrainment criterion to be sought is concealed fusion. Entrainment with concealed fusion indicates that the pacing site is in a protected isthmus located within or attached to the reentrant circuit. Whether

eFig. 22.11 Mid-Diastolic Electrical Activity During Reentrant Ventricular Tachycardia (VT). VT is shown with small mid-diastolic potentials (*arrows*) on the ablation recording. *Abl_{dist}*, Distal ablation site; *Abl_{prox}*, proximal ablation site; *His_{prox}*, proximal His bundle; *RVA*, right ventricular apex.

this protected isthmus is crucial to the reentrant circuit or is just a bystander site needs to be verified by other criteria, mainly comparing the PPI to the TCL and comparing the stimulus-exit interval to the electrogram-exit interval. Furthermore, the ratio of the stimulus-exit interval to the TCL can provide information regarding the location of the pacing site within the diastolic pathway of the reentry circuit. Long (51% to 70% of TCL), intermediate (31% to 50% of TCL), and short ($\leq 30\%$ of TCL) stimulus-exit intervals are observed during pacing from the entrance, central isthmus, and exit site of the reentry circuit, respectively. Features of entrainment when pacing from different sites are listed in Box 22.2 (Fig. 22.20; and see Fig. 5.16).⁷²

BOX 22.2 Entrainment Mapping Reentrant Ventricular Tachycardia

Pacing From Sites Outside Ventricular Tachycardia Circuit

- Manifest fusion on surface ECG and/or intracardiac recordings
- PPI – TCL > 30 msec
- S-QRS interval > local electrogram to QRS interval

Pacing From Sites Inside Ventricular Tachycardia Circuit but Outside Protected Isthmus

- Manifest fusion on surface ECG and/or intracardiac recordings
- PPI – TCL < 30 msec
- S-QRS interval = local electrogram-to-QRS interval

Pacing From Protected Isthmus Outside Ventricular Tachycardia Circuit

- Concealed fusion
- PPI – TCL > 30 msec
- S-QRS interval > local electrogram to QRS interval

Pacing From Protected Isthmus Inside Ventricular Tachycardia Circuit

- Concealed fusion
- PPI – TCL < 30 msec
- S-QRS interval = local electrogram to QRS interval (± 20 msec)

ECG, Electrocardiogram; PPI, postpacing interval; S, stimulus; TCL, tachycardia cycle length; VT, ventricular tachycardia.

Entrainment With Concealed Fusion

Entrainment with concealed fusion (sometimes also referred to as “concealed entrainment” or “exact entrainment”) is defined as entrainment with orthodromic capture and a QRS complex on all 12 surface ECG leads identical to that of the VT, and it suggests that the pacing site is within, attached to, or at the entrance to a protected isthmus that forms the diastolic pathway of the circuit (see Figs. 22.16 and 22.21). However, the positive predictive value of entrainment with concealed fusion in identifying effective ablation sites is only 50% to 60%, indicating that entrainment with concealed fusion can often occur at sites that are not critical to the maintenance of reentry (i.e., bystander pathways), such as a blind alley, alternate pathway, or nondominant inner loop. Even when such sites are believed to reside within the reentrant circuit isthmus, ablation can fail if lesions are too small to interrupt the circuit completely. Other mapping criteria can be helpful in increasing the probability of identifying an effective site for ablation of VT in combination with entrainment with concealed fusion (Table 22.3).

1. PPI equal to the TCL (± 30 milliseconds)
2. Electrogram-QRS interval is equal to the S-QRS interval (this criterion improves the positive predictive value for successful ablation to approximately 80%).
3. Ratio of the S-QRS interval to the TCL less than 70% (this criterion improves the positive predictive value for successful ablation to approximately 70%).
4. An isolated mid-diastolic potential that cannot be dissociated from VT (this criterion increases the positive predictive value for identifying an effective ablation site to approximately 90%).

Postpacing Interval

The PPI is the interval from the last pacing stimulus that entrained the tachycardia to the next recorded local electrogram at the pacing site (see Fig. 22.16). The PPI remains relatively stable when entrainment of VT is performed at the same site, regardless of the length of the pacing drive. This is in contrast to overdrive suppression seen in automatic arrhythmias, which would be associated with progressive delay of the first tachycardia beat return cycle with progressively longer overdrive pacing drives.

Assessment of the PPI helps differentiate early presystolic electrical activity from late diastolic activity, which can be unrelated to the tachycardia circuit (see Fig. 22.21). During entrainment from sites within

TABLE 22.3 Sensitivity, Specificity, and Predictive Values of Analyzed Mapping Criteria in Association With Concealed Entrainment for Effective Ablation Sites

Mapping Criterion	Sensitivity (%)	Specificity (%)	Positive Predictive Value (%)	Negative Predictive Value (%)
Concealed entrainment	—	—	54	—
IMDP

Fig. 22.20 An Algorithmic Approach to Entrainment in Ventricular Tachycardia. The accompanying illustration is a schematic representation of a macroreentrant ventricular tachycardia circuit, showing a common diastolic pathway (critical isthmus), entrance and exit sites, inner and outer loops, and bystander dead-end paths in three locations. *EGM*, Electrogram; *PPI*, postpacing interval; *S*, stimulus; *TCL*, tachycardia cycle length.

the reentrant circuit, the orthodromic wavefront from the last stimulus propagates through the reentry circuit and returns to the pacing site following the same path as the circulating reentry wavefront. The conduction time required is the revolution time through the circuit. Thus the PPI, measured from the pacing site recording, should be equal (± 30 milliseconds) to the TCL. At sites distant from the circuit, stimulated wavefronts propagate to the circuit, then through the circuit, and finally back to the pacing site. Thus the PPI should be equal to the TCL (representing one complete revolution through the reentry circuit) plus the time required for the stimulus to propagate from the pacing site to the

tachycardia circuit and back (see Fig. 22.20). The greater the difference between the PPI and the TCL, the longer the conduction time and distance between the pacing site and the reentry circuit. The PPI – TCL value is highly reproducible during repeated entrainment attempts at the same PCL.^{72,93}

The PPI should be measured to the near-field potential that indicates depolarization of tissue at the pacing site (see Figs. 22.16 and 22.21). Far-field potentials (caused by depolarization of adjacent myocardium) are common during mapping of infarct-related VT and can confound interpretation of the PPI. Measurement of the PPI to a far-field potential

Fig. 22.21 Entrainment During Post-Myocardial Infarction Ventricular Tachycardia (VT) From the Critical Isthmus. The mid-diastolic potential (arrow) is present at the pacing site. Dashed lines denote QRS onset. Each stimulated complex is identical to that of VT at right (entrainment with concealed fusion). This, and findings that the stimulus-QRS (S-QRS) interval with pacing equals the electrogram-QRS (EGM-QRS) interval in VT and that the PPI equals the TCL, indicates that pacing is from the protected diastolic corridor. Radio-frequency delivery at this site terminated VT in 4 seconds. Abl_{dist}, distal ablation site; Abl_{prox}, proximal ablation site; CL, cycle length; His_{dist}, distal His bundle; PCL, pacing cycle length; PPI, postpacing interval; RVA, right ventricular apex.

introduces an error, the magnitude of which is related to the conduction time between the pacing site and the source of the far-field potential (Fig. 22.22). When the PPI appears to be shorter than the TCL, the potential used for measurement is likely a far-field potential. Analysis of the potentials recorded during entrainment often allows identification of the far-field potential so that it can be excluded from activation maps and the PPI measurement and, hence, improves the accuracy of mapping scar-related arrhythmias. The stimulus artifact obscures the potential produced in the tissue immediately at the stimulation site (i.e., near-field potentials). Thus the local potential is not visible during pacing, but reappears after the last entrained QRS complex. On the other hand, far-field potentials usually fall sufficiently late after the pacing stimulus to be visible, and remain undisturbed during entrainment (see Fig. 22.22). These far-field potentials are accelerated to the pacing rate, but are not changed in morphology compared with those observed during tachycardia. The far-field potentials often precede the next stimulus by a short interval so that the tissue generating the far-field potential is probably refractory at the time of the next stimulus. Hence, the stimulus is not directly depolarizing the tissue generating the far-field potential. That these potentials are distant from the distal recording electrode is further supported by the lack of effect of RF ablation on the far-field potential.^{69,94,95}

The validity of the difference between the PPI and TCL (PPI – TCL) is based on the assumption that the recorded electrogram represents depolarization at the pacing site. Ideally, electrograms are recorded from the mapping catheter electrodes used for stimulation, but this is

sometimes difficult. Electrical noise introduced during pacing can obscure the electrograms at the stimulating electrodes, and some recording systems do not allow recording from the pacing site. When the electrograms from the pacing site are not discernible because of stimulus artifact, relating the timing of the near-field potential to a consistent intracardiac electrogram or surface ECG wave can be used to determine the PPI. A reasonable alternative is to calculate the PPI from electrograms recorded by electrodes adjacent to those used for pacing (i.e., from the proximal electrodes of the mapping catheter), provided such electrograms are also present in the distal electrode recordings (eFig. 22.12). However, this does introduce potential error, particularly if low-amplitude local electrograms present at the pacing site are absent at the proximal recording site. A more accurate alternative is assessment of the (PPI – TCL) value from the conduction time between the last pacing stimulus that entrains tachycardia and the second beat after the stimulus (the N + 1 beat) by comparing this interval with the electrogram timing at the pacing site in any following beat (Fig. 22.23). Additional errors can also be introduced by the decremental conduction properties of the zone of slow conduction that might cause a rate-dependent lengthening of the PPI.^{94,95}

Electrogram-to-QRS Interval Versus Stimulus-to-QRS Interval

This criterion is helpful in differentiating a critical component of the zone of slow conduction from a blind alley or noncritical alternate (bystander) pathway, in a manner analogous to that of the (PPI – TCL) method (see Fig. 5.16). During entrainment with concealed fusion, an

eFig. 22.12 Using the Proximal Electrogram Recording as a Surrogate for the Distal Electrogram. Entrainment of ventricular tachycardia (VT) is shown. The postpacing interval cannot be directly assessed owing to saturation of the distal ablation electrode (*Abl_{dist}*) recording (*blue arrow*). The interval from the proximal ablation electrode (*Abl_{prox}*) recording electrogram to QRS can be compared with the same interval during VT (*red arrows*) to serve as a surrogate for the distal ablation recording electrogram, as long as there is minimal disparity in the timing of these two recordings. *EGM*, electrogram; *His_{dist}*, distal His bundle; *RVA*, right ventricular apex.

Fig. 22.22 Entrainment During Postmyocardial Infarction Ventricular Tachycardia (VT) at a Site With Both Systolic and Late Diastolic (Arrows) Potentials. Stimulation (S) entrains VT with an identical QRS configuration (concealed fusion) and a very long S-QRS interval, suggesting pacing at the entrance of the protected isthmus. The sharp electrogram (arrows) at this site is present and accelerated to the PCL, suggesting that the tissue generating this potential is not directly depolarized by the pacing stimulus and is, therefore, a far-field potential. The PPI measured from the last stimulus to this far-field potential is falsely short. The local potential (red arrow) is not discernible during pacing, consistent with direct capture, but reappears after the last stimulus. The true PPI is measured from the last stimulus to this local potential. *Abl_{dist}*, Distal ablation site; *Abl_{prox}*, proximal ablation site; *CL*, cycle length; *EGM*, electrogram; *His_{prox}*, proximal His bundle; *PCL*, pacing cycle length; *PPI*, postpacing interval; *RVA*, right ventricular apex.

electrogram-QRS interval equal to the S-QRS interval (± 20 milliseconds) suggests that the pacing site lies within the reentry circuit and not in a dead-end bystander pathway attached to the circuit (see Figs. 22.21 and 22.22).

During entrainment of reentrant tachycardia, the interval between the pacing stimulus and the onset of the QRS complex reflects the conduction time from the pacing site to the exit of the reentrant circuit (S-QRS interval), regardless of whether the pacing site is inside or outside the reentrant circuit. This is because activation starts at the pacing site and propagates in sequence to the circuit exit site. Pacing from the outer loop and remote bystander sites generates very short stimulus-exit intervals because the myocardium outside the circuit is directly activated by the pacing stimulus. In contrast, pacing from protected sites, such as the diastolic pathway (isthmus) of the reentry circuit or attached bystander or inner loop sites (communicating with the isthmus of the circuit and sharing the same exit), produces longer S-QRS intervals that reflect the conduction time from the pacing site through the protected pathway to the exit site of the circuit.

On the other hand, during tachycardia, the interval between the local electrogram at a given mapping site and circuit exit site (electrogram-QRS interval) can reflect the true conduction time between those two sites if they are activated in sequence (as occurs when the mapping site is located directly within the reentrant pathway), or it can be shorter than the true conduction time if those two sites are activated in parallel (which occurs when the mapping site is located outside the reentrant circuit).^{69,72} Consequently, when mapping along the diastolic pathway of the reentry circuit, the electrogram-QRS interval becomes progressively shorter as the mapping catheter is sequentially moved from the entrance toward the central isthmus and then the exit site of the circuit. Electrograms from the isthmus are generally fractionated and low amplitude, and occur during diastole resulting in early- (entrance), mid- (central), and late- (exit) diastolic (or presystolic) potentials. In

contrast, mapping sites located at bystander sites attached to the isthmus of the circuit are activated in parallel with the exit site, resulting in a shortened electrogram-QRS interval (i.e., a “pseudo-interval” that does not represent a true conduction time between the two locations).

Because a diastolic electrogram is not specific for the isthmus and can be recorded from bystander sites, comparing the S-QRS interval during entrainment to the electrogram-QRS interval (measured at the pacing site) during tachycardia can help distinguish the isthmus sites from attached bystander and inner loop sites. At isthmus sites, activation from those sites to the exit of the circuit follow the same pathway during both tachycardia and entrainment. In contrast, attached bystander and inner loop sites are activated in parallel with the exit site during tachycardia but in sequence during entrainment, resulting in a significantly shorter (more than 20 milliseconds) electrogram-QRS interval than S-QRS interval. On the other hand, at any given pacing site, an electrogram-QRS interval that is equal (± 20 milliseconds) to the S-QRS interval indicates that the pacing site lies within the reentry circuit and excludes the possibility that the site is a dead-end pathway attached to the circuit (i.e., not a bystander).

This method requires that the stimulated orthodromic wavefronts exit from the circuit at the same site as the tachycardia wavefronts (i.e., presence of entrainment with concealed fusion). Any degree of QRS fusion indicates that the stimulated wavefronts could be exiting from another route, invalidating this analysis. However, QRS fusion is often difficult to detect when less than 22% of the QRS is fused, which poses a major limitation to the S-QRS method.⁷¹ To avoid this limitation, a modification of the S-QRS interval method has been proposed whereby the S-QRS interval is measured to the second beat, which unquestionably results from a wavefront that has emerged from the tachycardia circuit and is not fused. The QRS complex and electrogram inscribed during or immediately after the pacing stimulus are defined as QRS(N) and electrogram(N), respectively; the following QRS and electrogram

Fig. 22.23 The $N + 1$ Rule. Entrainment of ventricular tachycardia (VT) is shown. The postpacing interval cannot be directly assessed because of saturation of the distal ablation electrode (Abl_{dist}) recording. The interval from stimulus (S) to the next VT complex ($N + 1$) can be compared with the interval from the electrogram after it is again visible, to a subsequent VT complex ($N + 3$ in this case). If the difference between these intervals is less than 20 milliseconds, the site of stimulation is likely in the circuit. Abl_{prox} , Proximal ablation site; EGM, electrogram; His_{dist} , distal His bundle; RVA , right ventricular apex.

are defined as $QRS(N+1)$ and $electrogram(N+1)$, respectively. The $S-QRS(N+1)$ interval and $electrogram(N+1)-QRS(N+2)$ interval are then determined; the difference between these two intervals is defined as the $N+1$ difference. Because the $S-QRS(N+1)$ interval is not influenced by QRS fusion during entrainment, an endocardial electrogram that is remote from the pacing site can potentially be used as the timing reference, instead of the QRS onset. Often, the endocardial recording is more precise and easily used for the fiducial point.

The $S-QRS$ criterion increases the positive predictive value of successful ablation outcome at sites demonstrating entrainment with concealed fusion to 80% (see Table 22.3). However, the electrogram-QRS interval may not be equal to the $S-QRS$ interval at sites within the reentrant circuit. Several factors can explain this. Decremental conduction properties of the zone of slow conduction can potentially lengthen the $S-QRS$ interval during pacing, and stimulus latency in an area of diseased tissue can also account for a delay in the $S-QRS$ interval compared with the electrogram-QRS interval. In addition, failure of the

recording electrodes to detect low-amplitude depolarizations at the pacing site can account for a mismatch of the $S-QRS$ and electrogram-QRS intervals (Fig. 22.24).⁷²

Ratio of Stimulus-to-QRS Interval to Tachycardia Cycle Length

Some investigators have proposed that critical areas of slow conduction within the reentrant circuit could be identified by overdrive pacing from LV sites associated with prolonged conduction times from the pacing site to the exit from the infarct scar, as reflected by the $S-QRS$ interval. Although sites requisite for the reentrant circuit that exhibit slow conduction can behave in this manner, the mere presence of prolonged conduction from the $S-QRS$ interval does not prove that the slow conduction is part of a reentrant circuit pathway. Multiple areas within the infarct zone can exhibit fractionated or abnormal electrograms and reduced excitability, which are associated with increased $S-QRS$ intervals, yet may have nothing to do with the VT circuit itself.

Fig. 22.24 Pacing Capture During Inferobasal Postinfarct Ventricular Tachycardia (VT) Without Recorded Electrogram. At left is VT during which the distal ablation electrode (Abl_{dist}) recording shows no clear diastolic activity; however, stimulation at this site readily captures the ventricle. The red arrow shows the timing during VT equal to the stimulus-QRS interval during pacing. A, Atrial recording; Abl_{prox} , proximal ablation site; RVA, right ventricular apex.

Other investigators have used a prolonged stimulus-to-local electrogram time during entrainment to identify pathways containing slow conduction. This again does not prove that the electrogram at the recording site has anything to do with the VT because slow conduction involved in the orthodromic capture of this electrogram can occur inside or outside the circuit. In fact, whenever ECG fusion occurs, some electrograms outside the circuit (i.e., those activated after leaving the exit that is part of the VT wavefront) will be orthodromically activated and will fulfill the requirements for entrainment. For the same reason, termination with block before this orthodromically entrained electrogram does not mean that it was a critical component of the circuit.

On the other hand, during entrainment with concealed fusion, the S-QRS interval is an approximate indication of the location of the pacing site relative to the reentry circuit exit. A short S-QRS interval (less than 30% of the TCL) suggests a site near the exit. Long S-QRS intervals (greater than 70% of the TCL) suggest bystander sites rather than a critical isthmus. Therefore, at sites demonstrating entrainment with concealed fusion, an S-QRS interval-to-TCL ratio of 70% or less suggests that the sites lie within the common pathway (isthmus) of the reentrant circuit, and sites at which the ratio is more than 70% are considered to lie outside the common pathway (see Fig. 22.20). This criterion improves the positive predictive value of entrainment with concealed fusion to approximately 70%. Moreover, the negative predictive value of this criterion is 92%, indicating that ablation at sites with entrainment with concealed fusion at which the S-QRS interval-to-TCL ratio is more than 70% is unlikely to be successful (see Table 22.3).

Limitations of Entrainment Mapping

There are several limitations to the entrainment mapping technique. Entrainment requires the presence of sustained, hemodynamically well-

tolerated tachycardia of stable morphology and TCL. Furthermore, overdrive pacing can result in termination, acceleration, or transformation of the index tachycardia into a different one, making further mapping challenging. In addition, pacing and recording from the same area is required for entrainment mapping. This is usually satisfied by pacing from electrodes 1 and 3 and recording from electrodes 2 and 4 of the mapping catheter. However, this technique has its own limitations. Differences, albeit slight, exist in the area from which electrodes 2 and 4 record as compared with electrodes 1 and 3, as do differences in the relationship of the site of stimulation from poles 1 and 3 to the recorded electrogram from poles 2 and 4 (i.e., proximal or distal to the recording site). Also, the total area affected by the pacing stimulus can exceed the local area, especially when high currents (more than 10 mA) are required for stimulation, in addition to the fact that the pacing artifact can obscure the early part of the captured local electrogram.⁹⁴

Pace Mapping

In the setting of post-MI VT, pace mapping serves only as a corroborative method of localizing the VT circuit. It can be used to identify the presumptive exit or isthmus region of the VT circuit, but is not sufficiently specific or sensitive to be the sole guide for ablation. Pace mapping can also be used in conjunction with substrate mapping when other mapping techniques are not feasible, so that it can provide information on where ablation can be directed.⁹⁶

Technique of Pace Mapping

Pace mapping in NSR after VT termination is attempted at potential isthmus sites (as identified by activation and entrainment mapping during VT). Either bipolar or unipolar pacing can be used; however, pace mapping is preferably performed with unipolar stimuli (10 mA,

2 milliseconds) from the distal electrode of the mapping catheter (cathode) and an electrode in the inferior vena cava (IVC; anode). Although bipolar pacing produces a smaller stimulus artifact, there is the possibility of capture at the proximal ring electrode and at the tip electrode, which may reduce accuracy, particularly if larger interelectrode distances (8 to 10 mm) and high-current strength are used (Fig. 22.25). Pacing only slightly above the threshold is likely to improve accuracy. The PCL is usually in the range of 500 to 700 milliseconds, which is faster than the sinus rate and slower than the rate of the induced VTs.

The resulting 12-lead ECG morphology is compared with that of the VT. ECG recordings should be reviewed at the same gain and filter settings and at a paper-sweep speed of 100 mm/s. It is often helpful to have a split-screen display of the target VT in one panel, and to compare this with all 12 leads of the paced QRS complexes in another panel,

Fig. 22.25 Effect of Bipolar and High-Output Stimulation on the Paced QRS Complex Morphology in Scarred Myocardium. The diagram illustrates a catheter stimulating a site within scar tissue on the left ventricular (LV) anterior septum. (A) With low-output unipolar pacing, a relatively small zone is captured (*blue halo*) resulting in a long stimulus (S)-QRS interval because the impulse must travel through scar until it encounters enough tissue to generate a QRS complex. (B) Bipolar or higher-output unipolar pacing captures a larger area, resulting in a shorter S-QRS but using the same path, resulting in the same QRS morphology as at lower output unipolar pacing. (C) High-output bipolar pacing captures a much larger area and can now activate normal myocardium directly, bypassing the slow conduction zone in scar tissue. This results in a very short S-QRS and a very different QRS complex morphology than previously, despite pacing at the same site.

and with regular printed 12-lead ECGs for side-by-side comparison on paper. Also, automated pace map matching is now available in some recording and electroanatomic mapping systems (see Figs. 5.25 and 5.26). The greater the degree of concordance between the morphology during pacing and tachycardia, the closer the catheter is to the exit zone of the VT isthmus (see Fig. 5.24).

Evaluation of the S-QRS is also of value. The S-QRS interval is measured to the onset of the earliest QRS on the 12-lead ECG. Sites from which pace mapping produces the same QRS as that of the initial isthmus site with different S-QRS delays are identified in an attempt to trace the course of the VT isthmus (see Figs. 5.16, 5.23, and 22.20).

QRS Morphology During Pacing Versus Tachycardia

When ventricular activation originates from a point-like source (e.g., during focal VT or during pacing from an electrode catheter), the QRS configuration recorded in the surface ECG is determined by the sequence of ventricular activation, which is largely determined by the initial site of ventricular depolarization. Analysis of specific QRS configurations in multiple leads allows estimation of the pacing site location to within several square centimeters (see Fig. 5.24 and eFig. 5.5). Therefore comparing the paced QRS configuration with that of VT is particularly useful for locating a small arrhythmia focus in a structurally normal heart (e.g., idiopathic RVOT VT).

On the other hand, reentry circuits in healed infarct scars often extend over several square centimeters and can have a variety of configurations. In many circuits, the excitation wavefront circulates through surviving myocytes within the scar, the depolarization of which is not detectable on the standard surface ECG. The QRS complex is then inscribed after the reentry wavefront exits the scar and propagates across the ventricles. Consequently, QRS morphology during pacing in NSR at sites in the vicinity of the VT circuit depends on where the paced wavefront exits the scar region to activate the larger myocardium. A 12-lead QRS morphology during pacing that matches that during VT suggests proximity to the exit or isthmus of the VT reentry circuit (see Fig. 5.23). Pace mapping at sites more proximally located in the isthmus can also produce a similar QRS complex, but with a longer S-QRS interval (due to the delay of conduction of the paced wavefront to the exit site). The S-QRS interval lengthens progressively as the pacing site is moved along the isthmus, consistent with pacing progressively farther from the exit (see Fig. 5.23). Conversely, a poor pace map is typically observed during pace mapping at sites located closer to the entrance zone of the VT isthmus. As noted above, using all 12 ECG leads for comparison of paced versus VT morphologies is critical.

However, it is important to recognize that pace mapping has been less useful for guiding the ablation of post-MI VT. Paced QRS configurations that are different from VT morphology can be observed even when pacing in the vicinity of the VT isthmus, and match paced and VT morphologies can be observed when pacing from bystander sites that are not optimal targets for ablation (see later).⁹⁶

Stimulus-to-QRS Interval During Pace Mapping

Pacing in normal myocardium is associated with an S-QRS interval of less than 40 milliseconds. Longer S-QRS intervals suggest that the pacing site is located within a protected zone, forcing the paced wavefront to propagate slowly within the scar before exiting at remote scar borders to activate the larger myocardium, causing the latency between myocardial capture and the onset of surface QRS. These sites are typically associated with abnormal fractionated electrograms during NSR. In the setting of post-MI VT, it is likely that pacing sites with long S-QRS delays identify slowly conducting channels that traverse dense scar and can potentially form VT isthmuses. However, although such sites often are located *within the vicinity of putative isthmuses of clinical VT*, they

can be part of the reentrant circuit (i.e., critical isthmus) or just a bystander (see Figs. 5.16 and 5.18), and other mapping maneuvers are required for confirming the role of such sites in the clinical VT circuit. Creating a latency map using an electroanatomic mapping system to represent the regions of S-QRS latency graphically can also be a useful method for initially screening sites during NSR (see Fig. 5.23).

Parts of VT reentry circuit isthmuses can be traced during NSR by combining both the QRS morphology and the S-QRS delay during pace mapping in anatomical maps. The reentry circuit exit, which is more likely to be at the border of the infarct and close to the normal myocardium, often has no delay during pace mapping in NSR, even though it can be reasonable to target for ablation. Sites with long S-QRS intervals can be more proximal in the isthmuses; therefore they are more likely to be associated with propagation of the paced wavefront in the antidromic direction away from the reentry circuit, producing a QRS different from that of the VT (see Fig. 5.23). Sites with prolonged S-QRS intervals during pace mapping are frequently associated with other markers of reentry circuit sites; however, this can be a somewhat limited mapping guide. Approximately 25% of likely reentry circuit sites have short S-QRS intervals during pace mapping, and more than 20% of sites with long S-QRS intervals do not appear to be in the reentry circuit.

Limitations of Pace Mapping

In infarct-related VT, pace mapping has significant limitations in its ability to identify the critical isthmus of the VT circuit. A paced QRS configuration different from that during VT does not reliably indicate that the pacing site is distant from the reentry circuit. In fact, it is rather uncommon to have similar or even almost identical morphology result from pacing from a known isthmus determined by mapping.

During VT, the wavefront propagates in one direction (i.e., orthodromically) within the reentry circuit. Similarly, during entrainment of the tachycardia from sites within the critical isthmus, the paced wavefront propagates in the orthodromic direction along the VT isthmus, while collision with the previous tachycardia wavefront prevents its antidromic propagation, resulting in a QRS morphology that is identical to that of the VT. Conversely, during pace mapping in NSR (when there is no preexisting orthodromic wavefront propagating along the VT isthmus), the paced wavefront (even when pacing from the critical

isthmus) can potentially propagate in at least two directions—orthodromic and antidromic (relative to the direction of VT propagation) and, hence, exit the scar region at different sites, resulting in different QRS morphology. This pattern of activation during pace mapping can vary depending on the proximity of the pacing site relative to the entrance and exit sites along the critical isthmus. During pacing at sites closer to the entrance zone, the stimulated antidromic wavefront leaves the protected isthmus at the entrance before the orthodromic wavefront reaches the exit site. As a result, myocardial activation results predominantly from the antidromic wavefront, producing a QRS morphology that is significantly different from that of the VT (see Fig. 5.23). If the orthodromic wavefront reaches the exit, a fusion QRS is produced that includes depolarization from both the antidromic and orthodromic wavefronts.⁹⁶

In addition, the presence of functional block during VT but not during NSR further limits the value of pace mapping. Functional block can be critical in defining a protected channel for conduction that allows reentry. Such block can vary or be absent during NSR when pace mapping is performed and, as a consequence, the paced wavefront (even when pacing from the critical isthmus) may not be forced to follow the same path as that of the VT wavefront (Fig. 22.26). This is further exaggerated by the fact that pace mapping is usually performed at rates slower than the VT to avoid VT induction during the mapping process, which can reduce the likelihood of development of a line of functional block.

Furthermore, the area over which the current is delivered, especially where high current is required for relatively inexcitable tissue, can influence the pattern of subsequent ventricular activation, presumably by capturing more distant (i.e., far-field) tissue. When this occurs, it can indicate pacing in a region of a protected isthmus, where pacing at low output would capture only the isthmus, whereas pacing at a higher output can capture both the isthmus and far-field tissue, resulting in different QRS morphologies and S-QRS intervals (Fig. 22.27).

On the other hand, pacing during NSR from sites attached to the reentrant circuit but not part of the circuit can occasionally produce QRS morphology identical to that of the VT because the stimulated wavefront can be physiologically forced to follow the same route of activation as the VT as long as pacing is carried out between the entrance and exit of the protected isthmus. Although this strategy can result in

Fig. 22.26 Functional Block During Ventricular Tachycardia (VT). At left, VT propagates through a diastolic corridor maintained by lines of block. At center, pacing during VT within the diastolic corridor (asterisk) propagates in the same manner as VT because of maintenance of lines of block. At right, pacing during sinus rhythm at the same site results in a completely different activation pattern and QRS complex if the lines of block during VT were functionally, rather than anatomically, determined. EGM, Intracardiac electrogram; PCL, pacing cycle length.

Fig. 22.27 Effect of Stimulus Strength on QRS Complex and Stimulus (S)-QRS During Pace Mapping. QRS complexes resulting from pacing from the same site, but at different current strength, are shown from higher (left) to lower (right) output. Note the dramatic changes in QRS configuration as well as the progressively longer S-QRS interval. This was easily reproducible; increasing output reversed the electrocardiogram and S-QRS interval findings, and lowering output again recapitulated the data shown here.

the identification of irrelevant inner loop and adjacent bystander sites as well as the desired isthmus sites, it can still be helpful in gross identification of the region of the VT circuit.

At best, a pace map that matches the VT would only identify the exit site to the normal myocardium, which can be distant from the critical sites of the circuit required for ablation. Thus pace mapping remains only a corroborative method of localizing reentrant VT.

Substrate Mapping During Baseline Rhythm

Substrate mapping refers to delineation of the infarcted myocardium and portions of the myocardial scar that likely support the VT reentry circuit (called conducting channels). Conducting channels represent isolated bundles of viable myocardium embedded within areas of dense fibrosis. Conduction through these bundles is typically slow and anisotropic, resulting in low-amplitude, multipotential, fractionated bipolar electrograms. Further, when these bundles form isolated regions deep within confluent scar areas, local activation can become delayed, occurring much later than the surrounding larger myocardium, and resulting in late or isolated near-field potentials recorded after the far-field potential and after the offset of the QRS complex. These channels can potentially form protected diastolic isthmuses necessary to support VT.

Substrate mapping is performed during baseline rhythm (NSR, AF, or ventricular pacing) and aims to identify: (1) abnormal local elec-

trogram amplitude (voltage mapping); (2) electric unexcitability with high-output pacing; (3) abnormal local electrogram configuration (fractionated electrograms, multipotential electrograms, late potentials, or electrograms with isolated delayed components); and (4) local pacing capture with a long S-QRS interval.

Post-MI VTs can be unstable or unsustainable and therefore not approachable by conventional point-by-point activation mapping and entrainment maneuvers. Therefore mapping during the baseline rhythm rather than during VT is of significant value. Substrate mapping also facilitates ablation of multiple and pleomorphic VTs. Even in well-tolerated SMVTs, substrate mapping is also of value, because it can help focus activation and entrainment mapping efforts on a small region harboring the VT substrate and, therefore, minimize the duration during which the patient is actually in VT. In these patients, prolonged periods of sustained VT during the mapping procedure can induce ischemia or exacerbation of heart and renal failure.

Voltage (Scar) Mapping

In post-MI VT, the diastolic pathway (isthmus) of the circuit is typically located within areas of scar, while the circuit exit is often located in the scar border zone. Voltage mapping helps identify the infarct and infarct border zones, which are likely to harbor the tachycardia circuit (see Fig. 22.17).⁵⁴

Bipolar voltage mapping has been correlated with dense scar defined by histopathology and CMR. Electrical scarring is defined by low amplitude of local electrograms and tissue unexcitability during high-output pacing. Although the true range of normal electrogram amplitude is often difficult to define, endocardial ventricular bipolar electrogram amplitude less than 1.5 mV has been accepted as an abnormally low voltage, and a cutoff of 0.5 mV as the signal amplitude that best defines the anatomical region of dense infarct scar. The border zone at the margins of confluent postinfarct scarring tend to have relatively more preserved voltages (in the range from 0.5 to 1.5 mV). The distinction between normal and abnormal bipolar signals in most patients with prior MI tends to be very discrete and dramatic.⁵⁴

A more rigid voltage cutoff criterion is used during epicardial bipolar voltage mapping to limit the influence of epicardial fat and coronary vasculature. Normal epicardial electrogram amplitude is defined as greater than 1.0 mV. As epicardial fat overlying normal myocardium insulates the underlying tissue, attenuated low-amplitude signals can be mistaken for abnormal myocardial tissue. Dense scar is defined as confluent areas with bipolar electrogram amplitude less than 0.5 mV, and border zone in regions with bipolar electrogram amplitude between 0.5 and 1.0 mV. Because epicardial fat can decrease signal amplitude, low-voltage areas during epicardial mapping should also show abnormal electrogram configuration.⁵⁴

Importantly, bipolar recordings have a limited field of view such that the amplitude of the bipolar electrogram is primarily driven by local tissue activity, while far-field activity is subtracted out. Although voltage properties of the endocardium are well represented in the bipolar signal, intramural or epicardial scar that can potentially harbor the arrhythmogenic substrate can be missed by purely endocardial bipolar voltage mapping. In contrast, unipolar electrograms reflect the voltage difference between the exploring electrode in contact with myocardium and a second electrode that is distant from the heart (usually the Wilson central terminal). Thus the unipolar electrode has a wide field of view, and unipolar electrogram amplitude primarily represents more remote, far-field tissue depolarization.⁹⁷ Therefore unipolar voltage mapping has recently been proposed to improve myocardial sensing with a wider field of view to detect the presence of midmyocardial and epicardial scar. A voltage cutoff of 8.3 mV is used to distinguish normal from abnormal LV unipolar endocardial electrogram amplitude.⁵⁴

Pacing provides complementary information to electrogram amplitude; only 2% of sites with amplitude more than 0.5 mV have a pacing threshold more than 10 mA, whereas a substantial number of very low-amplitude sites have high pacing thresholds, and many sites in reentry circuit isthmuses have very low amplitudes. A dense scar is defined by the lack electrical excitability during high-output pacing.

Identification of areas of scar and scar border zones by voltage mapping is frequently not adequate to guide ablation. In patients with post-MI VT, the low-voltage infarct areas are relatively large (average area, 39 ± 35 cm²; range, 6 to 205 cm²), so that complete encirclement with RF ablation lesions is likely to be difficult. Therefore an important goal of substrate mapping is to also identify conducting channels within the infarct region, which are relatively small bundles of viable tissue compared with the scar areas. This helps focus the diagnostic techniques and ablation on defined areas that potentially harbor the VT substrate. Relative voltage preservation within denser regions of scar is a hallmark of central conducting channels that may form anatomically constrained diastolic isthmuses during VT, and adjusting the voltage representation on the isopotential map can help visualize these zones. Analysis of electrogram morphology and pace mapping can help identify potential channels within low-voltage regions.

Technique of voltage mapping. The LV is mapped during baseline rhythm (NSR or ventricular pacing) to construct a color-coded

voltage map displaying peak-to-peak bipolar electrogram amplitude sampled at each site and is measured automatically by the mapping system. The color range is set between 0.5 and 1.5 mV, so that all areas of viable myocardium are given the same color code and the scar can be differentiated further into different zones according to the local voltage.

Higher-density points are obtained around areas of scar, focusing on the scar border and electrograms within the scar. All scar borders need to be clearly defined. During the mapping process, areas of fractionated or late potentials (irrespective of the voltage obtained) are tagged on the electroanatomic map. At low-amplitude (less than 0.5 mV) sites, pacing is performed with 10-mA, 2-millisecond pulse width stimuli. A pacing threshold greater than 10 mA has been used to define unexcitable scar, provided electrode-tissue contact is adequate. In addition, sites with long S-QRS intervals during pacing need to be tagged.⁶⁶

A color-coded voltage map is then created and superimposed on the anatomical model to show the amplitudes of all selected points (eFig. 22.13).⁵⁴ Careful step-by-step manual adjustment of voltage upper and lower limits on the color-coded electroanatomic voltage map (scar thresholding) can help maximize the color contrast between adjacent myocardium with different electrogram voltage levels within the 0.5-mV scar and, thus, unmask channels of viable myocardium within a dense scar. For example, resetting the voltage limits to 0.3 to 0.5 mV as the upper limit and to 0.1 mV as the lower, may be required for the identification of viable myocardium and conducting channels within the scar area (see Figs. 22.17 and 22.28; eFig. 22.14). Conducting channels on the electroanatomic voltage map are identified corridors of voltage preservation (voltage channels) within denser regions of scar or corridors between a dense scar and a valvular annulus.⁶⁶ Recent evidence, however, has questioned the value of this method for identification of conducting channels. This technique likely has limited sensitivity and specificity. In comparison, mapping techniques utilizing electrogram morphology and late potentials are more capable at identifying a higher proportion of conducting channels that serve as the substrate for VTs. This may not be surprising because voltage mapping incorporates the larger far-field signals commonly present at sites recording smaller near-field late potentials.

Abnormal Local Ventricular Electrograms

The vast majority of post-MI VTs occur at sites that have abnormal or late electrograms during NSR (see Fig. 22.18). Infarct regions are well delineated as areas of low-amplitude abnormal electrograms. However, abnormal low-voltage electrograms can be recorded throughout extensive areas of scar that are not sufficiently specific for the components of the reentrant circuit and, hence, cannot be used as the sole guide for ablation. Therefore additional electrogram characteristics have been proposed to improve the accuracy of substrate mapping, including electrogram fractionation and late potentials.⁹⁸

Local abnormal ventricular activity. Conduction through the reentry circuit isthmus or at its entrance or exit is often slow and non-uniformly anisotropic because of the transverse uncoupling of myocytes by fibrosis. Therefore electrogram fractionation (i.e., electrograms with three or more sharp spikes, either separated by very low-amplitude signals or an isoelectric interval) is a common finding in areas of scar and VT substrate. In addition, during NSR, a typical local electrogram in the border of an infarct has a low voltage but is adjacent to more normal myocardium in the border, causing a multipotential electrogram that has markedly different amplitudes, with a large rounded potential (reflecting a far-field signal from activation of the large mass of surrounding tissue) and a small sharp potential (reflecting local depolarization of a small mass of fibers in the infarct). These abnormal electrograms (the so-called local abnormal ventricular activity [LAVA])

eFig. 22.13 Electroanatomic Voltage Map of Scar-Based Ventricular Tachycardia (VT) in a Patient With a Prior Inferior Wall Myocardial Infarction (Posterior View). The scale at right shows bipolar voltage; the red area denotes a very low-voltage (<0.5 mV) infarct zone with a small isthmus of higher voltage between this area and the mitral annulus. Red dots indicate a line of radiofrequency applications to transect this isthmus (additional *red dots* denote ablation at other sites that terminated the VT).

eFig. 22.14 Filtering Voltage Maps to Expose Conduction Channels. Right and left anterior oblique (RAO and LAO, respectively) and left lateral views of endocardial left ventricular voltage maps are shown (higher, normal voltages are *purple*, low voltages *red*; dense scar is *gray*). At top is the “raw,” unfiltered voltage. Successive panels beneath show different bandwidths of filtering as indicated at the top of each panel, revealing possible “channels” of viable tissue coursing with scar areas (*white arrows* in bottom panel). Ablation lines to transect these channels (which would not otherwise be evident) can then be performed.

Fig. 22.28 Voltage Channels. Bipolar voltage map of the left ventricle (modified anterior view) in a patient with ventricular tachycardia and prior anterior wall infarction. (A) Large inferior wall scar is obtained when the cut-off value is set at <0.5 mV (red area), and the border zone is set at 0.5 to 1.5 mV. (B) By modifying the color scale ("voltage scanning" or "scar thresholding"), different areas within the scar can be identified: very-low-voltage areas (<0.3 mV) corresponding to true scar (border zone is set at 0.3 to 0.5 mV) and corridors between them with slightly greater voltage (in green and yellow) constituting voltage channels and potential circuit isthmuses. (C) Further voltage scanning is performed, with red color corresponding to voltages <0.2 mV, and the border zone is set at 0.2 to 0.3 mV.

are common in the infarct region, but can be found throughout the scar and are not specific for the critical isthmus of the reentry circuit.^{89,99}

Late potentials. A bipolar electrogram is defined as "late" if any component is recorded after the end of the QRS complex on the surface ECG. Electrograms with isolated delayed components are defined as electrograms with double or multiple components separated by a very low-amplitude signal or an isoelectric interval of more than 50 milliseconds in duration. These electrograms can reflect local depolarization of surviving muscle bundles that are well insulated by dense scar, where local activation is recorded late, well after the higher-amplitude far-field electrogram and often well after the end of the surface QRS complex or T wave.^{89,99,100}

Late potentials are present in about two-thirds of post-MI patients with larger and more solid scars. Most critical isthmus sites display broad (greater than 200 milliseconds in duration) or isolated diastolic potentials during NSR (see Fig. 22.18). However, although sites with late potentials can be markers of an anatomically constrained, slowly conducting diastolic isthmus during VT and have been used to guide substrate-based ablation strategies, the sensitivity remains modest, likely due to the low amplitude of local signals and the direction of wavefront propagation obscuring isolated potentials. In one report, late potentials

during NSR were absent in 29% of central VT reentrant circuits and in 46% of VT termination sites. Furthermore, isolated potential mapping is limited by the imperfect specificity, and is unable to differentiate the central isthmus from bystander cul-de-sacs or nonspecific slowed conduction.^{100–102}

Nevertheless, this type of electrogram can help refine the area of interest. The areas demonstrating such electrograms are relatively small compared with scar areas; therefore this method permits a focus on the diagnostic techniques and ablation in defined areas. Furthermore, recording of these electrograms before and during VT induction serves to relate them and VT within seconds, provided that the isolated diastolic component of the electrogram precedes the first VT beat and then becomes mid-diastolic. In addition, pacing at these sites may capture the local potential and conduct slowly out of the scar, resulting in a long S-QRS interval and, if sharing an exit of a targeted VT, producing a good or excellent pace map. The ablation of all sites demonstrating electrograms with isolated diastolic components can overcome the lack of specificity of the selection of a single site as an ablation target when entrainment mapping criteria are not fulfilled. Ablation of these electrograms can also eliminate the substrate for different VTs otherwise not ablated by limited, conventional strategies.^{100–102}

During substrate mapping, sites recording abnormal electrograms are tagged on the electroanatomic map. Late potential conducting channels are defined as a path of more than two adjacent late potentials connecting with healthy tissue. Further, studies suggested a sequential activation pattern from the border of the scar through conducting channels. Late potentials are classified as being an entrance or an inner part of a given conducting channel, depending on the local activation time of the near-field component. The entrance of a conducting channel is tagged as sites within the border zone (i.e., voltage zone of 0.5 to 1.5 mV) recording the earliest late potential, that is, late potentials with the shortest delay between the far-field component of healthy/border zone myocardium (low frequency, usually high voltage) and the near-field component (delayed, high frequency, usually fractionated, and low voltage) corresponding to the local activation of myocardial fibers in the scar. Sites with longer delays likely reside farther along the conducting channel within the dense scar. The method involves high-density mapping of channels of activation of late potentials.^{102,103} Multielectrode catheters with small and closely spaced electrodes (PentaRay) or the mini-basket catheter (Orion) offer improved mapping resolution within the low-voltage areas and allow identifying channels of surviving myocardial bundles, otherwise considered dense scar by standard linear catheters.¹⁰⁴

In addition, 3-D electroanatomic late potential maps can be constructed, whereby the *terminal* portion of every local electrogram is manually marked during the mapping procedure (“isochronal late activation maps”). The lower time threshold of the color-coded map is set to the difference between the reference and end of the surface QRS complex. The isochronal late activation maps can be superimposed on voltage maps to further delineate their relationship to scar distribution.¹⁰⁵ Of note, late potentials in the latest isochrone of activation during NSR appear to be mostly bystander sites, and are infrequently correlated with successful ablation sites for VT. On the other hand, slow conduction regions with isochronal crowding propagating into the latest zone of activation were found to be better markers to guide substrate-based VT ablation.⁹⁸

The discrimination between far-field from near-field potentials is critical for substrate mapping approaches. Late potentials typically are of low amplitude and are often obscured by larger far-field electrograms produced by activation of the surrounding larger mass of myocardium outside the infarct region. Verification that a recorded electrogram is far-field rather than near-field can be achieved by pacing at the local site. When the recorded electrogram is near-field, capture of the pacing stimulus results in capturing the tissue generating all components of the electrogram, so that no clear electrogram component is identifiable during pacing. Conversely, when the recorded electrogram is far-field, pacing may not capture (due to dense scar) or, when it captures local tissue, the far-field electrograms remain discernable during pacing (because they reflect activation of myocardium adjacent to the pacing site). Furthermore, changing the direction of depolarization approaching the mapping site (e.g., sinus rhythm vs. RV pacing) and VES (causing decremental conduction) can help unmask some areas of block and slow conduction, expose late potentials, and separate local (near-field) from far-field potentials (Fig. 22.29).⁹⁹

Substrate Image Integration

LV scar and its border zone represent the target of “substrate modification” for VT ablations; therefore an exact anatomical delineation is critical. As noted, the current gold standard of voltage mapping has several limitations. Many of those limitations can be overcome by integrating scar imaging into the VT ablation. Multiple imaging modalities detailing the LV substrate in a 3-D format can be visualized and displayed simultaneously with the electroanatomic 3-D LV voltage map. These imaging approaches can be used to correctly predict abnormal voltage locations in advance of the mapping procedure, which allows the electrophysiologist to concentrate on areas of likely myocardial scar, obviate the need to perform a complete point-by-point voltage mapping, identify falsely low-voltage recordings in areas of normal perfusion due to sub-optimal catheter contact, and reduce procedure time and radiation exposure. In addition, some imaging modalities are able to characterize the transmural extent and intramyocardial location of scar tissue, which

Fig. 22.29 Effect of Direction of Wavefront Propagation on Electrogram (EGM) Configuration. A catheter is recording over an island of scar surrounded by normal tissue. At *left*, a wavefront arriving from the left side is split by the scar, but tissue on each side of the scar is activated at about the same time, resulting in a relatively normal EGM. At *right*, a wavefront arriving from right angles to the prior one is split by the scar, with tissue on the near side activated early and that on the opposite side activated much later, resulting in a markedly split recording.

can potentially help identify intramural and epicardial arrhythmia substrate, overcoming a limitation of endocardial voltage mapping.⁹⁰

PET-CT. Because PET scans alone do not provide the necessary anatomical information required for integration with electroanatomic maps, a CT angiography scan is required to provide an anatomical skeleton onto which the biological information acquired from the PET scan would be superimposed on its precise anatomical location.

Both PET and CT images can be spatially aligned using an automatic registration algorithm. All regions in the PET image with uptake greater than a threshold (50% of maximal uptake) are overlaid at the corresponding location on the CT image. Thus a fused image can be created having accurate anatomical information at the spatial resolution of the original CT with accurate metabolic information for the LV myocardium from the registered PET. The regions in the fused image showing [¹⁸F] fluorodeoxyglucose (FDG) uptake represent nonscarred myocardium, and regions with no uptake indicate scarred myocardium. Myocardial scar is displayed as an area of absent voxels (“hole in the wall”) within the reconstructed LV wall to indicate scar location and size. The use of PET 3-D reconstructions at multiple metabolic thresholds allows the characterization of the scar border zone and simultaneous 3-D display of myocardial scar and border zone embedded in the LV anatomy as well as the display of detailed scar anatomy, which can be targeted during the VT ablation.

The fused “anatomical-metabolic” PET-CT image is imported into the electroanatomic mapping system. To merge the PET-CT image, landmark points at the coronary ostia, coronary cusps, LV apex, coronary sinus (CS), and mitral annulus are usually acquired (guided by ICE; see later). The corresponding points are matched on the fused PET-CT image. Once the 3-D voltage map is created, surface registration is performed. Alternatively, multiple points can be acquired at different planes of the aorta as the catheter is dragged along the descending aorta, arch, and ascending aorta. Using an automated program available in the mapping system, the electroanatomic map and the fused PET-CT image are then aligned. After primary registration, the registered model is refined using a second set of fiducial points placed in stepwise fashion to further align both surfaces at sites of local mismatch.⁷⁸

CMR. The spatial resolution of PET/CT imaging is limited to 4 to 6 mm, which does not allow for determination of complex scar anatomy and mural location. Epicardial scar can have a low PET signal, but normal endocardial voltage. In contrast, delayed-enhancement CMR imaging provides excellent detail and is quickly becoming the gold standard for scar determination and is currently the only modality that can assess the transmural extent of the infarct (i.e., can determine whether the scar is endocardial, intramyocardial, or epicardial).⁷⁷ The CMR image can be merged with the 3-D electroanatomic voltage map employing landmark and surface registration (as discussed previously).

Contrast-enhanced CT. Cardiac contrast-enhanced CT scanning enables a comprehensive three-modality characterization (anatomical, dynamic, and perfusion) of LV scar from a single contrast-enhanced CT with high spatial (≤ 1 mm) and temporal resolution. Areas of CT hypoperfusion correlate best with areas of abnormal voltage (less than 1.5 mV) rather than scar alone (less than 0.5 mV). Perfusion imaging from CT can indicate scar transmural extent and intramyocardial scar location. The 3-D CT scan can be integrated into clinical mapping systems to guide VT ablation. Primary registration is performed with landmark points and visual alignments, as previously discussed.

Intracardiac ultrasound. Although preacquired CMR, PET, and CT images have been used to define LV scar and guide mapping and ablation in post-MI VT, registration is often difficult and can be imprecise. In addition, images obtained on different days can confound registration if LV geometry changes because of loading conditions.

Real-time ICE images can provide accurate chamber geometries and scar boundaries of the LV. Scar zones (identified on endocardial voltage maps) were found to have increased tissue echogenicity on ICE compared to myocardial areas without scar in ischemic and nonischemic patients. Border zones were found to have more heterogeneous signal intensities than normal myocardium.⁷⁶ Also, ICE provides both an anatomical and a functional assessment of the LV, allowing for real-time identification of wall motion abnormalities. Unlike PET/CT and CMR imaging, ICE imaging does not require potentially toxic contrast agents, nor does it expose the patient to ionizing radiation.

In addition, ICE can be used to guide catheter navigation. Real-time monitoring of the endocardial-catheter interface helps direct the catheter to the important anatomical structures that can be critical to the VT circuit, such as crypts and trabeculations, which may otherwise be missed. ICE can also be used as a facilitator of CT/MR image integration.

The CARTOSound image integration module (Biosense Webster) incorporates the electroanatomic map into a map derived from ICE and allows for 3-D reconstruction of the LV from real-time 2-D ICE images, facilitating interventional navigation within the LV. ICE imaging is performed using a phased-array transducer-catheter incorporating a navigation sensor (SoundStar; Biosense Webster), which records individual 90-degree sector image planes of the cardiac chamber of interest, including their location and orientation, to the CARTO workspace. A 3-D volume rendered image is created by obtaining ECG-gated ICE images of the endocardial surface of the LV.⁷⁶

To create the CARTOSound volume map of the LV, the ICE catheter is manipulated in the RA, RV, and RVOT to visualize all parts of the LV. The left ventricular outflow tract (LVOT), the aortic root, and the mitral valve are mapped with the probe positioned in the RA, whereas the body of the LV is mapped with the probe positioned in the RV, against the interventricular septum. The latter position provides a longitudinal view of the LV cavity. Lateral tilt allows base-to-apex scanning through the body of the LV with deeper insertion, withdrawal, or rotation of the probe used as necessary to complete the map. Short-axis cross-sectional views of the LV can be obtained with the ICE probe positioned in the RVOT. Images are acquired in end expiration and gated to the R wave or the pacing spike. Ultrasound imaging in which the wall segment is well visualized can reliably identify scar both by wall thickness and motion, a process that does not require wall contact. Akinetic and thinned wall segments are marked in a separate volume and labeled as scar on the ultrasound volume map. Normal or hypokinetic segments are labeled as nonscar. Separate geometries (scar and nonscar) are made of the LV and each of the papillary muscles. Once the ultrasound map is completed, a distinct CARTO voltage map is created (as described previously).

Limitation of Substrate Mapping

Voltage mapping relies heavily on consistent catheter contact. If catheter contact is suboptimal and falsely low voltage measurements are recorded, the voltage map will erroneously suggest a scar. The use of ICE and contact force catheters can help ensure adequate catheter contact. In addition, low mapping density is associated with significant interpolation of data between sampled points. The use of multielectrode catheters enables rapid high-density voltage mapping through simultaneous multiple-point acquisition, which reduces interpolation of data between points and improves mapping accuracy.¹⁰⁶

It is also important to note that, although an electrogram amplitude of 0.5 mV has been used to identify electrical scars, a minimal amplitude that distinguishes excitable tissue from unexcitable scar has not been established. Because different catheters with various electrode sizes and interelectrode spacings are becoming available, individualized validation

is required, and catheter-specific thresholds are needed to improve scar characterization.

Electrogram amplitude is annotated to the electrogram peak. In regions of scar, far-field signals are frequently of larger amplitude than local electrograms. Voltage annotation of the larger far-field electrograms can introduce errors in the voltage map. Manual tagging of abnormal potentials or manual annotation of near-field electrogram voltage can help improve the map accuracy, but this can be challenging with high-density point acquisition.

Bipolar electrogram amplitude is influenced by multiple variables that can affect the accuracy and resolution of the voltage map, including mapping electrode size, interelectrode distance, conduction velocity between the bipolar electrodes, vector of activation, the angle at which the electrode engages the tissue, and signal filtering. The spatial resolution of the standard mapping catheter is limited due to the large electrode surface area and wide interelectrode spacing. Although voltage mapping likely identifies large unexcitable areas of scar, small strands of fibrosis, which may still create important conduction block, may escape detection amid the background of high-amplitude far-field signals. Similarly, small strands of surviving myocardium within an area of dense scar may not be detected during voltage mapping. Mapping catheters with smaller electrodes and shorter interelectrode spacing (e.g., PentaRay, Orion) record signals from smaller tissue mass and are subjected to less signal averaging and cancellation effects, and minimal far-field signals and background noise. As a result, data acquisition with smaller electrodes allows for accurate detection of very small amplitude signals and improves the resolution of the voltage map. This can be of particular advantage in the low-voltage zones and areas of heterogeneous scar distribution.^{106–108}

The vector of propagation of the activation wavefront in relation to the two recording electrodes, and orientation of the recording electrode relative to the tissue influences the degree of signal cancellation and therefore the resultant bipolar signal amplitude. Therefore voltage mapping during more than one activation sequence (e.g., during NSR and ventricular pacing) can potentially increase the sensitivity to detect arrhythmogenic substrate. Dense scar appears to be less sensitive to wavefront changes compared with mixed scars, likely due to lesser available mass of normal far-field myocardium to contribute to the electrogram signal within the field of view of the mapping catheter.¹⁰⁹

Even when conducting channels within the scar area can be identified by substrate mapping, their functional contribution to the VT circuit remains to be assessed by other mapping methods (e.g., entrainment mapping). Substrate mapping does not distinguish abnormal bystander areas that are not involved in a VT circuit from clinically relevant channels. In one report, only 30% of “channels” identified with electroanatomic mapping contained a clinical VT isthmus, and only 44% of mappable VTs were associated with any identifiable channel. The presence of isolated late potentials within a channel, however, increases the likelihood that the channel will be important for maintaining VT.¹¹⁰

Furthermore, substrate mapping during NSR depends on the assumption that the arrhythmogenic substrate responsible for the reentry circuit is limited to fixed myocardial scar and anatomical barriers. It is now well known that functional lines of block (present during VT but not in NSR) play an important role in arrhythmogenesis, and these barriers cannot be detected by substrate mapping performed in NSR. Therefore the correlation between channels developing during arrhythmias and surrogates of channels identified by substrate mapping in NSR may not correspond.¹⁰

It is also important to recognize that the transmural distribution of the scar may not be reliably represented by voltage mapping from

either the endocardial or epicardial surface. In particular, identifying septal or midmyocardial substrates can be challenging.⁵⁴

Noncontact Mapping

When VT is short-lived, hemodynamically unstable, or cannot be reproducibly initiated, simultaneous multisite data acquisition using a noncontact mapping system (EnSite 3000; St. Jude Medical) can help localize the VT site of origin. The system has been shown to reliably identify presystolic endocardial activation sites (potential exits) for reentrant VTs and thus starting points for conventional mapping. It can also potentially help identify VT isthmuses and guide ablation.

The noncontact mapping system records electrical potentials from a multielectrode array (MEA) surrounding a 7.5-mL balloon within the LV cavity. Electrical potentials at the LV endocardial surface some distance away are calculated. Sites of mid-diastolic endocardial activity, which are likely adjacent to reentry circuit exits, are usually identifiable; in some cases, isthmuses can be identified (eFig. 22.15).

Voltages are displayed as a colored isopotential map on the virtual endocardium. The color scale is adjusted to create a binary display, with negative unipolar potentials in white on a purple background, producing a unipolar activation map. Diastolic depolarization is defined as activity on the isopotential map that can be continuously tracked back in time from VT exit sites, and is defined on the map as synchronous with the QRS onset. Diastolic activity and exit sites are then marked on the virtual endocardium, and the mapping catheter is navigated to them by the locator.

The noncontact mapping technology also enables substrate mapping based on scar or diseased tissue, which can be particularly helpful when the VT is not inducible during the procedure. Dynamic substrate mapping allows the creation of voltage maps from a single cardiac cycle and provides the ability to identify low-voltage areas, as well as fixed and functional block, on the virtual endocardium through noncontact methodology. The dynamic substrate mapping algorithm allows the creation of unipolar noncontact voltage maps from a single cardiac cycle, defined as the percentages of the maximal voltage recorded in the entire chamber. Until further studies define the correct dynamic substrate mapping percentage that can be compared with the scar and scar border zone defined by contact mapping, areas having values less than 50% may be defined as “abnormal myocardium.”

Technique of Noncontact Mapping

The EnSite 3000 system requires a 9 Fr MEA and a 7 Fr conventional (roving) deflectable mapping-ablation catheter. A standard ablation catheter is placed in the LV by a retrograde transaortic route. Using a separate arterial access site, the MEA catheter is advanced to the LV apex over a 0.032-inch J-tipped guidewire. Fluoroscopy is used to assess the correct position of the balloon catheter, placed parallel to the long axis and with the pigtail end as close as possible to the LV apex. The guidewire is then withdrawn and the balloon inflated with a contrast-saline mixture. The balloon is positioned in the center of the LV and does not come in contact with the LV wall. Care is taken to have a distance between the MEA catheter and the region of interest less than 40 mm; if necessary the catheter can be repositioned.

Construction of the virtual endocardium model is preliminarily obtained during sinus rhythm by moving the ablation catheter along the LV endocardial surface to collect a series of geometric points during NSR or VT. Using this geometric information, the computer creates a model of the LV. After the LV geometry is reconstructed, 5 seconds of NSR is recorded by the system, and the substrate map is superimposed on the anatomy. High-pass filters are adjusted at the lowest value that minimizes the shift of the isoelectric baseline to avoid confusing depolarization with repolarization.

eFig. 22.15 Use of Multipolar Electrode Array for Ventricular Tachycardia (VT) Mapping. Maps from the EnSite system are shown in a patient with inferior wall infarction. At left is a snapshot of the activation wavefront projected on the endocardial surface (*white* = activation). At right is the same instant of activation in a cutaway view, showing the wireframe of the endocardial balloon-based electrode array. At bottom right are contact and virtual electrograms from the array during VT; the wavefront propagates from left to right, along the mitral annulus (*curved blue arrow*).

Subsequently, VT is induced by programmed stimulation and mapping of the arrhythmia can begin. A 5- to 10-second segment of any induced VT is recorded with the noncontact system and the VT may then be terminated by overdrive pacing or electrical shock. The data acquisition process is performed automatically by the system, and all data for the entire LV are acquired simultaneously.

VT circuit exit points and potential ablation targets can be identified as sites where a QS unipolar electrogram morphology is recorded, which, on the color-coded isopotential map, corresponded to the site of earliest activation followed by a rapid activation wavefront. Projection of the virtual endocardial electrograms over this area is performed at different high-pass filter settings (1, 2, 4, 8, 16, and 32 Hz) to avoid misinterpretation with repolarization waveforms. This region is searched starting from the abnormal myocardium defined by dynamic substrate mapping and is considered a good target site for ablation when confirmed by EP criteria (contact activation mapping, entrainment mapping, and/or pace mapping).

The locator technology is used to guide the ablation catheter to the proper location in the heart. The system allows the operator to create linear ablation lesions that transect critical regions and then return precisely to areas of interest, visualizing lines of ablation as they are being created and performing the ablation during NSR.

Limitations of Noncontact Mapping

The most important shortcoming of the noncontact mapping system is the deterioration in the accuracy of noncontact electrograms for distances greater than 40 mm between the MEA catheter and the recording site, which can occur in dilated ventricles. Very low-amplitude signals may not be detected, particularly if the distance between the center of the balloon catheter and endocardial surface exceeds 40 mm, limiting the accurate identification of diastolic signals.

Because the geometry of the cardiac chamber is contoured at the beginning of the study during NSR, changes in chamber size and in contraction pattern during tachycardia can adversely affect the accuracy of the location of the endocardial electrograms. In addition, detection and display of activation from two adjacent structures, such as the papillary muscle and subjacent myocardium, is problematic.

Moreover, because isopotential maps are predominantly used, ventricular repolarization must be distinguished from atrial depolarization and diastolic activity. Early diastole can be especially challenging to map during VT. Care has to be taken to confirm that the virtual electrogram is related to local activation and not baseline drift or repolarization.

Because of the potential for thrombus formation, the use of this system requires the maintenance of a greater degree of anticoagulation (ACT >350 seconds) while the mapping balloon is in place than is generally required for the point-by-point mapping techniques. In addition, positioning of the MEA catheter in the LV can be difficult in the setting of atherosclerotic aorta or tortuous peripheral arteries, requiring a transseptal approach. The mapping sheath is 9 Fr in diameter; femoral hematomas and pseudoaneurysms are the most frequently encountered complications.

Mapping Postinfarction Premature Ventricular Complexes

In the majority of post-MI patients with frequent PVCs, the origin of the PVCs is mapped to sites of low voltage corresponding to the infarct location, similar to patients with post-MI VT. In addition, in patients with ischemic cardiomyopathy and VT that matches the PVC morphology, both types of arrhythmias have critical target sites within areas of low voltage, and the site of origin of PVCs often corresponds with the exit site of the VT reentrant circuit. Furthermore, as is the case with

VT, late potentials can be detected during diastole at the site of origin of most of the PVCs. The late potentials follow the ventricular electrogram during sinus rhythm and precede the ventricular electrogram during PVCs. Slight differences in morphology between PVCs and VT may be observed and may be rate related.

Possible mechanisms of PVCs in post-MI patients include reentry, triggered activity, and abnormal automaticity. Because of several features in common with post-MI VT, reentry may play a principal role in post-MI PVCs; however, this has not been confirmed by high-resolution mapping. Nevertheless, in a small percentage of patients, PVCs do not originate from scar tissue. In those patients, the PVCs can be due to triggered activity or abnormal automaticity, similar to idiopathic PVCs.

Because post-MI PVCs and VT often share critical areas, mapping of the PVCs can be used as a surrogate for mapping of the VT. Ablation of frequent PVCs can potentially eliminate VT in these patients. However, the sensitivity and specificity of this approach in an unselected population are not known, nor is the prevalence of PVCs indicating VT exit sites. If this concept is confirmed in larger series, PVC mapping can be used to identify exit sites of PVCs and to search for diastolic potentials prior to PVCs that may indicate areas of slow conduction relevant for the VT. Targeting the PVCs alone may be sufficient to eliminate the VTs that had an exit site near or at the PVC site of origin, obviating the need for induction of VT, which can be of great value in patients with unstable or unmappable VTs. Voltage mapping in these patients can be helpful in focusing the mapping procedure on the low-voltage areas because this area contains the arrhythmogenic substrate in most patients.¹¹¹

Furthermore, in post-MI patients with frequent PVCs, catheter ablation of the PVCs can potentially result in an improvement in the LVEF. It may be appropriate to screen patients with ischemic cardiomyopathy for frequent PVCs with a 24-hour Holter monitor before implanting an ICD for primary prevention of SCD. Ablation of the frequent PVCs may improve the LVEF such that the patient no longer meets the LVEF criterion for an ICD.

In addition, in patients with recurrent polymorphic VT or VF that are triggered by PVCs of consistent QRS morphology, ablation of the arrhythmia trigger (PVCs), rather than the substrate, is often successful in reducing the burden of those arrhythmias.^{1,4,14}

Mapping of Epicardial Circuits

The infarct scar is primarily located in the subendocardium and extends to the epicardium depending on the patient's specific coronary artery distribution. Therefore unlike VT substrates in patients with nonischemic cardiomyopathy, the arrhythmogenic tissue can be accessed from the endocardium in the majority of post-MI patients. Even in the presence of an epicardial substrate, endocardial ablation can often eliminate the overlying epicardial targets through thinned scar, minimizing the need for epicardial ablation.¹¹²

Nonetheless, VT originating from the subepicardium remains an important cause of failure of endocardial ablation approaches. In tertiary centers, epicardial ablation has been required in approximately 10% to 25% of post-MI VTs, and seems to be more common with inferior than anterior wall infarctions.¹¹³ Epicardial access, however, frequently is not feasible for patients who have undergone prior cardiac surgery (which is present in up to 55% of patients undergoing VT ablation).¹¹⁴

Currently, there are no consensus criteria to guide the need and appropriate timing of an epicardial approach in post-MI VT substrate ablation procedures. An epicardial approach is typically perused when extensive endocardial mapping or ablation fails in achieving the desired procedural endpoint. During endocardial mapping of post-MI VT, inability to identify the reentry circuit isthmus on the endocardium can suggest that the isthmus is epicardial or intramural. In these cases,

endocardial activation mapping can demonstrate a focal point of earliest endocardial activation where entrainment indicates a potential exit or outer loop site, but ablation fails to interrupt VT, suggesting that there is an epicardial or intramural circuit with a broad endocardial exit. In addition, endocardial unipolar (rather than bipolar) voltage mapping can predict the presence of and more closely approximate the greater extent of epicardial bipolar signal abnormalities, which can potentially serve as a substrate for VT.

Although various ECG characteristics have traditionally been used to predict whether an epicardial approach may be required based on the VT morphology, the surface ECG alone is not reliably predictive of the need for epicardial access and mapping for any given VT. QRS morphology is related solely to the VT exit site and this does not imply that some other component of the circuit (such as the critical isthmus or entrance site) cannot be ablated from the endocardium, even when an epicardial exit is implied by the ECG characteristics.

On the other hand, infarct transmuralities appear to predict epicardial arrhythmic substrate and the need for the epicardial approach to improve ablation outcome. Transmurality of the myocardial scar can be assessed by preprocedural cardiac imaging techniques (CMR, echocardiography, CT, and single photo emission CT), and can potentially help select post-MI VT patients in whom a combined endocardial-epicardial approach is appropriate as a first-line approach.^{103,115} Also, a large endocardial dense scar area on a bipolar voltage map (exceeding 10% area of endocardial surface area) was found to predict scar transmuralities.¹⁰⁰

The approach to epicardial mapping is essentially the same as for endocardial ablation, including activation mapping, entrainment mapping, substrate mapping, and pace mapping, and is discussed in detail in **Chapter 27**.

Practical Approach to Ventricular Tachycardia Mapping

The main goal of VT mapping is identification of the critical isthmus of the VT by activation and entrainment mapping techniques. Initially, substrate mapping is performed during NSR to delineate infarcted myocardium and the conducting channels within the myocardial scar that likely support the VT reentry circuit. This helps refine the area of interest and identify potential targets for further activation and entrainment mapping and, hence, minimize the time spent in sustained VT (**Box 22.3**).

When the VT is unstable or unsustainable, it may not be approachable by conventional point-by-point activation mapping and entrainment maneuvers. In this setting, substrate-based mapping becomes the main strategy to guide ablation by identifying the portions of the infarct region that most likely harbor the isthmuses of the clinical VT (**Fig. 22.30**).

Electroanatomic mapping is usually used to aid mapping and ablation. A standard 4-mm or 8-mm tip or, preferably, an irrigated-tip ablation catheter is used. High-density mapping can be facilitated by the use of a 20-pole catheter (PentaRay) or mini-basket catheter (Orion).⁸⁹

Identification of the Tachycardia Substrate

The majority of post-MI VTs are caused by macroreentry involving the dense myocardial scar interspersed with branching and merging bundles of viable myocytes with poor intercellular coupling and abnormal conduction properties. Buried in the arrhythmogenic substrate is the common central pathway (critical isthmus), which is a narrow path of tissue with abnormal conduction properties, causing slowing of impulse propagation and allowing reentry to occur. The isthmus itself can be surrounded by dead ends or branches that do not participate in the common pathway of the main reentrant circuit (bystander).¹⁰

BOX 22.3 Approach to Mapping of Postinfarction Ventricular Tachycardia

Identification of the Tachycardia Substrate

- Preprocedural substrate imaging:
 - Echocardiography, CT, or CMR.
 - Substrate mapping during baseline rhythm (sinus rhythm, or ventricular pacing).
 - Identification of scar location and distribution:
 - Dense scar: bipolar voltage <0.5 mV and electric unexcitability (pacing threshold >10 mA).
 - Border zone: bipolar voltage between 0.5 and 1.5 mV.
 - Identification of conducting channels within the scar region:
 - Voltage channels on the electroanatomic voltage map.
 - Local abnormal ventricular activity (amplitude \leq 0.5 mV; duration \geq 60 msec).
 - Late potentials.
 - Long (>40 msec) S-QRS interval during pacing.
- Pace mapping during sinus rhythm:
 - Identification of potential exit sites at the infarct border zone:
 - Paced QRS morphology matching that of the VT.
 - Long S-QRS interval.

Identification of the Critical Isthmus

- Activation mapping during VT:
 - Identification of sites with isolated mid-diastolic potentials or continuous activity spanning diastole.
 - Verification that the diastolic electrograms cannot be dissociated from the VT.
- Entrainment mapping during VT:
 - Confirmation of the presence of entrainment.
 - Entrainment criteria consistent with isthmus location:
 1. Concealed QRS fusion.
 2. PPI = TCL (\pm 30 msec).
 3. Electrogram-QRS interval = S-QRS interval (\pm 20 msec).
 4. Ratio of the S-QRS interval to the TCL less than 70%.

CMR, Cardiac magnetic resonance; CT, computed tomography; PCL, pacing cycle length; PPI, postpacing interval; S, stimulus; TCL, tachycardia cycle length; VT, ventricular tachycardia.

Substrate mapping is performed during baseline rhythm (NSR, AF, or ventricular pacing) and aims to identify: (1) scar location and distribution (as identified by low electrogram voltage and electric unexcitability); and (2) conducting channels within the scar region that can potentially serve as isthmuses for reentrant VTs (as identified by LAVA, late potentials, and long S-QRS interval during pacing).^{89,99}

Step 1: preprocedural substrate imaging. Echocardiography, CT, PET, or CMR imaging may be used to identify the size, location, and transmuralities of the infarct scar that potentially contains the arrhythmogenic substrate (see **eFig. 22.10**). Also, ICE can be of value for real-time identification of scar regions. In addition, integration of those imaging modalities into the 3-D electroanatomic mapping system can help visualize and display the LV substrate in a 3-D format and focus initial mapping efforts in those regions.

Step 2: scar mapping during sinus rhythm. Electrical scar is defined by low-amplitude local electrograms and tissue unexcitability during high-output pacing. Voltage mapping is utilized to identify the infarct and infarct border zones, which are likely to harbor the VT circuit. Bipolar voltage mapping is performed using a 3-D mapping system to identify areas of abnormal low-amplitude local electrograms during NSR or ventricular pacing.⁵⁴

Fig. 22.30 An Algorithmic Approach to Treatment of Scar-Based Ventricular Tachycardia (VT), Consisting of an Iterative Process. See text for details.

Conventionally, bipolar electrogram amplitude less than 0.5 mV defines dense scar, with signal amplitudes between 0.5 and 1.5 mV representing the infarct border zone. Endocardial electrogram voltage exceeding 1.5 mV generally defines normal myocardium (a voltage cutoff of 1.0 mV is used for normal epicardial bipolar electrograms). The LV is mapped during baseline rhythm to construct a voltage map displaying peak-to-peak bipolar electrogram amplitude, with the color range set between 0.5 and 1.5 mV. Higher-density points are obtained around areas of scar, focusing on the scar border and electrograms within the scar. All scar borders need to be clearly defined. A color-coded voltage map is then created and superimposed on the anatomical model to show the amplitudes of all selected points (see eFig. 22.13).⁵⁴

At low-amplitude (less than 0.5 mV) sites, pacing is performed with 10-mA, 2-millisecond pulse width stimuli. A pacing threshold greater than 10 mA has been used to define unexcitable scar, provided electrode-tissue contact is adequate.

Step 3: identification of conducting channels during sinus rhythm. In patients with post-MI VT, the areas of electrical scar identified by voltage mapping are relatively large; therefore identification of the conducting channels within the infarct region, which are relatively small bundles of viable tissue compared with the scar areas, helps refine the area that potentially supports the VT circuit.

Conducting channels within the scar region can be identified by: (1) voltage channels; (2) late potentials; and (3) S-QRS latency during pacing. During the voltage mapping, areas of fractionated or late potentials (irrespective of the voltage obtained) and sites with long S-QRS intervals during pacing are tagged on the electroanatomic map.^{66,103}

Voltage channels. Conducting channels on the electroanatomic voltage map are identified corridors of voltage preservation (voltage channels) within denser regions of scar or corridors between a dense scar and the mitral annulus. Careful step-by-step manual adjustment of voltage upper and lower limits on the color-coded electroanatomic voltage map can help maximize the color contrast between adjacent myocardium with different electrogram voltage levels within the 0.5-mV scar and, thus, unmask channels of viable myocardium within a dense scar (see eFig. 22.14).⁶⁶

Late potentials. Low-amplitude, high-frequency, fractionated electrograms with multiple components of prolonged duration and late potentials (defined as bipolar electrogram with any component is recorded after the offset of the QRS complex on the surface ECG) can

reflect local depolarization of surviving muscle bundles that are well insulated by dense scar.^{54,89,99,100}

Sites recording abnormal electrograms are tagged on the electroanatomic map. Conducting channels are defined as a path of more than two adjacent late potentials connecting with healthy tissue. Further, late potentials are classified as being an entrance or an inner part of a given conducting channel, depending on the local activation time of the near-field component. The entrance of a conducting channel is tagged as sites within the border zone (i.e., voltage zone of 0.5 to 1.5 mV) recording late potentials with the shortest delay between the far-field component of healthy/border zone muscle (low frequency, usually high voltage) and the near-field component (delayed, high frequency, usually fractionated and low voltage) corresponding to the local activation of myocardial fibers in the scar. Sites with longer delays likely reside farther along the conducting channel within the dense scar. Once a specific sequence of late potential activation has been identified, focal ablation of the earliest late potential is delivered with the endpoint of eliminating a consecutive series of late potentials. The method involves reconstruction with high-density mapping of channels of activation of late potentials.^{102,103}

In addition, 3-D electroanatomic late potential maps may be constructed, whereby the *terminal* portion of every local electrogram is manually marked during the mapping procedure. The lower time threshold of the color-coded map is set to the difference between the reference and end of the surface QRS complex. Late potential maps can be superimposed on voltage maps to further delineate their relationship to scar distribution.¹⁰⁵

Unmasking late potentials and distinguishing between local and far-field signals are critical for the accuracy of substrate mapping. This can require mapping pacing at the local site (to confirm local electrogram capture), changing the direction of depolarization approaching the mapping site (e.g., sinus rhythm vs. RV pacing), and VES (causing decremental conduction) to separate far-field from near-field potentials (see Fig. 22.29).⁹⁹

S-QRS intervals. Pacing during NSR at sites with low-amplitude electrograms can help identify potential conducting channels within low-voltage regions. S-QRS intervals longer than 40 milliseconds suggest that the pacing site is located within a protected zone, forcing the paced wavefront to propagate slowly before exiting this zone to activate the larger myocardium, causing the latency between myocardial capture and the onset of surface QRS. These sites are typically associated with

abnormal fractionated electrograms during NSR. In the setting of post-MI VT, it is likely that pacing sites with long S-QRS delays identify slowly conducting channels that traverse dense scar and can potentially form VT isthmuses.¹⁰³

Identification of the Critical Isthmus

Identification of the critical isthmus of macroreentrant VT employs activation and entrainment mapping techniques, which have several prerequisites, including inducibility of VT at the time of EP testing, hemodynamic stability of the VT (which usually requires a relatively slow VT rate), and stability of the VT reentry circuit (i.e., stable VT morphology and TCL).

When hemodynamic compromise during the VT is the main limitation for conventional activation and entrainment mapping methods, inductions of brief episodes of VT (with the mapping catheter at the optimal site, as identified by substrate and pace mapping approaches) can allow assessment of the relationship of the abnormal electrograms to the VT circuit. This can also allow entrainment maneuvers to be performed at those sites to help distinguish sites critical to the VT circuit from bystander sites. VT is then quickly terminated before significant hemodynamic compromise ensues. In addition, poorly tolerated rapid VTs can sometimes be slowed by antiarrhythmic drugs to allow for mapping. Furthermore, the use of IV vasopressors and external hemodynamic support devices can potentially provide hemodynamic support and allow mapping of otherwise unstable VT.^{82–84} The use of a 20-pole catheter (PentaRay), the mini-basket catheter (Orion), and noncontact mapping can also provide large amounts of activation mapping data during nonsustained or unstable VT.

Activation mapping during tachycardia. After complete substrate mapping, electrical stimulation is used to induce VT and to ascertain the ease of inducibility for subsequent testing, unless the VT is incessant.

During electroanatomic activation mapping, the electrical reference is generally chosen as a morphologically stable and regular electrogram obtained from an endocardial (e.g., RV apical electrogram) or surface lead (e.g., surface ECG lead with a QRS complex during VT demonstrating a sharp apex and a strong positive or negative deflection). The width of the window of interest is adjusted to approximate, usually 20 milliseconds less than, the TCL. The middle of the window of interest is selected to coincide with the electrical reference. In general, bipolar electrogram recordings are used for activation mapping because they provide an improved signal-to-noise ratio and more clearly defined high-frequency components. The local activation time for each endocardial position under the mapping catheter is calculated as the interval between the electrical reference and the onset of the high-frequency bipolar electrogram as it leaves the baseline.

Care is taken to annotate only true near-field diastolic activity based on sharp near-field electrograms. Filtered unipolar electrograms can help ensure that the tip electrode, which is the ablation electrode, is responsible for the early component of the bipolar electrograms. In addition, demonstration of a fixed relationship of the diastolic electrograms to the subsequent VT QRS, despite spontaneous or induced oscillations of the TCL, is important to exclude the possibility that those electrograms do not reflect late activation from unrelated dead-end pathways.

Activation mapping during VT is then carried out, initially focusing mapping on regions of VT substrate as identified during substrate mapping.⁶⁶ Particular sites of interest identified by activation mapping include: (1) sites with an abnormal local bipolar electrogram (amplitude ≤ 0.5 mV; duration ≥ 60 milliseconds); (2) sites at which the local electrogram precedes the QRS complex by at least 50 milliseconds (activation times are taken from the onset of the bipolar electrogram); (3) sites with the earliest local activation closest to mid-diastole (isolated

mid-diastolic potentials); (4) sites with continuous activity spanning diastole; and (5) adjacent sites with electrical activity spanning diastole (bridging of diastole). The resulting reentrant circuit is considered to be the spatially shortest route of unidirectional activation encompassing a full range of mapped activation times (greater than 90% of the TCL) and returning to the site of earliest activation.

It is important to recognize that mid-diastolic sites can also be part of a larger area of abnormal slow conduction unrelated to the VT circuit (i.e., a dead-end pathway), and can be recorded from a bystander site attached to the isthmus. Therefore, regardless of where in diastole the presystolic electrogram occurs (early, mid, or late), it is important to confirm that the electrogram cannot be dissociated from the VT and is required for VT maintenance (see eFig. 5.2).

Entrainment mapping during tachycardia. Entrainment mapping during reentrant VT is used to verify whether a site recording diastolic activity (regardless of where in diastole it occurs, its position, and its appearance on initiation of VT) is functionally involved in the VT circuit.

Entrainment mapping is directed to sites identified by other mapping modalities (such as activation, substrate, and pace mapping) as potentially related to the reentrant circuit. These include areas of slow conduction (manifest as fractionated electrograms), sites with mid-diastolic electrograms, or those displaying long S-QRS intervals.

Pacing is performed at a PCL just shorter (10 to 30 milliseconds) than the TCL, and is continued for a long enough duration to allow for entrainment. After cessation of each pacing drive, the presence of entrainment and resumption of the same tachycardia morphology should be verified.^{69,70}

Once the presence of entrainment is verified, several criteria can be used to indicate the relation of the pacing site to the reentrant circuit. The first entrainment criterion to be sought is concealed fusion. Entrainment with concealed fusion indicates that the pacing site is in a protected isthmus located within or attached to the reentrant circuit. Whether this protected isthmus is crucial to the reentrant circuit or is just a bystander site needs to be verified by other entrainment criteria including the PPI versus the TCL and the local electrogram-QRS interval during VT versus the S-QRS interval.⁷²

The following four criteria are used to define the critical isthmus and predict the success of RF application in elimination of the VT: (1) there is entrainment with concealed fusion; (2) the PPI is equal to the TCL (± 30 milliseconds); (3) the electrogram-QRS interval is equal to the S-QRS interval; and (4) the ratio of the S-QRS interval to the TCL is less than 70%.⁹⁴

Pace mapping during sinus rhythm. Pace mapping can be used to complement activation and entrainment mapping findings, although it may not always be necessary, especially when several criteria localizing the VT isthmus have been identified. In the setting of post-MI VT, pace mapping serves only as a corroborative method to identify the presumptive exit or isthmus region of the VT circuit, but is not sufficiently specific or sensitive to be the sole guide for ablation.

Pace mapping during NSR is performed at the border zone between scar and normal tissue to approximate the exit site of each inducible VT and at isthmus sites defined during VT. Preferably, pace mapping is performed with unipolar stimuli (10 mA, 2 milliseconds) from the distal electrode of the mapping catheter (cathode) and an electrode in the IVC (anode). The same PCL is usually used for each site in an individual patient (500 to 700 milliseconds), slightly faster than the sinus rate and slower than the rate of the induced VTs.

Pacing at each site is evaluated for two criteria: paced QRS morphology matching that of the VT and long S-QRS interval. The greater the degree of concordance between the morphology during pacing and tachycardia, the closer the catheter is to the exit site of the tachycardia

isthmus. Pace mapping at sites more proximally located in the isthmus can also produce a similar QRS complex, but with a longer S-QRS interval (due to the delay of conduction of the paced wavefront to the exit site). The S-QRS interval lengthens progressively as the pacing site is moved along the isthmus, consistent with pacing progressively farther from the exit (see Fig. 5.23).⁹⁶ It is important to recall that pace mapping at an isthmus may not produce a QRS identical to VT for reasons discussed previously.

ABLATION

Target of Ablation

Approaches for ablation include selective targeting of the critical isthmus that supports the development and maintenance of VT (as identified by activation, entrainment, and pace mapping techniques), more extensive substrate modification to reduce the arrhythmogenicity of a scar without any specific arrhythmia targeting, or a hybrid of both techniques.^{54,66,116,117}

Identification and ablation of the critical isthmus of the VT circuit is the gold standard for macroreentrant VT. This approach provides focused, high-yield ablation, and avoids unnecessary ablation at bystander sites. However, this strategy may not be feasible when the VT is not reproducibly inducible or poorly tolerated. Even in the setting of stable SMVT, this approach can be time-consuming and expose the patient to the detrimental hemodynamic consequences of prolonged periods of sustained tachycardia, especially when multiple VTs are targeted.¹¹⁷

On the other hand, substrate-based ablation approaches aim at modifying the potential arrhythmogenic substrate without requiring mapping during VT. These strategies involve more extensive, nonselective ablation, frequently involving nonarrhythmogenic regions of the scar. Although substrate-based ablation strategies offer the ability of performing the ablation during NSR and, hence, maintaining hemodynamic stability, these approaches typically require extensive ablation given the less precise localization of the reentry circuit. Furthermore, a purely substrate-based mapping and ablation strategy may not address the focal mechanism of VT that can be observed in patients with structural heart disease.¹¹⁷

Selective Ablation of the Critical Isthmus of the Reentrant Circuit

The reentrant VT wavefront rotates around the isthmus boundaries and propagates slowly through the critical isthmus, which harbors diastolic potentials. Focal ablation of multiple sites defined as in the reentrant circuit may not eliminate post-MI VT. Elimination requires ablation of an isthmus bordered by barriers on either side. These isthmuses are usually found at the border zone of the infarct and are defined as conductive myocardial tissue delineated by nonconductive tissue. The nonconductive tissue can be a scar area or an anatomical obstacle, such as the mitral annulus.

VT isthmuses measure, on average, approximately 30 mm long by 16 mm wide. The axis of a critical isthmus is typically oriented parallel to the mitral annulus plane in perimitral circuits and perpendicular to the mitral annulus plane in other circuits. Successful ablation of post-MI VT is achieved by selectively targeting the critical isthmus where the circuit can be interrupted with linear RF lesions transecting the isthmus. The isthmuses are the preferred targets for VT ablation because they are usually narrow and critical parts of the VT reentry circuit, allowing ablation with a small set of RF lesions.¹⁰

Results of ablation of infarct-related VTs have been improving over the past decade because of better understanding and selection of ablation sites. Initial attempts at ablation targeted early presystolic potentials, followed by targeting mid-diastolic potentials; both approaches yielded

unsatisfactory results. Presystolic potentials were found to be nonspecific, because they might be in an area of scar tissue—for example, inner loop, bystander (inner sites attached to the central pathway), and not related to the VT circuit. Mid-diastolic potentials that cannot be dissociated from the VT during entrainment can be related to a bystander site. Demonstration of entrainment of VT with concealed fusion as a guide to VT ablation has increased ablation success rates. However, entrainment with concealed fusion alone to guide VT ablation has only a 50% positive predictive value for terminating VT because concealed entrainment can be observed during pacing from bystander sites connected to, but not integral parts of, the reentrant circuit. Multiple criteria activation and mapping criteria have been suggested, alone or in combination, to improve identification of the critical zone of the VT. These criteria have a different sensitivity and specificity with variable positive predictive values whenever they are used in different combinations (see Table 22.3).

For stable VTs, reentry circuit isthmuses are defined by activation and entrainment mapping as sites with: (1) continuous activity or isolated mid-diastolic potentials that cannot be dissociated from the tachycardia; (2) entrainment with concealed fusion; (3) a PPI equal to the TCL (± 30 milliseconds); (4) an S-QRS interval equal to electrogram-to-QRS interval (± 20 milliseconds); and (5) a ratio of S-QRS interval of the TCL between 30% to 70%. These criteria have the highest ablation success rates, with a positive predictive value of 100% and negative predictive value of 96% (see Box 22.3).^{54,116}

In addition, there are other criteria that can identify the location of the critical isthmus. Reproducible alteration of the TCL or termination of VT by subthreshold or nonpropagated pacing stimuli is also an indication that the pacing site is in a circuit isthmus (see eFig. 22.9). The stimulus likely captures local myocardium, but the propagated impulse blocks before exiting the scar region and creates bidirectional conduction block in the reentry circuit. Alternatively, the stimulus prolongs refractoriness at the site through an electrotonic effect. This finding is specific for predicting a successful ablation site, but is observed infrequently, with a sensitivity of only 16%. Furthermore, mild mechanical trauma caused by the mapping catheter occasionally terminates the VT and may render the tachycardia noninducible for a variable period of time, preventing further mapping. This event suggests that the vulnerable region for the VT is small and superficial, and ablation at the site can be successful. Empiric thermal mapping (RF application for 10 seconds to assess VT termination) can also help confirm sites within the VT isthmus. VT termination during short RF applications without induction of PVCs suggests an isthmus location. When RF application fails to terminate the VT at a site that appears to be in the circuit, catheter-tissue contact may be inadequate, the site may be a bystander, or the isthmus may consist of a broad band.

The inability to find the appropriate target site can be caused by: (1) inadequate density of mapping points; (2) the presence of a large amount of scar tissue; (3) intramyocardial or epicardial location of the VT isthmus; (4) technical difficulty in catheter manipulation; or (5) acceleration, termination, or changing of VT to a different arrhythmia during attempts at entrainment limiting mapping of the VT.

Substrate-Based Ablation

Over the past three decades, two effective surgical strategies have been developed for treatment of post-MI VT. Subendocardial resection, guided by the presence of the endocardial scar and involving removal of the subendocardial layer containing the arrhythmogenic tissue, is associated with a 70% to 80% arrhythmia cure rate. Such surgical therapy is performed when uniform sustained VT cannot be initiated at the time of surgery. The second technique is encircling endocardial ventriculotomy, whereby circumferential surgical lesions are placed through the border

zone, presumably interrupting potential VT circuits. This experience was critical in establishing the concepts on which substrate-based ablation is based; the arrhythmogenic substrate is predominantly located in the subendocardium and resides, at least partly, in the border zone between densely infarcted or fibrotic tissue and normal tissue. This substrate has distinguishing electrogram characteristics, and removal or interruption of this arrhythmogenic tissue can abolish the VT.⁵⁴

Substrate-based approaches to ablation of post-MI VT, guided by delineation of the infarct region from sinus rhythm electrograms, have dramatically improved ablation outcomes in patients with complex substrates. These approaches often allow successful ablation to be performed during NSR without the need for detailed mapping of the critical isthmus of the VT circuit. Although substrate-based ablation was initially proposed for the treatment of unstable or noninducible VT, it has recently emerged as an effective primary ablation strategy for any type of scar-related VT. The added value of VT induction and activation mapping has recently been challenged.¹¹⁶

Strategies for substrate ablation range from a thorough ablation of the entire abnormal substrate harboring abnormal electrograms (e.g., ablation of late potentials and fragmented electrograms, and scar homogenization) to more selective ablation approaches such as linear ablation, “scar dechanneling,” and “core isolation” (Fig. 22.31). These different strategies have not been directly compared and differences in outcomes are not apparent in the literature. Further, the optimal targets and sequence of ablation when combined with mapping during VT are uncertain and continue to evolve. Variations in anatomy may also influence the effectiveness of the different methods. In many patients, a combination of these techniques is needed for successful identification and ablation of critical sites of the reentrant circuit.^{54,90,102,116}

Scar homogenization. This approach aims to completely eliminate all the abnormal electrograms (fragmented electrograms and late potentials) within the scar defined by bipolar voltage mapping (Fig. 22.32).

Extensive RF ablation is performed throughout the entire scar based on the substrate and targeting all sites with abnormal electrograms in NSR. Ablation is continued until abnormal and late potentials are extinguished, as confirmed by reduction of electrogram amplitude to the noise level and electrical unexcitability in response to high-output pacing (20 mA at 10 milliseconds).

However, the infarct size or area of low-voltage electrograms is usually large (averaging 21 cm in circumference in one study), necessitating extensive and transmural ablation lesions, which is difficult to achieve using the current catheter-based ablative techniques and can result in increased risk of complications, including damage to functioning myocardium. Therefore ablation over the entire infarct region is often not feasible, nor necessarily desirable.^{54,66,102}

Scar dechanneling. Scar dechanneling involves RF ablation of all conducting channels within the scar as identified by substrate mapping. This strategy attempts to limit the extent of ablation required to achieve scar homogenization by preferentially targeting the entrance sites to the conducting channels. Ablation at the entrance of these channels can result in disappearance of conduction downstream in the channel and its ramifications, as confirmed by elimination of a consecutive series of late potentials within the conducting channel (Fig. 22.33).

Conducting channel entrances are identified by substrate mapping as sites within the border zone (i.e., zone with 0.5 to 1.5 mV voltage) recording the earliest late potential, that is, late potentials with the shortest delay between the far-field component (low frequency, usually high voltage) and the near-field local ventricular activity (typically delayed, high frequency, fractionated, and low voltage). This is in contrast to the inner points of conducting channels within the dense scar, which are characterized by longer delays between the local and far-field electrogram components.

The endpoint of this ablation strategy is conducting channel entrance conduction block, manifesting as the disappearance of the

Fig. 22.31 Substrate-Based Ablation Strategies. (A) Isthmus ablation. (B) Scar homogenization. (C) Ablation lines applied parallel to the scar border within the low-voltage area encompassing the exit region. (D) Ablation lines placed perpendicular to all defined isthmuses between islands of unexcitable segment or extend perpendicular to the scar border from the area of dense scar, across the border zone and connecting out to normal myocardium or anatomical barrier (e.g., mitral valve). RV, Right ventricular. (From Tanawuttiwat T, Nazarian S, Calkins H. The role of catheter ablation in the management of ventricular tachycardia. *Eur Heart J*. 2016;37:594–609.)

Fig. 22.32 Scar Homogenization. A voltage map of the left ventricle (posteroinferior [left] and right anterior oblique [right] views) is shown in a patient with prior inferior wall infarction. A large inferior wall scar (bipolar electrogram amplitude <0.5 mV, red area). Substrate-based ablation (tagged as red dots) is performed to achieve extensive scar homogenization. Ablation targets included fragmented electrograms and late potentials. Blue dots denote sites of good pace mapping. MA, Mitral annulus.

inner point of the conducting channels or delayed activation of conducting channel inner points, usually with the activation sequence in reverse order.^{54,102,103,118,119}

Core isolation. Core isolation refers to circumferential ablation around all critical or “core” areas of the scar containing the putative VT circuit elements or around the dense scar (voltage less than 0.5 mV) when VT is not inducible. The putative VT circuit elements are defined by conventional mapping techniques, including conducting channels identified on voltage mapping (voltage channels), sites with late potentials, sites with good pace maps and long S-QRS intervals, and isthmus sites defined by entrainment mapping. Once the critical area is identified, contiguous ablation lesions are delivered all around that area or using anatomical anchors (when present) to minimize the amount of ablation necessary (Fig. 22.34).^{54,102,119}

The goal of core isolation is electrically isolating the segment of low-voltage scar confirmed by the demonstration of exit block from the core of the scar (i.e., failure of global ventricular capture during high-output pacing from multiple, discrete sites inside the core that had previously demonstrated capture). In addition, entrance block can be demonstrated by dissociated fragmented electrical activity inside the core. Core isolation obviates the need for extensive ablation within the scar as proposed by scar homogenization.^{120,121}

Linear ablation. Linear ablation targeting the VT substrate is also widely used.⁵⁴ Linear RF lesions are placed using one of several guiding principles:

- Ablation lines extending perpendicular to all potential isthmuses (i.e., conducting channels identified on substrate mapping) within the scar areas or between islands of unexcitable segments within the infarct (identified as a region of relatively larger voltage bordered by low voltage within the scar and abnormal electrograms during NSR).
- Ablation lines extending parallel to the scar edge at the scar border zone (voltage 0.5 to 1.0 mV) encompassing all approximate exit sites identified by pace mapping.¹⁰²
- Ablation lines extending perpendicular to the scar border, from the area of dense scar (i.e., voltage less than 0.5 mV) across the border

zone and connecting out to normal myocardium (i.e., voltage greater than 1.5 mV) or to anatomical barriers (e.g., mitral annulus).¹⁰²

Multiple Inducible Ventricular Tachycardias

In patients referred for post-MI VT ablation, an average of three to four VTs is commonly inducible by programmed electrical stimulation. When multiple VTs are inducible during EP testing, several investigators have targeted the predominant morphology of VT. Ablation that focused on the clinical VT but did not target other inducible VTs successfully abolished the clinical VT in 71% to 76% of cases. However, during follow-up, approximately one-third of patients with acutely successful ablation of the clinical VT had arrhythmia recurrences, some of which occurred because of a VT different from that initially targeted for ablation. Furthermore, there are several difficulties with selecting a dominant, clinical VT for ablation. Often, it is not possible to determine which VT is the one that has occurred spontaneously. Only a limited recording of one or a few ECG leads may be available. In patients with an ICD, the device typically terminates VT before an ECG is obtained, and VT is documented only on intracardiac recordings. Even if one VT is identified as predominant, other VTs that are inducible can subsequently occur spontaneously. An alternative approach is to attempt ablation of all inducible VTs that are sufficiently tolerated to allow mapping. The 3-year risk of recurrent VT after such an approach is 33%.

At present, the clinical endpoint for VT ablation remains unclear. Targeting of all inducible SMVTs is a prevalent strategy because recordings of all VTs before ablation often are not reliably obtainable to define clinically relevant VTs. Nonetheless, the level of aggressiveness to achieve this endpoint must be weighed against hemodynamic stability, volume shifts, and prolonged anesthesia in tenuous patients.⁶⁶ Therefore the goal(s) of ablation should be individualized. In patients undergoing ablation because of frequent ICD shocks or tachycardia-induced cardiomyopathy, elimination of problematic VT morphologies is appropriate. On the other hand, elimination of all inducible VTs should be considered especially for patients who cannot undergo or decline ICD implantation.¹¹⁶

Fig. 22.33 Scar Dechanneling. Inferior view of left ventricular (LV) bipolar voltage electroanatomic substrate maps during sinus rhythm before (MAP) and after (reMAP) scar dechanneling in a patient with healed myocardial infarction. Electrograms recorded as conducting channel entrances are labeled with black dots and inner sites with blue dots. Examples of bipolar electrograms at entrances (1 and 5) and inner parts (2–4) are shown (left). Delayed components of the electrograms are highlighted with arrows. Electrogram aspect after elimination of the delayed component (asterisks) in the same sites after scar dechanneling is shown (left). MA, mitral annulus. (From Berruezo A, Fernández-Armenta J, Andreu D, et al. Scar dechanneling: new method for scar-related left ventricular tachycardia substrate ablation. *Circ Arrhythm Electrophysiol*. 2015;8:326–336.)

Ablation Technique

Catheter ablation of scar-related VT usually requires relatively extensive tissue injury to abolish the arrhythmia substrate, which can be facilitated by the use of larger electrodes or irrigated electrodes. In general, irrigated RF electrodes are preferred to large (8-mm)-tip electrodes. Cooled RF ablation allows increased power delivery, deeper lesions in myocardial scar, and potentially improved outcomes. In contrast, increasing the size of the electrode both reduces the spatial resolution of mapping and increases the disparity in temperatures across the surface of the electrode such that hot regions can lead to coagulum formation despite relatively low temperatures recorded from the electrode. On the other hand, external irrigation involves administration of potentially large amounts of IV saline, which can cause acute heart failure. Internal irrigation catheters, large-tip catheters, or external irrigation catheter designs employing lower irrigation flow rates (e.g., ThermoCool SF, Biosense Webster) should be considered if intravascular volume administration will be difficult to manage, as in patients with renal failure or severe heart failure.

The external irrigation system (ThermoCool; Biosense Webster) uses an 8 Fr catheter that has an electrode 3.5 mm in length with six holes in the tip through which saline flows at 30 mL/min during RF application. In the internal irrigation system (Chilli; Boston Scientific, Natick, MA), saline flows at 36 mL/min through the electrode and returns through a second lumen to be discarded outside the patient. For both cooled RF systems, RF application is initiated at a power output of 20 to 30 W; the power is gradually increased to achieve a fall in impedance of 5 to 10 Ω or a maximal measured electrode tip temperature of 40°C to 45°C. Energy application is continued for 30 to 120 seconds. RF current application is discontinued if measured impedance increases by more than 10 Ω , the catheter changes position, or VT fails to terminate after 30 to 60 seconds.

Alternatively, RF current can be delivered generally during VT from a mapping catheter with a solid 8-mm tip. RF energy is delivered in a temperature-controlled mode for 60 to 120 seconds at each ablation target site, with a maximal temperature target of 60°C to 70°C and 50 to 70 W of maximal power delivered. Impedance is monitored during RF delivery. In case of an impedance rise, the ablation catheter is removed

Fig. 22.34 Core Isolation. (A) Endocardial voltage map (anteroposterior view) in a patient with ventricular tachycardia (VT) and a large anterior myocardial infarction. The VT circuit core was defined by good pace map (PM) sites (stars depict examples), as defined in the text and was isolated by contiguous ablation at the junction between dense scar and border zone or regions without pacing capture at baseline. (B) Late potential activation map performed after core isolation identifying a single site of endocardial breakthrough within the isolated area. A multipolar catheter (MPC) was positioned within the core isolation area, and the ablation catheter (ABL) at the site of endocardial breakthrough. (C) Ablation at the earliest breakthrough results in core isolation, with entrance block demonstrated by disappearance of near-field late potentials from the MPC during ablation (arrows). (D) After core isolation, dissociated potentials were recorded (arrows). (E) After isolation, pacing from the MPC shows local myocardial capture (arrows) with exit block. (From Tzou WS, Frankel DS, Hegeman T, et al. Core isolation of critical arrhythmia elements for treatment of multiple scar-based ventricular tachycardias. *Circ Arrhythm Electrophysiol.* 2015;8:353–361.)

from the body and the distal electrode is wiped clean of the coagulum before continuing with the procedure.

At isthmus sites identified by entrainment, successful ablation sites usually result in VT termination within 5 to 15 seconds of the RF application. A second RF application is typically given at successful target sites if VT cannot immediately be reinitiated and the catheter has not moved. If there is no termination of VT after 30 seconds of RF application, it is suggested to discontinue RF energy delivery to decrease the likelihood of ablation of noninvolved myocardial tissue, with potential impairment of LV function. However, assuring adequate catheter-tissue contact is important before abandoning what appeared to be a good target site.

Application of RF energy at successful exit, central, or entry VT isthmus sites usually results in termination of the VT within a mean time of 10 ± 11 seconds. When RF application at other sites terminates the VT, the average time to termination is 19 ± 16 seconds, which suggests that a larger region must be heated for interruption of reentry. Persistence of inducibility of VT after successful termination with a

single RF application, despite further applications of RF energy at the same site, is probably secondary to inadequate lesion size because of a wide isthmus, epicardial location, or the presence of significant fibrosis, thrombus, or calcification. In some cases, lack of consistent electrode-tissue contact can result from dislodgment of the electrode when a sudden change in rhythm occurs (such as VT termination).

When RF application fails to terminate the VT at a site that appears to be in the circuit, the site may be a bystander. Failure of ablation has been attributed to a number of factors, including inaccurate mapping because of failure to apply appropriate criteria for localizing a protected isthmus and/or inability to find such a site, and also to inadequate lesion size produced by the RF application. Occasionally, successful termination of VT is achieved with RF application at a site at which failure is predicted. This may occur if the site is not at the isthmus region but in the nearby vicinity, with good conduction of temperature to the isthmus.

For ablation of unstable VT, RF energy is delivered during NSR. A series of ablation lesions are made to transect the critical isthmus in

the most convenient area, targeting the narrowest portion of the isthmus when allowed by catheter positioning and stability. To join the isthmus boundaries, RF lines are usually drawn perpendicular to the mitral annulus plane in perimitral circuits (see eFig. 22.13) and parallel to the mitral annulus plane in all other circuits. RF lesions are applied to the region until pacing with 10-mA, 2-millisecond strength stimuli fails to capture, or reversal of ventricular electrograms in CS recordings occurs (eFig. 22.16). After completion of each set of RF lesions, programmed electrical stimulation is repeated.

For intramural circuits, catheter ablation from both sides of the scar (epicardially and endocardially) may be necessary. Midseptal circuit can require high-energy RF ablation at the endocardial breakthrough sites from the right and left sides of the interventricular septum, but can be associated with increased risk of AV block. RF delivery within a perforator vein of the great cardiac vein may be considered in some cases. RF ablation of midseptal targets frequently result in acute tachycardia termination, but persistent inducibility later during the procedure as well as high recurrence of clinical tachycardias during follow-up. Alternative ablation modalities have been described, including bipolar RF, high-intensity focused ultrasound, needle ablation, or intracoronary ethanol injection, but currently these modalities are not available for routine clinical application.⁵⁸

Endpoints of Ablation

Noninducibility of All Sustained Monomorphic Ventricular Tachycardias

Noninducibility of any VT (excluding ventricular flutter, polymorphic VT, and VF) is the preferred and recommended endpoint of the ablation procedure. In a meta-analysis and a large-scale, multicenter cohort, elimination of inducibility of all SMVTs was found to be associated with a significant reduction in both mortality and recurrence of VT/VF events. However, the mortality benefit has not been consistent across different studies.^{54,91,119,122,123}

For verification of VT inducibility, the entire programmed electrical stimulation protocol should be performed and should include up to three VESs delivered from at least two ventricular sites, with the shortest coupling intervals of 180 to 200 milliseconds or to refractoriness. If the initial stimulation protocol required additional LV pacing sites or catecholamine infusion to induce VT, then that protocol should be repeated following ablation. The complete protocol of programmed electrical stimulation is again repeated after a 30-minute waiting period, unless such aggressive stimulation places the patient at risk of cardiopulmonary deterioration.

However, while noninducibility of VT is considered an ideal endpoint of the ablation procedure, it has several limitations. VT may not be inducible at baseline. In addition, the inducibility of some VTs may not be reproducible. Furthermore, an aggressive ventricular stimulation protocol at the conclusion of a long procedure in marginally stable patients can potentially lead to hemodynamic compromise. Importantly, the predictive value of noninducibility for VT recurrence is limited; VT recurs in 26% to 44% of patients who were rendered noninducible by catheter ablation. On the other hand, more than 50% of patients who remained inducible for a previously undocumented (nonclinical) VT do not experience VT recurrences on short-term follow-up, suggesting that pursuing elimination of nonclinical VTs can lead to overtreatment in a large proportion of patients. Finally, it is important to recognize that noninducibility of all SMVTs may not be achievable in a relatively large proportion of patients despite aggressive ablation attempts.^{56,122,123}

Noninducibility of All Clinical Ventricular Tachycardias

“VT modification” is defined as noninducibility of all clinical VTs (i.e., all inducible VTs that are known to have the same 12-lead ECG QRS

morphology and approximate TCL as spontaneous VTs), but with other SMVTs remaining inducible. Following ablation of one or more reentry circuits, the remaining inducible VTs are often faster, suggesting that regions of slow conduction have been ablated; the remaining circuits that can form have a shorter revolution time. Thus the arrhythmia substrate appears to have been modified. Modification of the reentry substrate is a common outcome of ablation, and is usually associated with a favorable outcome and a decrease of the arrhythmia burden in most patients.¹²³

When clinical or presumed clinical VTs have been adequately documented previously and can be induced at the outset of the procedure, the minimal endpoint of ablation should be to eliminate the induction of that VT during postprocedure programmed stimulation. On the other hand, the mere change in the “intensity” of stimulation required to induce VT (greater number of extrastimuli and alternative stimulation sites) is not a reliable endpoint. Nevertheless, in patients who present with incessant VT, restoration of stable sinus rhythm may represent a reasonable clinical endpoint, irrespective of the outcome of subsequent programmed stimulation.¹²³

This endpoint, however, does not apply in the majority of patients in whom morphology of the spontaneous VTs have not been documented on a 12-lead ECG prior to the ablation procedure.^{116,123}

Elimination of the Arrhythmogenic Substrate

Complete elimination of all fragmented and late potentials, scar homogenization, scar dechanneling, or core isolation (as described previously) may also be utilized as alternative procedural endpoints, especially in patients in whom VT is not reproducibly inducible at baseline. Furthermore, even in patients with inducible VTs, some reports suggested an improvement in outcome (reduction in VT recurrence cardiac mortality) when these substrate-based endpoints are combined with VT noninducibility. As noted, noninducibility of VT is not a perfect endpoint; the rate of VT recurrence remains relatively high even in patients whose VT is rendered noninducible after ablation. Substrate-based endpoints can potentially improve outcome by eliminating the arrhythmogenic substrate and reducing the risk of developing new VTs or preexisting VTs that were not inducible during the ablation procedure. However, achieving substrate-based endpoints is more challenging than noninducibility of a given VT and typically requires more extensive, nonselective ablation.^{120,122,123}

Management After Ablation

Following successful catheter ablation, antiarrhythmic drugs may be discontinued in some patients. Nonetheless, because of the relatively high risk of VT recurrence and the progressive nature of the VT substrate, antiarrhythmic drug therapy is often continued in most patients following VT ablation. In some cases, cessation of antiarrhythmic drugs that had suppressed some VTs may allow them to occur. Therefore freedom from antiarrhythmic drugs may not be a reasonable goal of ablation; instead, dose reduction may be an important goal, particularly for amiodarone, for which the incidence of side effects is closely related to daily dose. In various trials, dose reduction of amiodarone has been feasible following ablation. Reduction of amiodarone dose may be attempted in a progressive manner starting within the first 3 to 6 months post ablation in patients who remain free of VT/VF.

Within the first 3 months post ablation in the LV, there may be a risk of systemic thromboembolism, particularly if extensive ablation lesions were applied. Antiplatelet agents (aspirin, clopidogrel, or both) are typically used in all patients with ischemic heart disease. In addition, short-term (6 to 12 weeks) warfarin therapy may be considered for higher-risk patients (documented thrombus, previous stroke or transient ischemic attack, AF, severe LV dysfunction), especially those

eFig. 22.16 Mitral Isthmus Block in Inferior Wall Postinfarction Ventricular Tachycardia (VT). During VT, shown in the left panel (as well as sinus rhythm and right ventricular pacing [data not shown]), ventricular electrograms in the coronary sinus (CS) recordings propagate from distal to proximal (*red arrow*). After ablation to the mitral annulus, pacing from a coronary vein branch distal to the ablation line (*right panel*) shows propagation now from proximal to distal CS (*blue arrow*), indicating conduction block in the mitral isthmus. *Abl_{dist}*, Distal ablation site; *Abl_{prox}*, proximal ablation site; *RV*, right ventricular.

patients who received extensive ablation over large areas (e.g., several centimeters).

Outcome

Success and Recurrence

Clinical studies have demonstrated the superiority of catheter ablation compared with medical therapy in controlling recurrent post-MI VT. However, long-term freedom from VT remains an issue, with reported long-term success rates of only 35% to 60%.⁶⁶ Nonetheless, in patients with drug-refractory post-MI VT, catheter ablation generally results in improved arrhythmia control, reduced frequency of ICD therapies, and significant reduction in the use of antiarrhythmic drug therapy in the majority (50% to 83%) of patients, even when occasional recurrences of VT persist during follow-up. Reductions in VT episodes and ICD shocks lead to a decrease in hospitalizations as well as improvements in anxiety and depression.^{116,124}

Ablation targeting critical isthmuses for stable VTs is successful in abolishing the inducible “targeted” or “clinical” VT in 71% to 93% of selected patients. During average follow-ups ranging from 9 to 42 months, noninducibility of the clinical VT immediately postprocedure is associated with a lower risk of VT recurrence and nonfatal VT (13% to 46%), compared with persistent inducibility of the clinical VT (up to 80%); the risk of SCD is low (0% to 6%), reflecting the common use of ICDs for patients felt to be at risk. Substrate-based ablation has been used as an adjunctive or an alternative approach, and appears to further reduce the risk of recurrence of any VT at follow-up when compared with ablation targeting only mappable VTs.⁶⁶ However, in the largest three prospective studies, complete elimination of VT inducibility as a procedural endpoint was achieved in 40% to 75%, whereas elimination of “clinical” VT was achieved in 72% to 93% of patients. In addition, a recent meta-analysis failed to show superiority of either approach in terms of acute procedural success (noninducibility of the targeted VT), procedural complications, VT recurrence, or mortality.¹²⁵

In patients with a single stable spontaneous VT morphology well documented prior to the procedure, the persistent induction of “non-clinical” VTs that are faster than the targeted VT was reported to have little influence on subsequent spontaneous recurrence rates. Although the occasional spontaneous occurrence of these “nonclinical” VTs during follow-up is well documented, ablation of only the clinical VT (but not necessarily all VTs) can be associated with a lower incidence of electrical storm and cardiac death, despite a high likelihood of sporadic VT recurrence. On the other hand, complete elimination of VT inducibility at the conclusion of the ablation procedure is associated with improved survival and reduced long-term risk of VT recurrence.

In patients with incessant VT or VT storm, catheter ablation can be life-saving with an acute success rate of VT ablation of 72%, recurrence rate of 6%, and procedure-related mortality rate of 0.6%.⁵⁴ Although single episodes of VT recur in approximately one-third of patients, 74% to 92% remain free of incessant VT or VT storm.

Procedural success, long-term prognosis, and procedure-related mortality and complications appear to be better in patients who undergo the ablation procedure early in the course of disease. Successful VT ablation may have benefit beyond arrhythmia control, and was found to be strongly associated with improved transplant-free survival, independent of heart failure severity.¹²⁶ Two small randomized controlled trials examined catheter ablation as primary treatment for VT in patients with prior MI. In the Ventricular Tachycardia Ablation in Coronary Heart Disease (VTACH) trial, 110 patients with ischemic cardiomyopathy who were receiving an ICD for hemodynamically stable SMVT were randomly assigned to undergo VT ablation before ICD implantation or to a control group receiving no additional intervention. In the Substrate Mapping and Ablation in Sinus Rhythm to Halt Ventricular

Tachycardia (SMASH-VT) trial, 128 patients with ischemic cardiomyopathy who had hemodynamically unstable VT and an ICD were randomly assigned to undergo substrate-guided VT ablation or no ablation. Both studies showed that catheter ablation significantly reduced arrhythmia recurrence but had no impact in mortality (likely due to the fact that ICDs were implanted in both study groups). The rate of complications was 5% and no periprocedural mortality was observed.⁵⁴

A more recent study (the Ventricular Tachycardia Ablation versus Escalated Antiarrhythmic Drug Therapy in Ischemic Heart Disease [VANISH] trial) examined the value of catheter ablation versus escalation of antiarrhythmic drug therapy (usually in terms of increasing the dose of amiodarone or adding mexiletine) in patients with ischemic cardiomyopathy and an ICD, who had recurrent VT despite first-line antiarrhythmic drug therapy. The rate of the composite outcome of death at any time or VT storm or appropriate ICD shock after 30 days was lower in the ablation group than among patients who received escalated antiarrhythmic drug therapy. In addition, sustained VT at a rate below the detection limit of the ICD and adverse events that were attributed to treatment were more frequent among patients in the escalated-therapy group. This trial provides evidence supporting the consideration of catheter ablation in patients with recurrent VT refractory to an initial regimen of antiarrhythmic drug therapy, in preference to an escalating antiarrhythmic drug regimen.¹²⁷

In contrast, short- and long-term outcome remains poor (mainly driven by VT recurrences and heart failure–related death) in patients with severe LV systolic dysfunction undergoing ablation for recurrent VT as a last resort (after failure of multiple antiarrhythmic medications), independent of the acute outcome of the procedure. Induction of multiple morphologies of VT and unstable VT at baseline appear to be associated with a higher risk of VT recurrence. Although possibly affected by selection bias, an early intervention with VT ablation aiming at noninducibility seems to be appropriate.^{54,56}

Importantly, recurrence of VT after ablation is an independent predictor of all-cause mortality. The prognostic impact of VT recurrence after ablation appears to be time dependent; early recurrences (within the first month post ablation) are associated with the highest risk of adverse prognosis, and the risk decreases gradually with later recurrences.¹²⁸

Causes of Arrhythmia Recurrence

The causes of recurrent VT after an acutely successful ablation procedure are speculative. Recurrence of the patient’s initial spontaneous VT is usually presumed to occur if the 12-lead ECG demonstrates the same VT morphology as the initial VT, or the TCL as recorded from the ICD is within 20 milliseconds of the initial TCL (if there has been no change in antiarrhythmic drug therapy). When the clinical VT recurs, it generally has a longer TCL. This occurs because (1) the RF lesion might have produced slowing of conduction, and not block, in the critical isthmus, possibly because the width of the isthmus exceeds the size of the ablation lesion; (2) the RF lesion might have increased the length of the central common pathway by increasing the barrier around which the impulse circulated, without changing the circuit exit; or (3) the RF lesion might actually have been successful in eliminating the critical isthmus of the VT circuit, but an inner loop, which was present and not part of the primary reentry circuit, became an active participant in a new longer circuit that had the same exit site as the original VT.¹¹⁴

The majority of VTs recurring after prior ablation display morphologies not seen or targeted at the initial procedure.⁵ This likely reflects different exit sites or different potential reentrant circuits in the vicinity of prior ablation lesions. Long-term evolution and progression of underlying myocardial and coronary disease and continued infarct remodeling can potentially lead to the formation of new VT circuits. Patients with

VT recurrence tend to have more extensive scarring than those without recurrent VT. In addition, lack of inducibility at the time of ablation likely account, at least in part, for the inability to identify areas participating in the arrhythmogenic substrate, which can become manifest much later or after withdrawal of antiarrhythmic drug therapy.^{54,91,96}

The acute failure of catheter ablation to terminate an inducible SMVT often reflects inaccurate mapping or inadequate RF lesion size due to poor tissue contact or a deep intramural or epicardial circuit. Furthermore, ablation can be hindered by the proximity of the ablation target to the HB, coronary artery, or phrenic nerve, or by anatomical obstacles that preclude access to the ablation target (e.g., mechanical aortic and mitral valves or epicardial adhesions).^{54,96}

Complications

Patients with post-MI VT typically have depressed LV function and multiple comorbidities. Ablation is often a late attempt at controlling refractory arrhythmias, sometimes after significant hemodynamic compromise has developed. Therefore significant complications (e.g., worsened heart failure, stroke, transient ischemic attack, MI, cardiac perforation, or heart block) occur in approximately 3% to 10% of patients. Procedure-related mortality ranges from 0% to 3%. Vascular access complications (large hematomas or arterial pseudoaneurysms, arteriovenous fistula) occur in more than 2% of patients. Strokes and transient ischemic attacks occur in approximately 1%, and cardiac tamponade in 1%.

In one series, acute hemodynamic decompensation (i.e., persistent hypotension despite vasopressors and requiring mechanical support or procedure discontinuation) occurred in 11% of patients during 24 ablation procedures, and was associated with increased mortality over follow-up. This is likely related to prolonged times of reduced cardiac output, myocardial stunning with VT and long anesthesia times, and target organ hypoperfusion occurring before and during the procedure.¹²⁹

Exacerbation of heart failure can develop in the acute phase post ablation. Extensive ablation in viable myocardium, injury to the aortic or mitral valves during LV catheter manipulation, repeated hemodynamically unstable VT episodes, and saline administration from externally irrigated ablation catheters are procedural factors that can potentially exacerbate heart failure and myocardial ischemia. Therefore it is prudent to restrict ablation lesions to areas of infarction, as identified from low-amplitude electrograms in regions observed to have little contractility on echocardiography or ventriculography. Of note, coronary artery injury is not common during endocardial RF application of post-MI VT. Larger coronary vessels are less susceptible to injury than small vessels, likely due to the greater cooling effect of blood flow. In addition, ablation in infarct-related areas is likely to involve territories of occluded infarct arteries. Of 215 patients in one series, only a single patient suffered MI from occlusion of a marginal artery.

Although ablation guided by substrate mapping avoids the hemodynamic consequences of prolonged mapping during VT, the lack of a precise reentry circuit target is compensated by extensive ablation lesion sets, which increases the potential for complications. In a multicenter study, major complications including worsening heart failure were observed in 7.3% of patients, and 3.0% died within 7 days of ablation.

Importantly, many of the patients with prior MI and VT undergoing ablation have very severe heart disease and, despite good arrhythmia control with catheter ablation, the overall mortality remains high, exceeding 10% per year in some studies, mainly driven by progressive heart failure.^{5,54}

Predictors of periprocedural complications include advanced age, depressed LVEF, NYHA class III/IV, presentation with VT storm, anemia, chronic obstructive pulmonary disease, renal insufficiency, operator

experience, and use of general anesthesia.^{54,130,131} In addition, failure to eliminate clinical VT during ablation, the need for intraoperative intraaortic balloon pump insertion for hemodynamic support, and procedure duration are associated with hospital mortality. In one report, recurrent VT accounted for 46% of hospital deaths, and 85% of patients with hospital deaths presented with VT storm.^{131,132} In patients with multiple risk markers, prophylactic mechanical hemodynamic support and adoption of substrate-based ablation approaches (without inducing VT) need to be considered to minimize the risk of hemodynamic decompensation.¹²⁹

Video 22.1 Ventricular Fibrillation Triggered by Coronary Artery Spasm. Ambulatory cardiac monitor (Holter) recordings in a patient with recurrent syncope and presyncope. There was no evidence of structural heart disease on echocardiogram and cardiac stress testing. During the monitored period, patient developed several episodes of ST elevation (indicative of acute myocardial injury) associated with a high burden of PVCs. The last episode of ST elevation triggered sustained VT that degenerated into VF. The arrhythmia terminated spontaneously within less than 3 minutes, followed by AIVR and then NSR with resolution of ST elevation. The patient was found to have coronary artery spasm, which was treated medically with resolution of symptoms and arrhythmias. *AIVR*, Accelerated idioventricular rhythm; *NSR*, normal sinus rhythm; *PVCs*, premature ventricular complexes; *VF*, ventricular fibrillation; *VT*, ventricular tachycardia.

Video 22.2 Postinfarction Ventricular Tachycardia: Rhythmia Activation, Propagation, and Voltage Maps. Electroanatomic (rhythmia) maps of the left ventricle are acquired during sustained ventricular tachycardia in a patient with a previous large anteroapical infarction. Voltage scanning (scar thresholding) involves careful step-by-step manual adjustment of voltage upper and lower limits on the color-coded electroanatomic voltage map can help maximize the color contrast between adjacent myocardium with different electrogram voltage levels within the 0.5-mV scar and, thus, unmask channels of viable myocardium within a dense scar. Local electrograms at different sites of the electroanatomic map (as indicated by the catheter tip icon) are also shown. Ablation at the isthmus of the tachycardia circuit resulted in elimination of the tachycardia. *EGM*, Electrogram; *LV*, left ventricle.

PATHOPHYSIOLOGY

Ventricular tachycardia (VT) is usually associated with structural heart disease—most commonly coronary artery disease and cardiomyopathy. However, about 10% of patients who present with VT have no obvious structural heart disease (idiopathic VT). Absence of structural heart disease is usually suggested if the electrocardiogram (ECG) (except in Brugada syndrome and long QT syndrome), echocardiogram, and coronary arteriogram collectively are normal.

Nevertheless, cardiac magnetic resonance (CMR) may demonstrate mild structural abnormalities and subtle areas of diminished wall motion in some patients with idiopathic VT, even if all other test results are normal. In addition, focal dysautonomia in the form of localized sympathetic denervation has been reported in patients with VT and no other obvious structural heart disease. However, there is no conclusive evidence that such structural abnormalities are causally related to idiopathic ventricular arrhythmias (VAs). Of note, idiopathic VAs can also occur in patients with apparent structural heart disease, in whom the structural cardiac abnormalities are not related to the VAs. Furthermore, frequent or incessant idiopathic VAs can be a cause of cardiomyopathy.

Several distinct types of idiopathic VTs have been recognized and classified with respect to the chamber of origin of the VT (right ventricle [RV] vs. left ventricle [LV]), VT morphology (left bundle branch block [LBBB] vs. right bundle branch block [RBBB] pattern), response to exercise testing, response to pharmacological agents (adenosine-sensitive versus verapamil-sensitive vs. propranolol-sensitive VT), and behavior of VT (repetitive salvos vs. sustained).

A prototype of an idiopathic focal VAs is outflow tract (OT) VAs. Approximately 90% of OT VAs are caused by one of two phenotypic forms of adenosine-sensitive VT. Repetitive monomorphic VT is the most common form (60% to 90%) and is characterized by frequent isolated monomorphic premature ventricular complexes (PVCs), couplets, or salvos of nonsustained VT, interrupted by brief periods of normal sinus rhythm (NSR; Fig. 23.1). This form of VT usually occurs at rest or following a period of exercise, and typically decreases during exercise, but can be incessant. On the other hand, paroxysmal exercise-induced VT is characterized by sustained episodes of VT precipitated by exercise or emotional stress, separated by long intervals of NSR with infrequent PVCs (Fig. 23.2). Evidence has suggested that both types represent polar ends of the spectrum of idiopathic VT caused by triggered activity, and there is considerable overlap between the two types. Furthermore, this

Fig. 23.1 Surface Electrocardiogram of Repetitive Monomorphic Right Ventricular Outflow Tract Tachycardia. Repetitive bursts of ventricular tachycardia are present, with occasional sinus complexes.

Fig. 23.2 Surface Electrocardiogram of Sustained Right Ventricular Outflow Tract Tachycardia.

subtype classification, although useful, is not necessarily precise and depends on the means and duration of rhythm recordings. Patients are typically categorized based on their presenting or index arrhythmia. Prolonged telemetry and long-term ambulatory ECG recordings have demonstrated that most patients with one subtype of OT VAs show

evidence for at least one other subtype with an identical morphology. Almost all patients with nonsustained VT have high-density repetitive runs and frequent PVCs. In patients who present with repetitive PVCs, nonsustained VT can also be observed in approximately 70%; however, only 20% of these patients develop runs of more than five beats.

Mechanism of Focal Idiopathic Ventricular Tachycardia

Idiopathic VT comprises multiple discrete subtypes that are best differentiated by their mechanism, QRS morphology, and site of origin.¹ Most forms of focal idiopathic VAs are adenosine-sensitive and are thought to be caused by catecholamine-induced, cyclic adenosine monophosphate (cAMP)–mediated delayed afterdepolarizations (DADs) and triggered activity. Several features of idiopathic VAs support triggered activity as the underlying mechanism (see Chapter 3). Heart rate acceleration facilitates VT initiation. This can be achieved by catecholamine infusion or rapid pacing from either the ventricle or the atrium. In addition, termination of the VT is dependent on direct blockade of the dihydropyridine receptor by calcium channel blockers or by agents or maneuvers that lower cAMP levels (e.g., by activation of the M₂ muscarinic receptor with edrophonium or vagal maneuvers, inhibition of the beta-adrenergic receptor with beta-blockers, or activation of the A₁ adenosine receptor with adenosine). Furthermore, a direct relationship exists between the coupling interval of the initiating ventricular extra-stimulus (VES) or ventricular pacing cycle length (CL) and the coupling interval of the first VT beat. In addition, VT initiation is CL-dependent; pacing cycle lengths (PCLs) longer or shorter than a critical CL window fail to induce VT. This critical window can shift with changing autonomic tone. Notably, a small proportion (11%) of VAs are insensitive to adenosine.²

A subset of idiopathic focal VAs arises from the Purkinje system in either ventricle. Focal Purkinje VTs (classified as “propranolol-sensitive automatic VTs”) are typically provoked by exercise and catecholamines and are suppressed by beta-blockers (but not verapamil). Furthermore, programmed electrical stimulation fails to induce or terminate those arrhythmias. Purkinje VTs are transiently suppressed by adenosine and with overdrive pacing. These characteristics suggest abnormal automaticity as the underlying mechanism of focal Purkinje VTs, in contrast to the reentrant verapamil-sensitive fascicular VT. Purkinje VAs can manifest as monomorphic VT or PVCs, or as an accelerated idioventricular rhythm that competes with and can be suppressed by NSR.³

Other subtypes of idiopathic VAs include verapamil-sensitive, reentrant fascicular VT (see Chapter 24), and idiopathic polymorphic VT and ventricular fibrillation (VF; see Chapter 31). Those arrhythmias are discussed in elsewhere in this book. In this chapter, focal idiopathic monomorphic PVCs and VT are collectively referred to as “idiopathic ventricular arrhythmias (VAs).”

Mechanism of Premature Ventricular Complex-Induced Cardiomyopathy

Frequent idiopathic nonsustained VT or PVCs can precipitate a reversible form of dilated cardiomyopathy. The mechanisms of how frequent PVCs cause LV systolic dysfunction have yet to be elucidated. Potential mechanisms include (1) dyssynchronous ventricular contraction caused by abnormal ventricular activation during PVCs (similar to LBBB or ventricular pacing); (2) alterations in intracellular calcium handling and membrane ionic currents (caused by short PVC coupling intervals and post-extrasystolic potentiation of contractility); (3) abnormal ventricular filling (due to the postextrasystolic pause); (4) myocardial and peripheral vascular autonomic dysregulation; and (5) alterations in heart rate dynamics and hemodynamic parameters. Although PVC-induced cardiomyopathy was originally thought to be a type of tachycardia-induced cardiomyopathy, tachycardia is an unlikely mechanism, since the overall heart rates in patients with frequent PVCs have remained within the normal range due to the usual compensatory pause following the PVC. Interpolated PVCs can increase the overall heart rate.^{4–6}

The most prominent predictor of cardiomyopathy in patients with frequent PVCs appears to be the daily burden of PVCs. However, the

PVC burden necessary to induce LV dysfunction is not yet clearly defined.⁷ Although a PVC burden as low as 4% to 10% can be associated with cardiomyopathy, a PVC burden of more than 13% to 24% appears to be more likely to cause PVC-induced cardiomyopathy.

Nonetheless, it is well recognized that considerable variability exists in susceptibility to PVC-related cardiomyopathy, even among patients with high PVC burden. Multiple other factors were linked to the development of PVC-induced cardiomyopathy, including (1) lack of symptoms (with the consequent delay of diagnosis and treatment); (2) broader PVC-QRS duration (>140 or >153 milliseconds, likely due to more pronounced mechanical dyssynchrony); (3) longer PVC coupling interval (due to more pronounced LV dyssynchrony); (4) percent PVC interpolation; (5) non-OT site of origin of PVCs (in particular papillary muscle and epicardial foci); (6) presence of retrograde P waves following PVCs (likely related to worsened hemodynamics caused by simultaneous atrial and ventricular contraction); and (7) constant PVC burden throughout the day and night (i.e., less circadian fluctuation in PVC frequency). However, it is important to recognize that there is inconsistent evidence as to whether these factors represent independent predictors of PVC-induced cardiomyopathy. In fact, different studies arrived at different conclusions regarding the association of the different factors with developing LV dysfunction. Furthermore, a significant overlap in these parameters usually exists between groups with and without PVC-induced cardiomyopathy, limiting their prognostic utility.^{6,8–13}

ANATOMICAL CONSIDERATIONS

Most idiopathic VAs originate from the OT region of either ventricle (most frequently from the right ventricular outflow tract [RVOT]). Other variants of OT VAs (with similar underlying electrophysiology [EP] mechanism) include VAs arising from the aortic sinuses of Valsalva, pulmonary artery, mitral or tricuspid inflow tracts, papillary muscles, and epicardial foci in close proximity to the coronary venous system (in the LV summit or cardiac crux). The thorough knowledge of the unique and complex anatomical relationships of the OTs is of utmost importance for analyzing the ECG and mapping findings during OT VAs, as well as for safe catheter maneuvering and ablation.

Right Ventricular Outflow Tract

The RVOT is the tube-like portion of the RV cavity above the supra-ventricular crest, and is defined superiorly by the pulmonic valve and inferiorly by the RV inflow tract and the top of the tricuspid annulus (the region of the His bundle [HB] and proximal right bundle branch). The RVOT passes cephalad in a posterior and slightly leftward direction. The lateral aspect of the RVOT region is the RV free wall. The medial aspect is formed by the anterior interventricular septum at the base of the RVOT and RV musculature opposite to the anterior left ventricular outflow tract (LVOT; as a cephalad continuation of the interventricular septum) and the root of the aorta (immediately adjacent to the right aortic sinus of Valsalva) at the region just inferior to the pulmonic valve (eFig. 23.1).

Although the medial aspect of the RVOT is frequently referred to as the “septal” wall, it should be noted that the OT per se is not part of the interventricular septum, and the septum is a component only of the most proximal (inferior) part of the RVOT at the branch point of the septomarginal trabeculation. Above this area, the RVOT curves to pass anterior and cephalad to the LVOT, and, therefore, any perforation in the “septal” part is more likely to go outside the heart than into the LV (Fig. 23.3).

From the coronal view above the pulmonic valve, the RVOT region is seen wrapping around the LVOT and the root of the aorta and extending leftward (see eFig. 23.1). Whereas the inflow portion of the RV lies

eFig. 23.1 Anatomy of the Outflow Tracts and Aortic Sinuses. These heart specimens illustrate the anatomical arrangement between the right ventricular outflow tract (RVOT) and the aortic sinuses. (A) Supero-anterior view shows that the RVOT passes leftward and superior to the aortic valve. (B) The superoposterior view shows the left (L) and right (R) coronary aortic sinuses adjacent to the pulmonary infundibulum. The noncoronary (N) aortic sinus is remote from the RVOT but is related to the mitral valve (MV) and central fibrous body. The dotted line marks the ventriculoarterial junction (VAJ) between the wall of the pulmonary trunk (PT) and right ventricular muscle. Note the cleavage plane behind the pulmonary infundibulum and in front of the aortic root. (C) and (D) These simulated parasternal long-axis sections show two halves of the same heart and display the left and right coronary orifices. The right- and left-facing pulmonary sinuses (R and L in circles, respectively) are situated superior to the aortic sinuses. The fibrous continuity between the aortic and mitral valves (arrowheads in C) lies between the noncoronary leaflet and the posterior part of the left coronary leaflet, to a greater or lesser extent. The posterior part of the right coronary aortic sinus is adjacent to the central fibrous body (asterisk in C), which carries within it the penetrating His bundle. The dotted line marks the epicardial aspect of the subpulmonary infundibulum in the so-called "septal" area (as illustrated in E). *Inf*, Inferior; *LAA*, left atrial appendage; *LCA*, left coronary artery; *LV*, left ventricle; *RAA*, right atrial appendage; *RCA*, right coronary artery; *SVC*, superior vena cava; *Sup*, superior; *TV*, tricuspid valve; *VS*, ventricular septum. Repetitive monomorphic ventricular tachycardia originating from the aortic sinus cusp: electrocardiographic characterization for guiding catheter ablation. *J Am Coll Cardiol*. 2002;39:500.)

Fig. 23.3 Anatomical Relationships for Ablation of Outflow Tract Ventricular Tachycardia (VT). Most right ventricular outflow tract (RVOT) VTs arise from just proximal to the pulmonic valve; note that the RVOT in this region is all free wall (not septal wall) and the leftward aspect of the RVOT is very near the left main coronary artery (LM), making it vulnerable to injury. Note also the close relationships among RVOT, aortic sinuses of Valsalva, and subaortic left ventricle (LV), explaining why VTs from this general region can have similar electrocardiographic morphologies. Ao, Aorta; PA, pulmonary artery; RV, right ventricle.

to the right and anterior to the inflow portion of the LV, the RVOT courses anterior to the LVOT such that the distal RVOT and pulmonic valve are located to the left of the aortic valve and the distal LVOT. The pulmonic valve is typically placed approximately 1 to 2 cm cephalad and to the left of the aortic valve and offset 90 degrees from the aortic valve in the horizontal plane. Hence the supra-ventricular portion of the aorta lies in immediate proximity to the portions of the pulmonic valve. Immediately anterior to the aortic valve is the posterior muscular infundibular portion of the RVOT.¹⁴

The top of the RVOT can be convex or crescent-shaped, with the posteromedial region directed rightward and the anterolateral region directed leftward. The anteromedial aspect of the RVOT actually is located in close proximity to the LV epicardium, adjacent to the anterior interventricular vein and in proximity to the left anterior descending coronary artery. The aortic sinuses of Valsalva sit squarely within the crescent-shaped posterior region of the RVOT and are inferior to the pulmonic valve (see eFig. 23.1). The most posterior aspect of the RVOT is adjacent to the region of the right sinus of Valsalva, and the posteromedial (leftward) surface is adjacent to the anterior margin of the right sinus of Valsalva or the medial aspect of the left sinus of Valsalva.

The thickness of the RVOT wall is variable, ranging from approximately 3 to 6 mm, and is thinnest in the rightward, anterior, and subpulmonic valve portions, and thickest in the posterior infundibular part that is adherent to the anterior LVOT as a cephalad continuation of the interventricular septum. Of note, despite the absence of epicardial connections, subendocardial fibers connect the RVOT and LVOT across the infundibular septum.¹⁵

Pulmonary Root

The pulmonic and aortic valves are not at the same level (see eFig. 23.1). The pulmonic valve, the most superiorly situated of the cardiac valves, lies at the level corresponding to the third left costal cartilage at its junction with the sternum. The transverse plane of the aortic valve slopes inferiorly, away from the plane of the pulmonic valve, such that the orifice of the aortic valve faces rightward at an angle of at least 45 degrees from the median plane.

Because of its anterior and leftward location, only the posterior and rightward parts of the pulmonary artery have important relations with other cardiac structures. Of the three cusps of the pulmonic valve, the septal (right) pulmonic cusp lies at variable distances from and sometimes adjacent to the distal portions of the right atrial (RA) appendage. The left pulmonic cusp, being the most superficial, lies immediately beneath the pericardium and has no other cardiac structures related to it. The posterior pulmonary cusp overlies in the proximal portion of the left main coronary artery and the distal portions in the LA appendage. The supra-ventricular portion of the aorta lies close to and in some cases adjacent to the junction and surrounding parts of the right and posterior pulmonic cusps.

The pulmonary sinuses are not as prominent as the aortic sinuses. Nonetheless, owing to the semilunar configuration of the valvular leaflets, the hinge line of each leaflet crosses the ventriculo-arterial junction at two points. Consequently, there are always small segments of the infundibular myocardium at the nadirs of the three sinuses. Between adjacent sinuses, the wall comprises small triangles of fibrous tissue that become incorporated into the RV when the valve closes. On the epicardial aspect, the ventriculo-arterial junction is not always a sharply defined line. Sleeves of ventricular myocardium extend above the semilunar valves for a variable distance (a few millimeters and up to more than 2 cm).

The subpulmonary infundibulum is an entirely muscular funnel that supports in uniform fashion the leaflets of the pulmonic valve. As a result, all three pulmonary sinuses are continuous with myocardium of the RVOT.¹⁶ The muscular fibers typically extend circumferentially

around the pulmonic valve between and above all three cusps just above the annulus; more distally the extension is patchy and generally asymmetrical. The presence of fibrosis and fatty tissue among these muscular sleeves may create a possible substrate for VAs.¹⁷ In studies using pulmonary arteriography or intracardiac echocardiography (ICE) to accurately identify the location of the pulmonic valve, up to 50% of “RVOT” arrhythmia foci were actually localized beyond the pulmonic valve.^{18–20}

Left Ventricular Outflow Tract

Unlike the RV, the inflow and outflow regions of the LV are at an acute angle to one another. Although commonly referred to as the LVOT, there is no tubular muscular “tract” in the LV outflow region. The LVOT consists of both muscular and fibrous portions. This contrasts with the RVOT, which is composed entirely of myocardium. The central location of the aortic valve places the LVOT between the mitral valve and the ventricular septum. The curvature of the ventricular septum forms the anterosuperior wall of the LVOT, and this continues smoothly into the LV wall. The major portion of the septal component is primarily muscular, but also includes the membranous portion of the ventricular septum. Adjoining the membranous septum is the fibrous half of the LVOT that makes up the posterior wall. This is formed by the area of fibrous continuity between the aortic valve and the anterior leaflet of the mitral valve. The mitral leaflet hangs like a curtain between the inflow and OTs of the LV.²¹ The extremities of the fibrous continuity are the left and right fibrous trigones, the right trigone forming the central fibrous body. The LVOT passes underneath the RVOT in a rightward and cephalad direction pointing toward the right shoulder (see Fig. 23.3).²²

The atrioventricular node (AVN), located in the wall of the right atrium at the apex of the triangle of Koch, is relatively distant from the aortic root. As the conduction axis penetrates through the central fibrous body, however, it is positioned at the base of the interleaflet triangle between the noncoronary and right aortic sinuses (eFig. 23.2).²³

Aortic Root

The aortic root is the portion of the LV outlet that supports the leaflets of the aortic valve and represents the interface between the LV and the ascending aorta. The aortic root extends from the sinotubular junction in the aorta to the plane defined by the bases of the aortic valve leaflets attaching to the crown shaped aortic annulus. Within these boundaries, the aortic root is composed of the aortic valve leaflets, the sinuses of Valsalva, and the interleaflet triangles (eFig. 23.3).

Sinotubular Junction

The sinotubular junction marks the junction of the sinuses and the aorta proper. On the innermost aspect of the aortic wall, the sinotubular junction forms a slightly raised ridge of thickened aortic wall (known as the sinotubular ridge or supra-aortic ridge) at the upper margin of each sinus.²³

Aortic Valve

The aortic valve is normally composed of three symmetrical, semilunar-shaped leaflets (cusps). Each aortic cusp has (1) a functional hinge point where it attaches to the aortic root, (2) a body of the semilunar valve, and (3) a coaptation surface of the leaflet with a thickened central nodule (nodule of Arantius). The hinge points of the aortic leaflets attach to the fibrous skeleton within the aortic root in a semilunar fashion, instead of the traditional sense of a ring-like, annular valvular attachment. Therefore the hinge line of the attachment of the aortic valvular leaflets actually forms a crown-like structure (the annulus fibrosus) with the tips right at the sinotubular junction and the nadirs within the LVOT (see eFig. 23.3). The apices of the leaflets attaching to the annulus fibrosus

eFig. 23.2 Schematic Illustration of Aortic Root Anatomy in Relation to the Atrioventricular Conduction Axis. The cartoon shows the location of the atrioventricular conduction axis as it would be seen by a surgeon looking down through the aortic root. (Reproduced by kind permission of Professor Robert H. Anderson. Mrs. Gemma Price retains the intellectual copyright in the drawings used.)

eFig. 23.3 Schematic Illustration of Aortic Root Anatomy. (A) The cartoon shows a bisected aortic root, and illustrates how the semilunar attachment of the valvar leaflets incorporates aortic wall in the interleaflet triangles, and ventricular tissues at the base of each of the coronary aortic sinuses. (B) The cartoon shows an idealized aortic root. The attachments of the valvar leaflets, shown in red, extend through the entire length of the root, from the sinotubular junction, in blue, to the virtual basal ring, shown in green, and produced by joining together the basal attachments of the leaflets. The crown-like attachments of the leaflets cross the anatomical ventriculo-aortic junction, shown in yellow. (C) The cartoon shows a longitudinal section across the aortic root. C

eFig. 23.3—cont'd

attach to the sinotubular junction. The bases of the aortic leaflets attach to the annulus at or below the anatomical ventriculo-arterial junction. The semilunar hinge lines of adjacent leaflets meet at the level of the sinotubular junction, forming the commissures.²¹

Aortic Sinuses

Corresponding with each of the three valvular leaflets, the aortic root is expanded forming the three aortic “sinuses of Valsalva.” The aortic sinuses of Valsalva are defined inferiorly by the attachments of the aortic valve leaflets and superiorly by the sinotubular junction (see eFig. 23.3). Three equally spaced sites of minimal tethering within the aortic root mark the junctions of the sinuses of Valsalva. Each sinus is associated with a leaflet of the aortic valve, whereas the junctions between the adjacent sinuses are aligned with the commissures between the aortic valve leaflets. Two of the aortic sinuses give rise to the left and right coronary arteries, and these sinuses are termed right and left coronary sinuses (CS), respectively (see eFig. 23.2). Usually no vessels arise from the third sinus, which is then termed the noncoronary aortic sinus. In anatomical descriptions, however, the aortic sinuses (and cusps) are named anterior (for right coronary), left posterior (for left coronary), and right posterior (for noncoronary). In attitudinal orientation, however, the sinuses are in anterior, left posterolateral, and right posterolateral positions, respectively (see eFig. 23.1).²¹

Interleaflet Triangles

Because of the semilunar nature of the attachments of the valvular leaflets, there are three triangular extensions of the LVOT that reach to the level of the sinotubular junction. Therefore, when considered as a whole, the aortic root is divided by the semilunar attachment of the aortic leaflets (i.e., leaflet annulus) into supra- and subvalvular components. The supra- and subvalvular components, the aortic sinuses, are primarily aortic in structure, but contain structures of ventricular origin at their base. The supporting subvalvular parts (the interleaflet triangles) are primarily ventricular (eFig. 23.4). However, these triangles are formed not of ventricular myocardium but of the thinned fibrous walls of the aorta between the expanded sinuses of Valsalva.^{16,18}

Ventriculo-Aortic Junction

Unlike the tricuspid and pulmonic valves that occupy opposite ends of the banana-shaped RV, the aortic and mitral valvular orifices are fitted alongside each other (with no muscle in between) within the elliptical ostium of the LV. As a result, the leaflets of the aortic valve are attached only in part to the muscular walls of the LV. About half of the circumference of the lower part of the aortic root is connected to the muscular ventricular septum, with the remaining half in fibrous continuity with the anterior leaflet of the mitral valve.^{16,21,23}

The “anatomical” ventriculo-aortic junction is a circular locus within the aortic root, marking the interface between the ventricular structures and the fibro-elastic walls of the aortic sinuses. This discrete ring, however, is markedly discordant with the morphology of the semilunar attachment of the leaflets of the aortic valve (the annulus fibrosus) that form the “hemodynamic” junction between the LV and the aorta. Indeed, ventriculo-aortic junction is crossed at several points by the hinge lines of the valvular leaflets. As a result, a crescent of ventricular musculature is incorporated at the base of each of the right and left aortic sinuses. In contrast, there is no muscular crescent at the base of the noncoronary sinus, since this sinus has exclusively fibrous walls, the basal part beneath the anatomical ventriculo-aortic junction being part of the aortomitral continuity (see eFig. 23.4).²³

Furthermore, sleeves (isolated strands) of ventricular myocardium extend beyond the aortic valve attachments for variable distances (analogous to atrial myocardial extensions in the pulmonary veins [PVs]).

Myocardial extensions can be seen in the aortic wall, in the valve leaflet itself, or in the intercuspular region. The myocardial extensions within the aortic sinuses are mostly asymmetrical and do not exceed more than a few millimeters above the basal valvar attachment. Whereas the right sinus of Valsalva and the anterior portions of the left sinus of Valsalva frequently exhibit these myocardial sleeves (given their anatomical contact with ventricular myocardium), the posterior portions of the left sinus and the entire noncoronary sinus of Valsalva, particularly in relation to the aortomitral continuity, are exclusively fibrous and do not come in direct contact with the LV myocardium. The noncoronary cusp at its junction with the right sinus of Valsalva may have sleeves of ventricular myocardium, and at present, it is not clearly known whether myocardial extensions into the noncoronary sinus represent atrial or ventricular myocardium.^{16,23}

Approximately 10% to 15% of idiopathic VAs require ablation within the aortic root. The left sinus of Valsalva is the most common source, followed by the right sinus, and then the left-right sinus junction. The substrate of this VT likely originates from the strands of ventricular myocardium present at the bases of those sinuses. In contrast, the base of the noncoronary sinus of Valsalva is composed of fibrous tissue and, thus, is an extremely rare site of origin of VT (7% of the idiopathic aortic root VAs). However, the nature of the actual substrate being ablated has not been clearly defined. For example, the ablation electrode placed in the depth of the right sinus of Valsalva may be mapping and ablating a focus arising from the supra- and subvalvular extension into the cusp, LVOT myocardium, or a deeper posterior RVOT myocardium.^{22,24}

Anatomical Relationships

The aortic valve is the cardiac centerpiece; it lies in contact or continuity with all four cardiac chambers and shares important proximate relationships with each of the other cardiac valves (see Fig. 9.1). It comes into contact with the RA, LA, interatrial septum, RVOT, mitral valve (aortomitral continuity), pulmonic valve, tricuspid valve, and conduction system (see eFig. 23.1). The aortic valve plane tilts rightward (at about 30 to 45 degrees) in the horizontal plane as it is joined to the LV ostium. This positions the noncoronary sinus of Valsalva as the most inferior of the aortic sinuses, the left sinus of Valsalva as the most superior, and the right sinus of Valsalva as the most anterior. The degree of tilt is determined by the axis of the LV and can vary substantially among different individuals. As the LV axis flattens horizontally, the right and noncoronary sinuses are displaced inferiorly relative to the left sinus.¹⁴ The aortic root is inferior, posterior, and somewhat rightward compared with the RVOT. The posterior subpulmonic valve portions of the RVOT are immediately anterior and more proximally continuous with the anterior myocardial subaortic LVOT and more distally to the right sinus (eFig. 23.5). The lateral and more distal portions of the left sinus of Valsalva lie immediately subjacent to the peripulmonic valve portions of the RVOT.^{16,23}

The triangle between the noncoronary and left sinuses is part of the aortomitral fibrous continuity. The triangle between the noncoronary and the right sinuses is directly continuous with the membranous part of the ventricular septum. The triangle between the left and right sinuses is the least extensive of the three, and abuts the muscular sub-pulmonary infundibulum (see Fig. 9.1).^{16,23}

Left Aortic Sinus of Valsalva

The left sinus of Valsalva lies to the left of the right sinus and is related to the posterior wall of the RVOT (see Fig. 9.1). The anterior part of the left sinus and the commissure between the right and left sinuses lie just posterior to the distal RVOT and are close but caudal to the posterior pulmonic valve annulus. The rest of the left sinus (more leftward

eFig. 23.4 Anatomy of the Ventriculo-Aortic Junction. The aortic root has been opened from behind and spread apart, so that the full width of the cylinder can be seen. The aortic valvar leaflets have then been removed, revealing the semilunar nature of their attachments. The purple dotted line shows the anatomical ventriculo-aortic junction, which is the union between the ventricular musculature and the aortic wall at the bases of the left and right coronary aortic valvar sinuses, but between the aortic wall and fibrous continuity with the mitral valve at the base of the noncoronary sinus. Note how the semilunar attachments incorporate muscle at the base of the right and left coronary aortic sinuses, but fibrous tissue within the ventricle as the hinge lines extend distally to reach the sinotubular junction. (Reproduced by kind permission of Professor Robert H. Anderson.)

eFig. 23.5 Anatomy of the Aortic Root and Left Ventricular Outlet. (A) and (B) are two halves of the same heart sectioned longitudinally through the left ventricle (LV), left atrium (LA), and aorta (Ao) to show the mitral leaflet between inflow and outflow regions in the LV. This section replicates the parasternal long axis echocardiographic cut. Note that the aortic root is the centerpiece of the heart. The right ventricular outflow tract (RVOT) is anterosuperior to the LV outlet. The three broken lines mark the levels of the aortic root at the sinotubular junction, at the sinuses, and at the bases of the aortic leaflets. (From Ho SY. Structure and anatomy of the aortic root. *Eur J Echocardiogr.* 2009;10:3–10.)

and posteriorly) lies in fibrous continuity with the anterior leaflet of the mitral valve (namely, the aortomitral continuity). Adjacent to this site lies the peripulmonic valve myocardium and, more laterally, the posterior lobe of the LA appendage (when present). Rightward tilting of the aortic root causes the left sinus to be situated higher than the right and noncoronary sinuses. The right sinus of Valsalva and anterior part of the left sinus are connected with the ventricular musculature at their bases because the semilunar leaflets are hinged superiorly to the aortic wall but inferiorly to muscle.²²

Right Aortic Sinus of Valsalva

The right aortic sinus is the most anterior sinus relative to the sternum, and it lies immediately posterior to the relatively thick posterior infundibular portion of the RVOT (see Fig. 9.1). Caudally, there is continuity with the anterior LVOT, and at the level of valve insertion there is either physical continuity or very close proximity between the myocardium that extends above this sinus, the LVOT, and the posterior RVOT (see eFig. 23.1). The posterior part of the right sinus of Valsalva is adjacent to the central fibrous body, which carries within it the penetrating portion of the HB. Anteriorly, the right sinus is related to the bifurcating AV bundle and the origin of the left bundle branch (see eFig. 23.2). The right sinus does not have a direct relationship with either atrium, but lateral to the commissure with the noncoronary sinus lies the RA appendage, trunk of the right coronary artery, and a variable amount of fat (eFig. 23.6).

Noncoronary Aortic Sinus of Valsalva

The noncoronary sinus of Valsalva is the most posterior, inferior, and medial of the aortic cusps. The noncoronary sinus lies immediately anterior to the interatrial septum and superior to the central fibrous body and has the RA and LA as the posterior right and left relations, respectively (see eFigs. 23.2 and 23.6). Because of this relationship to the atria, some atrial tachycardias (ATs) arising from the roof of the interatrial septum can be ablated only within the noncoronary sinus. For most of its anatomical course, the noncoronary sinus is attached to the anterior leaflet of the mitral valve from its most leftward extent in continuity with the left sinus commissure. Only the most anterior and rightward extension of the noncoronary sinus comes into contact with the interventricular septum near its junction with the right sinus of Valsalva. The commissure between the noncoronary and the right sinuses is located immediately adjacent to the commissure of the anterior and septal leaflets of the tricuspid valve (see Fig. 9.1). The joining of these commissures forms the membranous portion of the interventricular septum and is the location of the penetrating HB. The compact AVN itself is located more posteriorly and inferiorly to this commissure. The membranous septum is crossed on its right side by the hinge of the tricuspid valve, which divides the septum into *atrioventricular* and *interventricular* components. The membranous septum and anterior mitral leaflet almost completely separate the noncoronary sinus from the LV myocardium. Because of this limited relationship to the ventricle, VAs originating from the noncoronary sinus are very rare (7% of the idiopathic aortic root VAs).^{22,24}

Aortomitral Continuity

The cardiac skeleton consists of four rings of dense connective tissue that surround the AV canals (mitral and tricuspid) and extends to the origins of the aorta and the pulmonary trunk. The aortic valve occupies the central position with the other valve rings attached to it or nearby (pulmonic). The right fibrous trigone is formed by the triangular formation between the aortic valve and the medial parts of the tricuspid and mitral valves, and it represents the largest thickening and strongest portion of the cardiac skeleton. Together with the membranous

septum, the right fibrous trigone constitutes the central fibrous body (see Fig. 9.1).

Another junction between the mitral annulus and aortic valvular ring occurs at the left fibrous trigone, anchoring the anteromedial aspect of the mitral annulus to the base of the left aortic sinus of Valsalva. The left fibrous trigone is less substantial than the right fibrous trigone. Between the left and right fibrous trigones, a rigid and broad fibrous curtain (often referred to as the aortic curtain) extends across the anterior leaflet of the mitral valve and supports the aortic valve leaflets. The aortomitral continuity refers to a fibrous continuity of the medial part of the noncoronary and left sinuses and the anterior mitral leaflet.²²

The membranous interventricular septum is an inferior extension of the central fibrous body that attaches to the muscular interventricular septum. The membranous septum is crossed on its right aspect by the attachment of the tricuspid valve, dividing the septum into atrioventricular and interventricular components. As a result, the membranous septum separates the LVOT from both the RV and RA; the line of attachment of the tricuspid annulus determines the line of division between the RV and RA.²⁶ The penetrating HB runs through the portion of the membranous interventricular septum at the commissure where the right sinus of Valsalva meets the noncoronary sinus (see Fig. 9.1).

Although the aortomitral continuity is a fibrous structure, catheter ablation in this region can successfully eradicate VAs arising in this vicinity. The exact origin of arrhythmias ablated from this fibrous region is still uncertain.

Left Ventricular Summit

The LV summit refers to the most superior portion of the LV epicardium, which lies on the basal portion of the LV ostium next to the septum and the anterior mitral annulus, abutting on the left aortic sinus of Valsalva superiorly, laterally, and anteriorly.²⁷

The LV summit represents the triangular region in the epicardial LVOT with its apex at the bifurcation of the left main coronary artery (between the left anterior descending and the circumflex coronary arteries) and its base formed by an arc connecting the first septal perforator branch of the left anterior descending coronary artery and the circumflex coronary artery (eFig. 23.7). The left main coronary artery arises cranial to the left sinus of Valsalva (about 15 to 20 mm above the nadir of the cusp). The aortomitral continuity and LV summit face each other, with the superior end of the LV muscle between them.²⁹

The great cardiac vein bisects the LV summit into superior (closer to the apex of the summit) and inferior regions. Approximately 12% of VAs from the LV are estimated to occur from the LV summit. While the inferior portion of the summit is usually accessible to epicardial catheter ablation, successful ablation in the superior region is frequently limited by the close proximity of the coronary arteries and the thick layer of epicardial fat that overlies the proximal portion of these vessels.²²

Left Ventricular Papillary Muscles

The anterolateral (or anterior) and posteromedial (or posterior) LV papillary muscles are thick, finger-like processes attached to the ventricular wall at one end and to the mitral leaflets by multiple tendons (chordae tendineae) on the other end (Fig. 23.4). The anterior papillary muscle originates from the middle to apical region of the LV ventral wall, lies on the anterolateral free wall, and provides chordae to the anterolateral half of the anterior and posterior mitral leaflets. The posterior papillary muscle arises from the inferoseptal wall of the LV, lies between the LV septum and posterior free wall, and provides chordae to the posteromedial half of both leaflets. The anterior papillary muscle typically has a single head, while the posterior papillary muscle often has two heads.³¹ Focal VAs generally originate from the base of the papillary muscle.³¹

LCC, Left coronary cusp; NCC, noncoronary cusp; RA, right atrium; RCC, right coronary cusp; RVOT, right ventricular outflow tract; TV, tricuspid valve.

eFig. 23.7 Cardiac Computed Tomography Reconstruction Depicting the Anatomy of the Left Ventricular (LV) Summit. The LV summit is a triangular region of the LV epicardium with the apex at the bifurcation between the left anterior descending (LAD) and left circumflex (LCx) coronary arteries, and the base formed by an arc connecting the first septal perforator branch (SP) of the LAD with the LCx (white dotted line and arrows). The LV summit is bisected by the great cardiac vein (GCV) in 2 regions: (1) closer to the apex of the triangle (blue dotted line, inaccessible area), and (2) more lateral toward the base of the triangle (yellow dotted line, accessible area). AIVV, Anterior interventricular vein; LM, left main coronary artery. (From Santangeli P, Lin D, Marchlinski FE. Catheter ablation of ventricular arrhythmias arising from the left ventricular summit. *Card Electrophysiol Clin*. 2016;8:99–107.)

Fig. 23.4 Anatomy of the Left Ventricular (LV) Papillary Muscles. (A) Three-dimensional reconstruction of the cardiac multidetector computed tomography and integration to the mapping system guided by intracardiac echocardiography. This corresponds to a lateral view of the endocardial aspect of the LV. The papillary muscles are depicted in blue, whereas the aortic root and left coronary artery are depicted in red. (B) Left lateral view of the LV and aortic root. The anterior papillary muscle in blue and the rest of the LV in red. (C) Posterior view of the LV (red) and aortic root (gray). Notice the anterior and posteromedial papillary muscles in blue. (From Rivera S, Ricapito Mde L, Tomas L, et al. Results of cryoenergy and radiofrequency-based catheter ablation for treating ventricular arrhythmias arising from the papillary muscles of the left ventricle, guided by intracardiac echocardiography and image integration. *Circ Arrhythm Electrophysiol.* 2016;9:1–9.)

The peripheral Purkinje network extends to the surface of the papillary muscles. Free-running false tendons traverse the ventricular chamber and reattach at the free wall myocardium, projecting predominantly toward the papillary muscles. The left anterior fascicle crosses the antero-basal LV region toward the anterior papillary muscle and terminates in the Purkinje system of the anterolateral LV wall. The left posterior fascicle fans out extensively toward the posterior papillary muscle and terminates in the Purkinje system of the posteroinferior LV wall. The close relationship that exists between the Purkinje fiber and papillary muscles has caused some difficulties in distinguishing arrhythmias from the two structures. Furthermore, VAs originating from the body of the papillary muscle can exhibit multiple QRS morphologies caused by variable exit sites from an intramural focus or its attachment to false chordae.^{31,32}

Cardiac Crux

The cardiac crux (crux cordis, from Latin “crux” meaning “cross”) is the posteroseptal region (the diaphragmatic aspect) of the heart where the atrioventricular, interventricular, and interatrial grooves form a roughly cross-shaped intersection. This four-sided pyramidal space represents the confluence of all four cardiac chambers and the CS in their nearest proximity. The “basal” crux area lies in proximity to the ostium of middle cardiac vein, whereas the “apical” crux area lies near the posterior interventricular artery, more inferior and epicardial as compared with the basal crux area.³³ Hence the apical crux is often not accessible from the proximal CS or the middle cardiac vein, and a transcutaneous subxiphoid epicardial approach is typically required.³⁴

EPIDEMIOLOGY AND NATURAL HISTORY

Idiopathic VT comprises 10% of all patients referred for evaluation of VT. Idiopathic VAs are not evenly distributed, but have a predilection for originating from certain anatomical regions of the ventricles and aortic and pulmonary roots. Approximately 60% to 80% of idiopathic VAs arise from the ventricular outflow regions, including myocardium around the aortic and pulmonic cusps, as well as the summit of the LV. Although the RVOT has been the most common site of origin of OT VAs, a significant proportion (20% to 50%) arise from the LVOT and adjacent structures.²

Age at presentation is usually 30 to 50 years (range, 6 to 80 years). Women are more commonly affected, although LVOT VAs are more frequently observed in men. The clinical course is benign and the prognosis is excellent. Sudden cardiac death is rare. Spontaneous remission of the VT occurs in 5% to 20%. However, very frequent idiopathic nonsustained VT or PVCs can precipitate a potentially reversible form of LV systolic dysfunction (observed in about 5% to 7% of patients with a PVC burden >10%). The relationship between the LV dysfunction and VT may not be initially recognized, and those patients can present with heart failure symptoms and become diagnosed with idiopathic dilated cardiomyopathy, and may even undergo prophylactic implantation of a defibrillator, which unfortunately often results in the delivery of inappropriate shocks triggered by frequent nonsustained episodes of idiopathic VT. Rarely, monomorphic focal PVCs can trigger idiopathic polymorphic VT or VF in patients with no apparent structural heart disease.³⁵

CLINICAL PRESENTATION

When present, symptoms are mild in many of patients, but they can be disabling in some individuals. Most symptomatic patients present with palpitations, 50% develop lightheadedness, and a minority (<10%)

present with syncope. Symptoms can be attributed to the PVC, the subsequent compensatory pause, the hypercontractile sinus beat following the pause, or a combination of all. A sensation that the heart has “stopped” or pulsation in the head or neck can be noted.³⁶

Not infrequently, initial presentation can be related to effort intolerance due to fatigue and dyspnea, as a result of decreased effective cardiac function. Some patients can be completely asymptomatic and present with ectopy detected incidentally by an irregular pulse or on cardiac recordings obtained for other clinical reasons. Other patients present because of “low pulse rates,” which is related to ineffective ventricular contraction during PVCs with insufficient pressure to allow opening of the aortic valve.^{7,37}

Most commonly, patients present with frequent PVCs or short runs of repetitive nonsustained VT. Less frequently, paroxysmal sustained VT is observed. Idiopathic VAs are usually provoked by emotional or physical stress and stimulants such as caffeine. Not infrequently, however, VAs become quiescent during exercise and arise only during the recovery phase or during rest. In females, the burden of arrhythmia tends to increase during periods of hormonal variations (premenstrual and perimenopausal).

Frequent idiopathic nonsustained VT or PVCs can precipitate a reversible form of LV systolic dysfunction, and present with heart failure symptoms. Such arrhythmias may also exacerbate preexisting LV dysfunction and is a cause of loss of effective biventricular pacing in heart failure patients treated with cardiac resynchronization therapy. At the first clinical encounter, patients often present with both PVCs and LV dysfunction. In this setting, it can be difficult to determine the onset of frequent PVCs relative to the onset of LV dysfunction and whether the cardiomyopathy is PVC-induced or PVC-worsened.^{7,38}

INITIAL EVALUATION

The diagnosis of idiopathic VT is one of exclusion; structural heart disease, cardiomyopathy, and coronary artery disease should be excluded, usually by cardiac stress testing and echocardiography. Coronary angiography may be warranted, especially in those with LV systolic dysfunction and coronary risk factors.

Diagnostic features of idiopathic VAs include (1) structurally normal heart; and (2) QRS morphology consistent with site of origin from typical locations of idiopathic VAs (in particular, the RVOT or LVOT). The echocardiogram is normal in most patients. Slight RV enlargement is observed rarely.

Electrocardiography

The surface ECG during NSR is usually normal. Up to 10% of patients have complete or incomplete RBBB. Other ECG abnormalities may be observed when idiopathic VAs coexist with structural heart disease.

Idiopathic focal VAs are characterized by frequent monomorphic PVCs, couplets, or salvos of nonsustained VT, interrupted by brief periods of NSR (see Fig. 23.1). Paroxysmal exercise-induced VT is characterized by sustained episodes of VT precipitated by exercise or emotional stress (see Fig. 23.2). The tachycardia rate is frequently rapid (CL <300 milliseconds), but can be highly variable. A single morphology for the VT or PVCs is characteristic. QRS morphology during VAs on the surface ECG is discussed later in this chapter.

Ambulatory Cardiac Monitoring

Holter monitors can assess the burden of VAs and their correlation to symptoms. Cardiac event monitors are more appropriate when symptoms occur less frequently.

Several characteristics of idiopathic VAs can be observed on ambulatory cardiac monitoring. Idiopathic VAs typically occur at a critical

range of heart rates (CL dependence). The coupling interval of the first PVC is relatively long (approximately 60% of the baseline sinus CL). A positive correlation exists between the sinus rate preceding the VT and the VT duration. In addition, the VT occurs in clusters, and is most prevalent on waking and during the morning and later afternoon hours. Catecholamines increase during waking hours and nocturnal decrease in catecholamine levels, and predominance of vagal tone might account for the differences in the circadian PVC burden. The largest change in PVC burden is observed in the transition from the sleeping hours to the morning waking hours. Notably, the lack of circadian fluctuation in PVCs frequency has been correlated with increased risk of PVC-induced cardiomyopathy.

Idiopathic focal VAs are very sensitive to autonomic influences, resulting in poor day-to-day reproducibility. Therefore a single 24-hour recording may not reflect the true PVC burden. When frequent PVCs are strongly suspected, it may be necessary to obtain extended Holter recordings of 48 to 72 hours or several 24-hour Holter recordings.⁷

Exercise Electrocardiography

Exercise stress testing is recommended for evaluation of patients with exercise-related symptoms, but may not be clinically helpful in those in whom the arrhythmias have already been documented on ambulatory recordings.¹¹

Exercise testing can reproduce patients' clinical VT 25% to 50% of the time. Exercise-provoked VT usually manifests as nonsustained or, less often, sustained VT. In those with isolated PVCs, the frequency of PVCs tends to increase during exercise. The VT can be initiated either during the exercise test or during the recovery period. Both scenarios likely represent examples of the dependence of VT on a critical window of heart rates for induction. This window can be narrow and only transiently present during exercise, resulting in induction of VT only during recovery. In some patients with repetitive monomorphic VT, the VT can become suppressed during exercise. The response of VAs to exercise can be helpful in planning the strategy for arrhythmia induction during an ablation procedure.³⁹

Catecholaminergic polymorphic ventricular tachycardia (CPVT), also exercise dependent, can be distinguished by the alternating QRS axis with 180-degree rotation on a beat-to-beat basis (bidirectional VT) or polymorphic VT, which can degenerate into VF.¹¹

Cardiac Magnetic Resonance

CMR is of value when structural heart disease is suspected despite a normal echocardiogram. CMR can help exclude arrhythmogenic right ventricular cardiomyopathy (ARVC), amyloidosis, and sarcoidosis, among other diseases. CMR can also evaluate the presence and extent of myocardial fibrosis in patients with LV dysfunction.¹¹

It is important to recognize that CMR can reveal concealed myocardial structural abnormalities involving the RV and the LV among patients with apparently *idiopathic* VAs, including subepicardial or midmyocardial foci of fibrosis, acute inflammation, and focal fatty infiltration. Of note, the morphology of VAs appears to be related to the presence of such abnormalities on CMR. In contrast to the infrequent abnormalities noted among patients with VAs of LBBB pattern, CMR detected myocardial structural abnormalities (mainly involving the LV inferior and lateral wall) in a sizable proportion (41%) of patients with unexplained VAs with RBBB configurations (consistent with an LV origin). Whether these abnormalities are causally related to the observed VAs is uncertain; however, the presence of myocardial structural abnormalities on CMR seems to predict spontaneous sustained arrhythmias among patients presenting with apparently idiopathic VAs of LV origin.⁴⁰

DIFFERENTIAL DIAGNOSIS

It is important to differentiate idiopathic VT from other potentially malignant forms of VT that may also arise from the OT region, including VT in ARVC, CPVT, Brugada syndrome, and idiopathic polymorphic VT and VF. A Brugada ECG pattern, findings of reduced LV or RV function, polymorphic VT, multiple monomorphic VT morphologies, a history of recurrent syncope, or a family history of sudden cardiac death mandate further detailed evaluation.

Arrhythmogenic Right Ventricular Cardiomyopathy

RVOT VAs should, in particular, be distinguished from ARVC, a disorder with a more serious clinical outcome (see Chapter 29). Although RVOT VAs are associated with a benign prognosis with no familial basis, it can be extremely difficult to distinguish from the concealed phase of ARVC, in which typical ECG and imaging abnormalities are absent. The VT in ARVC also affects young adults, is commonly catecholamine-facilitated, and can originate from the RVOT. The distinction between the two entities has important prognostic and therapeutic implications.

Electrocardiogram During Sinus Rhythm

Although the VT in ARVC can have morphological features similar to RVOT VAs (LBBB with inferior axis), several ECG criteria during VT can help distinguish between the two arrhythmias. Longer QRS duration in lead I (≥ 120 milliseconds), late precordial transition (at lead V_5 or V_6), and the presence of notching in the QRS in multiple leads all favor ARVC over idiopathic RVOT VAs. In addition, the presence of an LBBB morphology with a superior axis is very unlikely in idiopathic RVOT VAs. Also, VAs in ARVC patients generally have lower QRS amplitude and more fragmentation, but these are qualitative differences and not always present.

In ARVC, the resting 12-lead ECG in NSR typically shows inverted T waves in the right precordial leads. When present, RV conduction delay with an epsilon wave (best seen in leads V_1 and V_2) is helpful in the diagnosis of ARVC. The resting surface ECG in NSR is typically normal in patients with idiopathic VT, with no epsilon wave, QRS widening or fragmentation, or other markers of delayed activation of the RV. Patients with idiopathic VT also have a normal signal-averaged ECG in NSR.

Nevertheless, the ECG can also be normal in up to 40% to 50% of patients with ARVC at presentation, but in almost no patient 6 years after initial diagnosis. Furthermore, approximately 10% of patients with idiopathic VT can have complete or incomplete RBBB during NSR.

Electrocardiogram During Ventricular Tachycardia

In general, patients with idiopathic VT typically present with a single-morphology VT. The presence of multiple VT morphologies and RV sites of origin of the VT that are inconsistent with idiopathic RVOT VT (e.g., LBBB with superior axis) should prompt the consideration of ARVC. Nonetheless, it should be recognized that patients with several idiopathic VT morphologies have been reported, and patients with ARVC can initially present with only one VT morphology consistent with an RVOT origin.⁴¹

During VTs with LBBB and inferior axis, certain features of the QRS complex favor ARVC over RVOT VT, including (1) late precordial transition (at V_5 or later); (2) QRS notching in at least two leads (in particular, leads I and aVL); and (3) QRS duration in lead I longer than 120 to 125 milliseconds. The most specific finding was late precordial transition (100% specificity at lead V_6 and 90% specificity at lead V_5 or later), and the most sensitive was duration of QRS in lead I exceeding

120 milliseconds, followed by the presence of any notching on the QRS complex. QRS notching and the longer QRS duration in ARVC reflect the abnormal myocardial substrate underlying the VT, which is lacking in idiopathic RVOT VT.^{42–44}

Invasive Electrophysiology Testing

An invasive EP study is usually not necessary to establish a diagnosis, although it can help exclude other forms of tachyarrhythmias in selected patients. The response of VT during EP testing can be helpful in distinguishing idiopathic RVOT VAs from ARVC. Reentry is the mechanism of VT in most ARVC patients, whereas RVOT VT almost always displays features of triggered activity. The repetitive initiation of these VAs by programmed ventricular stimulation suggests a reentrant mechanism, and is much more common in ARVC than idiopathic OT VAs (93% vs. 3%). In addition, recording fractionated diastolic electrograms during VT or NSR at the site of origin of VT or other RV sites is very rare with idiopathic RVOT VAs, but is typical for ARVC. As noted, the induction of VAs with different QRS morphologies is common in ARVC (observed in 73% of patients in one report) and is rare with RVOT VT. Furthermore, the VT in ARVC does not terminate with adenosine.⁴¹

In addition, electroanatomic voltage mapping can help distinguish early or concealed ARVC from idiopathic VT by detecting RV electroanatomical scars that correlate with the histopathological features pathognomonic of ARVC.

Isoproterenol Testing

An arrhythmogenic response to high-dose intravenous (IV) isoproterenol (45 $\mu\text{g}/\text{min}$ for 3 minutes, regardless of heart rate) can potentially help diagnose ARVC, particularly in the early stages of the disease. The occurrence of polymorphic VAs (PVCs and sustained and nonsustained VT) with predominant LBBB morphology (with features that are not typical for an RVOT origin) during isoproterenol testing (during isoproterenol infusion or within 10 minutes after the cessation of the infusion) is highly suggestive of ARVC (sensitivity, 91%; negative predictive value, 99%). In contrast, a sustained monomorphic RVOT VT response during isoproterenol testing is considered a negative response.⁴⁵

Cardiac Imaging

Patients with idiopathic VT have normal imaging studies (echocardiography, CMR, contrast ventriculography) of RV size and function. The presence of RV dilation or aneurysm is consistent with ARVC.

Dilated Cardiomyopathy

It is important to recognize that, in some patients, idiopathic VAs can coexist with structural heart disease, including cardiomyopathy, in which setting the VAs may not be related to the cardiac disease. On the other hand, very frequent idiopathic nonsustained VT or PVCs can precipitate dilated cardiomyopathy that can improve or completely resolve after elimination of the VAs. Therefore in patients who present with a dilated cardiomyopathy of unclear etiology and who have frequent PVCs or nonsustained VT, it is important to assess the contribution of VAs to LV systolic dysfunction. Failure to recognize a causal relationship between the arrhythmia and LV dysfunction can have important consequences. These patients can be misdiagnosed with “idiopathic” dilated cardiomyopathy and may not be offered therapeutic measures to reduce the PVC burden (e.g., catheter ablation), which can significantly impact LV systolic function and long-term outcome.

A reversible form of dilated cardiomyopathy precipitated by idiopathic VAs should be suspected when frequent PVCs or nonsustained VT are observed on a 24-hour Holter recording, especially when the QRS morphology is monomorphic and is suggestive of origin from typical locations of idiopathic VAs.

The diagnosis of PVC-induced cardiomyopathy is one of exclusion and often retrospective based on recovery of LV function after elimination of the arrhythmia, typically by catheter ablation. Although pharmacological suppression of the PVCs, such as by amiodarone therapy, may help evaluate the relationship between the arrhythmia and cardiomyopathy, the usefulness of this approach and duration of therapy required have not been defined.

Predictors of reversibility of LV systolic dysfunction in patients with PVC-induced cardiomyopathy include the absence of myocardial scar (on CMR), a large PVC burden baseline, and effective long-lasting elimination of PVCs. Although no single cutoff value of PVC burden completely discriminates reversible from irreversible LV dysfunction, a burden of $\geq 13\%$ at baseline was shown to predict recovery of left ventricular ejection fraction (LVEF) following ablation of PVCs.⁴⁶ Of note, early improvement in LVEF (at 1-week follow-up) post PVC ablation was shown to predict complete recovery of LV systolic function.⁴⁷ One report suggested that patients with PVC QRS duration of 170 milliseconds or longer are unlikely to normalize their LV function after ablation of the PVCs, suggesting that PVC QRS duration can be a marker of the presence and severity of underlying structural heart disease.^{12,38}

Given the large magnitude of potential improvement in LV systolic function that could be achieved by elimination of frequent PVCs (regardless of whether the cardiomyopathy is in fact PVC-induced or PVC-worsened), evaluation for the presence of frequent PVCs (by 24- or 48-hour Holter monitoring) needs to be considered in all patients with depressed LVEF. This is particularly important in patients who meet criteria for primary prevention implantable cardioverter-defibrillator (ICD) implantation, as the recovery of LVEF following ablation can potentially remove the ICD indication.⁴⁷

Idiopathic Ventricular Fibrillation

Idiopathic monomorphic focal VAs, although generally considered “benign,” can also trigger polymorphic VT and VF in some patients with idiopathic VF and no apparent structural heart disease (see Fig. 31.20). Hence, for patients presenting with idiopathic VF, it is imperative to pay special attention to recording potential monomorphic PVC “triggers,” since catheter ablation of those foci can potentially prevent further episodes of VF or reduce the burden of arrhythmias. Also, patients with polymorphic VT and VF should be carefully evaluated for underlying channelopathies.^{3,34,48}

Even in patients with no prior history of VF, it is also particularly important to distinguish the “malignant” from “benign” forms of idiopathic monomorphic VAs because the malignant form often leads to unexpected sudden cardiac death. Identification of patients presenting with idiopathic focal VAs carrying some risk for VF remains challenging. Malignant VAs should be suspected in patients with known idiopathic focal VAs who present with syncope. Patients with idiopathic VF frequently (57%) experience syncopal episodes before presenting with cardiac arrest.²

Several ECG parameters have been suggested as markers of malignant OT VAs. However, the diagnostic value of these ECG parameters is inconsistent and their clinical utility is limited. Although idiopathic VF and polymorphic VT can arise from triggers located in the RVOT and LVOT, PVCs arising from the Purkinje network, RV moderator band, papillary muscles, and apical cardiac crux, due to unclear mechanism, appear to be particularly prone to induce sustained VT and VF, leading to syncope or cardiac arrest. Therefore VAs with QRS morphology suggestive of those sites of origin should be carefully scrutinized.²

The prognostic implications of the coupling intervals of clinical PVCs have been debated. Although no absolute coupling interval cutoff identifies potentially “malignant” PVCs, shorter coupling interval to the preceding QRS complex, and a shorter CL during monomorphic

VT were found to predict the coexistence of VF or polymorphic VT in patients with idiopathic RVOT VT/PVCs; however, significant overlap exists. In contrast, one report showed that the prematurity index (defined as the ratio of the coupling interval of the first VT beat or isolated PVC to the preceding R-R interval of the sinus cycle just before the VT or isolated PVC), but not the coupling interval, was the only independent predictor for polymorphic VT. A more recent report found that the second coupling interval of nonsustained VT was significantly shorter in malignant OT VT than in benign OT VT. A second coupling interval of nonsustained VT of less than 317 milliseconds could predict a malignant OT VT with modest diagnostic accuracy (sensitivity 58%, specificity 87.5%). However, prospective validation of these criteria is yet to be tested in a larger population.⁴⁹

Other Arrhythmia Mechanisms

Idiopathic OT VT should be differentiated from other forms of VT with an LBBB pattern, including bundle branch reentrant VT (see Chapter 26), reentrant VT following surgical repair of congenital heart disease (see Chapter 30), and postinfarction VT originating from the LV septum (see Chapter 22). In addition, antidromic AVRT using an atriofascicular BT also presents with wide complex tachycardia with an LBBB pattern (see Chapter 18). Often the diagnosis of these VTs can be established without difficulty, given the frequently associated structural heart disease. Nevertheless, idiopathic focal VT also can occur in patients with unrelated structural heart disease, and the distinction of those “ablatable” VTs has important prognostic and therapeutic implications.

PRINCIPLES OF MANAGEMENT

Acute Management

Acute termination of most forms of idiopathic VT can be achieved by vagal maneuvers or IV administration of adenosine. IV verapamil is an alternative, provided the patient has adequate blood pressure and has a previously established diagnosis of a VT that is sensitive to verapamil. Hemodynamic instability warrants emergency cardioversion.

Chronic Management

Conservative Management

Given the generally benign long-term prognosis, reassurance and counseling, with no pharmacological therapy, are the preferred treatment for patients with idiopathic VAs who are asymptomatic or only mildly symptomatic and have normal LV function. Annual follow-up with ambulatory ECG monitoring and echocardiography is recommended in those with frequent PVCs ($>10,000$ PVCs per 24 hours) to monitor for possible development of cardiomyopathy, which should prompt the initiation of therapy.^{8,11,50}

Importantly, many patients with frequent PVCs do not complain of palpitations and present primarily with occult cardiac symptoms, such as weakness, fatigue, and effort intolerance. Such complaints should not be dismissed as “unrelated,” and those patients should not be labeled “asymptomatic.” Treatment to reduce the burden of PVCs should be considered to alleviate symptoms.^{11,37,51}

Although frequent PVCs can precipitate LV systolic dysfunction in some patients who are otherwise asymptomatic, there is currently no risk stratification model to reliably identify patients at risk. Therefore prophylactic PVC elimination for the sole purpose of preventing PVC-induced cardiomyopathy is not recommended.⁵¹

Pharmacological Therapy

Medical therapy can be considered in symptomatic patients. Beta-blockers, verapamil, and diltiazem are the first-line treatment. However,

these medications have a modest efficacy rate (only 10% to 15% of patients achieve $\geq 90\%$ PVC suppression), and they may not be well tolerated by the generally young patient population. Although class I and III antiarrhythmic drugs (sotalol, flecainide, mexiletine, propafenone, amiodarone) are more effective in reducing the burden of PVCs, they are not optimal as first-line therapy, given the potential for proarrhythmic risk and a greater side-effect profile.^{11,52–54}

Catheter Ablation

Catheter ablation is the treatment of choice for significantly symptomatic patients in whom long-term drug therapy is unsuccessful, not tolerated, or not desired. In addition, catheter ablation should be strongly considered in patients with “malignant” forms of idiopathic VAs, such as those with short-coupled PVCs and syncope or cardiac arrest, or in whom the PVCs were found to trigger polymorphic VT or VF.^{51–55}

Catheter ablation is also recommended for patients with frequent PVCs or nonsustained VT when they are presumed to be contributing to a cardiomyopathy or worsening of preexisting LV dysfunction, even in otherwise asymptomatic patients. Effective elimination of PVCs (reduction of PVC burden is by $>80\%$ or to <5000 PVCs per 24 hours) with ablation has been shown to improve LVEF, ventricular dimensions, mitral regurgitation, and functional status. A recent meta-analysis estimated a mean improvement of 12% in LVEF after PVC ablation, which was observed in the whole population of patients with frequent PVC and LV dysfunction. The magnitude of improvement is superior to that achieved by other heart failure treatments. Although improvement in LVEF after PVC ablation was initially described in patients with suspected PVC-induced cardiomyopathy, recent studies showed a comparable benefit in patients with previously diagnosed cardiomyopathy and therefore considered to have a “PVC-worsened” cardiomyopathy.³⁸ Importantly, the recurrence of PVCs (after initially successful ablation and subsequent normalization of LVEF) can again result in a decline of LVEF. Therefore long-term follow-up and reassessment of the PVC burden are recommended in these patients, particularly those whose PVCs were asymptomatic or pleomorphic.^{46,56,57}

Radiofrequency (RF) ablation now has cure rates of over 90%, which makes it a preferable option, given the young age of most patients with idiopathic VAs. Late recurrence (few months after an acutely successful ablation) of frequent PVCs (from the same area where the original predominant PVCs originated or from a different focus) can be observed in approximately 15% of the patients. Risk of recurrent PVCs after ablation is higher in patients who originally had multiple PVC morphologies, likely suggesting that nondominant PVCs can become dominant PVCs over time. Also, the risk of recurrence seems to be higher in patients in whom the PVCs originated from the papillary muscles.^{46,57}

Implantable Cardioverter-Defibrillator

ICD implantation is recommended in patients with prior cardiac arrest. ICD therapy also should be considered for patients with “malignant” idiopathic VAs that are found to trigger polymorphic VT or VF, especially those presenting with syncope and in whom the PVC trigger cannot be completely eliminated by catheter ablation.

Importantly, for patients presenting with frequent PVCs and LV systolic dysfunction (PVC-induced or PVC-worsened cardiomyopathy) who have a primary prevention indication for ICD implantation, it is advisable to consider therapeutic measures to reduce the PVC burden (such as catheter ablation) before implanting a prophylactic ICD. Elimination of PVCs with ablation has been shown to improve LVEF within a few months in the majority of these patients (especially those with PVC burden of $\geq 13\%$ at baseline) such that the patients no longer qualify for an ICD. Prophylactic ICD implantation in these patients

unfortunately often results in delivery of inappropriate shocks triggered by frequent nonsustained episodes of idiopathic VT. Therefore withholding the ICD and reevaluating within the first 6 months of ablation seems to be an appropriate and safe strategy.^{38,51}

ELECTROCARDIOGRAPHIC LOCALIZATION OF FOCAL VENTRICULAR TACHYCARDIA

Of all idiopathic VAs, approximately 70% arise from the ventricular OTs, more commonly in the RVOT. Up to 20% to 50% originate in the LV. For LV VAs, the aortic root (the right and left aortic sinuses of Valsalva or the commissure between the two sinuses) is the most common site of origin (70%). The LV summit accounts for 12%, while the LV ostium (septal para-Hisian, aortomitral continuity, and the mitral annulus) accounts for about 5% to 10%.^{58,59} Other less frequent sites of origin include the LV and RV papillary muscles, the moderator band, and cardiac crux (Table 23.1).^{3,22}

Due to the focal nature of most idiopathic VAs, the surface ECG is often very valuable for localizing the site of origin of the VT. Using the surface ECG to predict the site of origin of the OT VAS has important implications in preprocedural planning of the appropriate anatomical and cardiac access approach for mapping and ablation, and for counseling patients appropriately regarding anticipated procedural risks and outcome.

Importantly, the criteria for ECG localization of the site of origin of OT VAs utilize surface ECG electrodes accurately placed in standard anatomic positions. Even minor displacements of surface ECG electrodes can significantly alter the QRS morphology and adversely affect the diagnostic accuracy of surface ECG for localizing the VT focus. In particular, superior deviation of leads V_1 and V_2 in VAs originating from the LVOT can result in reduced R wave amplitude and R/S ratio, erroneously suggesting an RVOT origin, while inferior deviation of those leads in VAs of RVOT origin can result in increased R wave amplitude and R/S ratio, erroneously suggesting an LVOT origin. In addition, anterior displacement of the upper limb leads from shoulders to lateral chest wall (torso) can significantly reduce the R wave amplitude and reverse the QRS polarity in lead I, falsely suggesting a more anterior/leftward origin of RVOT VAs. Therefore verifying accurate positioning of the surface ECG leads is important, especially in the EP laboratory, where other patches on the chest frequently affect usual ECG lead placement.⁶⁰

Understanding the attitudinal anatomical relationships of the OTs and adjacent structures is critical for analyzing the ECG and predicting expected changes in QRS morphology when moving from one structure to the next. It is helpful to maintain a mental three-dimensional representation of the anatomical relationships as it lies within the chest (“attitudinally correct orientation”) while interrogating the ECG. With this in mind, R wave progression in precordial leads, and QRS frontal plane horizontal and vertical axis, are valuable for predicting the site of origin of OT VA.¹⁴

It is also important to note that while the ECG helps localize the region from which activation spreads across the ventricles, it does not necessarily identify the site of successful ablation. This is relevant, especially given the close anatomical relationship of the cardiac structures of the ventricular OT region.⁶¹

Precordial Transition

Lead V_1 is a unipolar lead positioned at the right anterior chest wall. Therefore VAs originating from anterior structures are expected to produce a predominantly negative deflection (i.e., LBBB pattern), whereas more posterior sites of origin produce more positive deflections (RBBB pattern). Since the RVOT and pulmonary artery are the most anterior cardiac structures, all VAs originating from these regions have an LBBB

TABLE 23.1 Common Sites of Origin for Idiopathic Ventricular Tachycardia

Sites of Origin	Prevalence	Mechanism	ECG Findings
1. Outflow tract VT RVOT	70%–80% of idiopathic VT	DAD-related triggered activity	LBBB inferior axis <ul style="list-style-type: none"> • Delayed R wave transition (at or after V₃ or later than sinus rhythm) • V₂ transition ratio^a <0.6
LVOT, aortic cusps, AMC	16% of outflow tract VT	DAD-related triggered activity	LBBB inferior axis <ul style="list-style-type: none"> • Early R wave transition • V₂ transition ratio ≥0.6 • Sometimes presents with >1 morphology
2. Fascicular VT Verapamil-sensitive VT	10%–15% of idiopathic VT	Macroreentry	Relatively narrow QRS <ul style="list-style-type: none"> • LPF: RBBB, LAD • LAF: RBBB, RAD
Focal Purkinje VT (Propranolol-sensitive automatic VT)	Rare	Enhanced automaticity	Relatively narrow QRS. <ul style="list-style-type: none"> • Depending on origin: LBBB (from RV distal Purkinje) or RBBB (from LV distal Purkinje)
3. Intracavity VT papillary muscle	2.4%–5.2% of idiopathic VT	Enhanced automaticity vs. DAD-related triggered activity	APM: RBBB (q in V ₁), inferior axis <ul style="list-style-type: none"> • PPM: RBBB (q in V₁), left superior axis. • RVPM: LBBB, more variable
Moderator band	2.5% of idiopathic VT	Enhanced automaticity vs. DAD-related triggered activity	LBBB with precordial transition later than V ₄ or later than sinus rhythm <ul style="list-style-type: none"> • Left superior axis • Relatively narrow QRS

configuration, with rare exceptions. Similarly, VAs originating from the anterior aspect of the LVOT (e.g., the right aortic sinus of Valsalva) typically exhibit an LBBB pattern. As the site of VT origin shifts progressively more posteriorly from the RVOT free wall toward the lateral mitral annulus (i.e., left aortic sinus, aortomitral continuity, LV summit, and lateral mitral annulus), the precordial transition (i.e., the first precordial lead where the R wave amplitude exceeds the S wave amplitude) becomes sequentially earlier, thereby transforming the precordial QRS morphology from a late transition LBBB pattern to a positively concordant RBBB pattern.¹⁴

Frontal Plane Horizontal Axis

Lead I primarily reflects the horizontal axis. Structures closer to the left axilla will produce a deeply negative complex in lead I (i.e., rightward axis); conversely, structures closer to the right axilla are strongly positive in lead I (i.e., leftward axis). Furthermore, leads II/aVL and III/aVR also have net leftward and rightward vectors, respectively. Hence, as the

site of origin of the VT moves progressively to the left (progressively from most rightward to leftward aspects of the RVOT, to the left aortic sinus, LV summit, and lateral mitral annulus), the QRS assumes progressively less positive/more negative deflection in lead I, a taller R wave in lead III than in lead II, and a larger S wave in lead aVL compared with lead aVR.¹⁴

Frontal Plane Vertical Axis

The inferior leads (II, III, and aVF) reflect the vertical axis. Given the high anatomical location of the left and right OTs in relation to the rest of the ventricles, all OT VAs exhibit positive deflections in the inferior leads (vertical axis). However, the magnitude of the inferiorly directed vector diminishes as the site of origin shifts from superior to inferior regions of the OT (such as from the subpulmonic region to the para-Hisian region). In addition, leads aVL and aVR exhibit QS complexes in the vast majority of OT VAs, as these two leads are not only leftward and rightward but also are superior leads. Therefore VAs

originating from the superior aspect of the ventricles produce negative deflection in leads aVL and aVR, whereas VAs arising from more apical locations exhibit positive deflections.

Right Ventricular Outflow Tract Tachycardias

VAs originating from the RVOT typically display LBBB morphology with a precordial QRS transition that begins no earlier than lead V₃ and more typically occurs in lead V₄. The frontal plane axis, precordial R/S transition, QRS width, and complexity of the QRS morphology in the inferior leads can more precisely indicate the origin of VT within the RVOT. For practical considerations, the RVOT can be viewed as two opposing crescentic surfaces: (1) an anterolateral or “free wall” surface and (2) a posteromedial (“septal”) surface. Both the free wall and posteromedial surfaces have leftward and rightward extensions. The RVOT free wall surface is the more anterior surface and will therefore give rise to VAs with a later precordial transition (V₄ or V₅); VAs from the “septal” surface transition earlier (typically V₃ or V₄).¹⁴

Most RVOT VAs originate from the anterosuperior aspect of the leftward (“septal”) aspects, just under the pulmonic valve. These tachycardias produce a characteristic surface ECG appearance with tall positive QRS complexes in leads II, III, and aVF, and large negative complexes in leads aVR and aVL (Fig. 23.5). The QRS morphology in lead I typically is multiphasic and has a net QRS vector of zero or is only modestly positive (see Fig. 23.2).

It is important to recognize that the prediction of the precise origin of OT VAs can still be challenging because of the close anatomical relationship of the different anatomical compartments of the OT region. For example, an R/S transition zone in precordial lead V₃ is common in patients with OT VAs, with a prevalence of up to 58%. The prevalence of R/S transition in lead V₃ in RVOT VAs is not statistically different from those originating outside the RVOT; therefore the predictive value for this ECG criterion is low. Approximately 50% of OT VAs with an R/S transition in V₃ could be successfully ablated from the RVOT, while other anatomical approaches can be required in other patients (including the LV, the aortic sinus of Valsalva, the CS, the pulmonary artery, and the epicardium via a percutaneous pericardial puncture).

Posteromedial versus free wall RVOT. QRS duration less than 140 milliseconds, monophasic R wave without notching (i.e., no RR' or Rr') in leads II and III, and early precordial transition (by lead V₄) suggest a posteromedial (“septal”) origin. On the other hand, the triphasic RR' or Rr' waves in leads II and III in VT of free wall origin probably reflect the longer QRS duration and the phased excitation from the RV free wall to the LV (see Fig. 23.5).

Left (anteromedial) vs. right (posterolateral) aspect of the RVOT. In general, a QS complex in lead I is generated from sites at or near the anteromedial aspect of the RVOT (the most leftward portion of the RVOT in the supine anteroposterior orientation). As the site of origin moves rightward, on either the posterior or the anterior wall, R waves appear in lead I and become progressively dominant and the QRS axis becomes more leftward. Similarly, a QS amplitude in aVL greater than that in aVR suggests an origin in the left side of the RVOT; a QS amplitude in aVR greater than that in aVL suggests an origin in the right side (see Fig. 23.5).

Superior vs. inferior aspect of the RVOT. The R wave amplitude tends to be larger in leads V₁ and V₂ at superior and leftward locations. As the site of origin shifts to the right or inferiorly, there is a trend toward lower right precordial R wave amplitude and a shift in the precordial transition zone to the left. Furthermore, R wave amplitude in lead V₂ or “r” wave amplitude in leads V₁ and V₂ greater than 0.2 mV suggests a superior origin. In addition, the closer the origin to the pulmonic valve, the more rightward and inferior the axis (i.e., R wave taller in lead III than in lead II) because of the anatomical leftward

location of the pulmonic valve and lead III being an inferior and rightward lead; the more posterior and inferior the origin, the more leftward the axis (see Fig. 23.5). Also, lead aVL (being a left-sided lead) becomes isoelectric or slightly positive as the site of origin moves inferiorly (close to the HB region), whereas aVR (being a right-sided lead) remains negative.

Suprapulmonic vs. subpulmonic RVOT. Because of the superior and leftward location of these sites, VAs arising above the pulmonic valve (particularly from the left pulmonic cusp) are associated with a small but definite vector toward the right, resulting in a small initial R wave in lead V₁. In addition, suprapulmonic origins exhibit a strong right inferior frontal plane axis (QS or rS wave in lead I, large R waves in leads II, III, aVF, and deep QS complexes in leads aVR and aVL, with the R wave being taller in lead III than in lead II and the S wave being deeper in aVL than in aVR). Those VAs also tend to display an R/S ratio in lead V₂ and R wave amplitude in inferior leads that are larger than those observed in subpulmonic RVOT VAs. However, moderate overlap exists between VAs originating above the pulmonic valve and RVOT VAs, and because the RVOT is the exit site of VT arising from the pulmonary artery, discriminating between the two groups using ECG parameters can be difficult.^{19,20}

Right Versus Left Ventricular Outflow Tract Tachycardias

Because of the close anatomical relationship between the RVOT and LVOT, VAs arising from the LVOT/aortic root can have similar ECG morphology to those originating from the RVOT. However, the presence of a prominent R wave in leads V₁ and V₂, and RS transition in leads V₁ or V₂ are characteristic of an LVOT origin (because of the posterior location of LVOT relative to the anterior precordial leads), whereas the absence of an R wave in lead V₁ and precordial transition zone in lead V₄, V₅, or V₆ predicts an RVOT origin (see Fig. 23.5). However, it is important to recognize that about 20% of VAs with arising from the aortic sinuses of Valsalva show a late QRS transition after lead V₃, and approximately 25% of the VAs with an aortic sinus of Valsalva origin had a preferential localized breakout site in the RVOT, which may also explain the difficulty in using ECG algorithms for accurate localization of VT arising in the aortic cusps.¹⁷

Given the continuity between the posterior RVOT and the anterior LVOT/aortic root, a very similar R wave in lead V₃ may be seen with arrhythmia that originates in either structure, and R/S transition in lead V₃ is not specific.¹⁴ In the latter setting, several algorithms using the ECG characteristics, especially the QRS transition in the precordial leads, have been proposed to help distinguish origins from the LVOT/aortic root versus RVOT, including the R wave duration index, R/S wave amplitude index, transitional zone index, V₂ transition ratio, and V₂S/V₃R index (Table 23.2; Fig. 23.6).

R wave duration index. R wave duration in leads V₁ or V₂ is determined from the onset of the QRS complex to the transition point between the R wave and the isoelectric line. The R wave duration index is calculated as a percentage by dividing the total QRS complex duration by the longer R wave duration in lead V₁ or V₂ (see Fig. 23.6). An R wave duration index of ≥50% suggests an aortic cusp origin in patients with a typical LBBB morphology and an inferior axis.⁶²

R/S wave amplitude index. The R/S wave amplitude ratio in leads V₁ and V₂ is measured from the QRS complex peak or nadir to the isoelectric line, expressed as a percentage. The R/S wave amplitude index is defined as the greater value of the R/S wave amplitude ratio in lead V₁ or V₂ (see Fig. 23.6). An R/S wave amplitude index ≥30% suggests an aortic cusp origin in patients with a typical LBBB morphology and an inferior axis.⁶²

V₂ transition ratio. The V₂ transition ratio compares the R wave amplitude divided by total QRS amplitude (i.e., R/[R + S]) in lead V₂

during VT with that during NSR (see Fig. 23.6). The V_2 transition ratio can help distinguish between LVOT and RVOT origins in patients with lead V_3 precordial transition. A transition ratio ($R/[R + S]_{VT} \div R/[R + S]_{NSR}$) of ≥ 0.60 is highly suggestive of an LVOT origin (with a sensitivity of 95% and a specificity of 100%).^{14,63}

V_2S/V_3R index. The V_2S/V_3R index is defined as the S-wave amplitude in lead V_2 divided by the R-wave amplitude in lead V_3 during the OT-VT (see Fig. 23.6). The V_2S/V_3R index is significantly smaller for LVOT origins than RVOT origins. An index of ≤ 1.5 predicted an LVOT origin with a sensitivity of 89% and specificity of 94%. In

the area under the curve and accuracy, the V_2S/V_3R index was found superior to other previously proposed ECG criteria in an analysis of all OT VAs.⁶⁴

Transitional zone index. Approximately 35% of patients with OT VAs present a shift of the precordial transitional zone during NSR. Cardiac rotation can result in a similar shift in the precordial transitional zone also during VT. The transitional zone index corrects the transitional zone to cardiac rotation (comparing the R/S transitional zone in precordial leads during VT with that during NSR) and can be useful for differentiating RVOT from aortic cusp origin with high sensitivity and

TABLE 23.2 Comparison of the Accuracy Among the ECG Criteria for Predicting the LVOT Origin of VT

	Sensitivity	Specificity	PPV	NPV
All Patients (n = 207)				
V ₂ S/V ₃ R index ≤1.5	89%	94%	84%	96%
Transitional zone index <0	83%	93%	80%	94%
R/S wave amplitude index ≥30%	79%	86%	66%	92%
R wave duration index ≥50%	45%	92%	67%	83%
Patients With a Lead V₃ Precordial Transition (n = 77)				
V ₂ S/V ₃ R index ≤1.5	94%	78%	79%	94%
Transitional zone index <0	78%	88%	85%	82%
V ₂ transition ratio	81%	61%	64%	78%
R/S wave amplitude index ≥30%	78%	68%	68%	78%
R wave duration index ≥50%	36%	88%	72%	61%

ECG, Electrocardiographic; LVOT, left ventricular outflow tract; NPV, negative predictive value; PPV, positive predictive value; VT, ventricular tachycardia.

specificity, regardless of cardiac rotation. The transitional zone score is graded with 0.5-point increments according to the site of the R wave transition. If the amplitudes of the R and S waves are equal (i.e., R/S-wave amplitude ratio is between 0.9 and 1.1) in any precordial lead (V₁ to V₆), the transitional zone score is the same as the lead number (e.g., transitional zone in V₂ = 2-point, transitional zone between V₂ – V₃ = 2.5-point, V₃ = 3-point, and V₃ – V₄ = 3.5-point). The transitional zone index is defined as transitional index score during VT minus transitional zone score during NSR (Fig. 23.7). When the transitional zone during VT occurs in one or more precordial leads earlier than during NSR (i.e., transitional zone index <0), an aortic cusp origin is favored, even when the transitional zone during VT occurs later than lead V₂.⁶⁵

Aortic Root Ventricular Tachycardias

The ECG discrimination characteristics between VAs originating from the RVOT and LVOT/aortic sinus of Valsalva regions are discussed above. For LVOT VAs, the presence of an S wave in leads V₅ or V₆ suggests an infravalvular origin. In addition, the presence of an R wave in lead aVL argues against an origin in the aortic sinuses of Valsalva.

Interestingly, the behavior of idiopathic VAs can potentially suggest the site of origin. PVCs occur at relatively fixed coupling intervals from the preceding normal QRS complex in most patients. A recent report found that highly variable coupling intervals from the prior QRS complex characterize foci in the aortic cusps and great cardiac vein compared with PVCs from other regions. It was postulated that PVCs originating from sites within narrow, relatively isolated muscle fibers such as the aortic cusps and great cardiac vein may behave more like a modulated parasystolic focus than a more typical PVC focus, and that this behavior may explain the differences in the coupling intervals. Lacking large amounts of surrounding myocardium to provide electrotonic inhibition,

Fig. 23.6 Electrocardiogram (ECG) Criteria for Predicting the Left Ventricular Origin of Outflow Tract Ventricular Tachycardia. Surface ECG leads V₁ to V₃ showing normal sinus rhythm with frequent premature ventricular complexes (PVCs) originating from the ventricular outflow tract. The measurements are as follows:

- A = S-wave amplitude (during PVC) in lead V₂ (mV).
- B = R-wave amplitude (during PVC) in lead V₃ (mV).
- C = R-wave amplitude (during PVC) in lead V₂ (mV).
- D = Total QRS amplitude (during PVC) in lead V₂ (mV).
- E = R-wave duration (during PVC) in lead V₂ (mV).
- F = Total QRS duration (during PVC) in lead V₂ (mV).
- G = R-wave amplitude (during sinus rhythm) in lead V₃ (mV).
- H = Total QRS amplitude (during sinus rhythm) in lead V₂ (mV).

ECG criteria are calculated as follows:

- V₂S/V₃R index = A/B.
- V₂ transition ratio = C/D ÷ G/H.
- R wave duration index = E/F.
- R/S wave amplitude index = C/A.

Fig. 23.7 Example of Calculating the Transitional Zone (TZ) Score and TZ Index. Red arrows indicate TZ scores during normal sinus rhythm (NSR). Blue arrows indicate the TZ scores of outflow tract premature ventricular complexes (PVCs). TZ index is calculated according to the following formula: TZ score of PVC minus TZ score of NSR. TZ index is -3 in (A) 1.0 in (B) and -2.5 in (C).

the narrow muscle strands in the aortic cusps and extending along the great cardiac vein may be more prone to partial entrance block, providing relative isolation and protection from the PVC focus from the modulation by the sinus rhythm.⁶⁶

Right aortic sinus of Valsalva. The right sinus of Valsalva lies directly posterior to the midposterior “septal” aspect of the RVOT; thus the VAs originating from both regions frequently appear similar. In fact, VAs originating from the aortic sinus of Valsalva often (25%) show preferential conduction to the RVOT, which can render some algorithms using the ECG characteristics less reliable. Approximately 20% of the VAs with an aortic sinus of Valsalva origin in that report showed a late QRS transition after V₃ (see Fig. 23.5). Nonetheless, the ECG criteria discussed above can help distinguish between VAs originating from the RVOT and LVOT/aortic sinus of Valsalva regions.^{67,68}

Left aortic sinus of Valsalva. Relative to the right sinus of Valsalva, the left sinus is positioned leftward, posteriorly, and more cranially

(superiorly). As such, when compared with the right sinus of Valsalva, VAs originating from the left sinus exhibit less positive (and often negative) deflection in lead I, larger R waves in the inferior leads, and taller R wave amplitude in lead III compared with lead II.¹⁴ In the precordial leads, the QRS is predominantly positive by lead V₁ or V₂ with VT from the left aortic cusp. Also, left aortic sinus of Valsalva VAs initially depolarize the LV and typically have a multiphasic QRS complex such as an M or W pattern in lead V₁, suggesting transseptal activation (see Fig. 23.5). A simple qR complex or a monophasic R wave in lead V₁ suggests an origin near the aortomitral continuity. In young patients with a vertical heart, the QRS complex in lead I can be negative in and around both the left and right aortic sinus of Valsalva regions. In patients with a horizontal heart, the area surrounding the aortic valve will be directed rightward relative to the LV apex–lateral wall, and a positive QRS complex in lead I can be seen. In general, when comparing origins from the right versus the left sinuses of Valsalva, RBBB morphology in lead V₁

argues against origins from the right sinus of Valsalva. In addition, the ratio of the R wave amplitude ratio in leads III/II is significantly greater (>0.9) for VAs with a left sinus of Valsalva origin than for those with a right sinus of Valsalva origin.^{14,67}

Right-left aortic sinus commissure. A common site of origin is the junction between the right and left aortic sinuses (which abuts the midposterior “septal” aspect of the RVOT). Because of the anatomical location, VAs with this origin seem to be associated with ECG findings that are between those of left and right sinus morphologies. This site of origin is often recognized by a QS complex with notching of the downstroke in lead V_1 with an intermediate precordial transition (relative to the right and left sinuses of Valsalva; see Fig. 23.5). A qRS pattern in leads V_1 to V_3 is very helpful for predicting an origin in the junction between the right and left sinuses.

Noncoronary aortic sinus of Valsalva. VAs originating from the noncoronary sinus of Valsalva tend to have similar QRS morphology to those originating from the right sinus of Valsalva, including an LBBB pattern, left superior or inferior axis, upright R wave in lead I, and frequent presence of S wave in lead III (see Fig. 23.5). However, several other ECG characteristics can help predict an origin from the noncoronary sinus, including a narrower QRS duration (typically <150 milliseconds), smaller lead III/II ratio (typically <0.65), a bifid QRS in lead V_1 , early precordial transition, and a negative QRS complex in aVL. Of note, foci from the noncoronary cusp predominantly exhibit VT rather than PVCs.^{24,69–71}

Basal Left Ventricular Tachycardias

The LV base includes the subaortic septal para-Hisian region, aortomitral continuity, as well as ventricular regions in close proximity to the mitral annulus. The majority of these VAs originate from the aortomitral continuity, and less commonly from the lateral, posterior, or posteroseptal mitral annulus. VAs arising from the left septal para-Hisian region typically exhibit a relatively narrow QRS duration with LBBB pattern, an early precordial transition (at or before lead V_3), and predominantly positive vector in lead I. More laterally, the aortomitral continuity produces VAs with a signature qR pattern (i.e., a fusion between LBBB and RBBB patterns) with broad monophasic R waves across the precordial leads (see Fig. 23.5). As the site of origin moves laterally (superolateral and lateral mitral annulus), the initial vector is directed away from lead V_1 , resulting in RBBB pattern (monophasic R waves or Rs complexes) in lead V_1 , and either no precordial transition or a late appearing s wave (in lead V_5 or V_6 ; for inferolateral basal LV sites). Posterior annular VAs display a dominant R in lead V_1 , whereas posteroseptal annular foci are characterized by a negative QRS component in lead V_1 (qR, qr, rs, rS, or QS; Fig. 23.8).

Lead I polarity transitions from predominantly positive for septal (anterior or posterior) annular foci to predominantly negative for lateral annular locations.¹⁴ Also wider QRS durations and notching in the late phase of the QRS in the inferior leads characterize the lateral free wall as compared with more medial/septal annular locations.

QRS polarity in the inferior leads is positive in VAs originating from the anterior/anterolateral annular locations, and negative during VAs arising from the posterior and posteroseptal mitral annulus. In addition, lead III/II R wave amplitude ratio becomes greater as sites of origin move from antero-septal to lateral annular locations. Also, lead III/II Q wave amplitude ratio is greater in posteroseptal VAs than in posterior annular VAs.

In LVOT VAs, an abrupt loss of the R wave in lead V_2 compared to leads V_1 and V_3 suggests an origin close to the anterior interventricular sulcus (anatomically opposite to lead V_2), which is the septal aspect of the LV summit, and in close proximity to the left anterior descending coronary artery (see Fig. 23.5).⁷²

Left Ventricular Summit Tachycardias

The LV summit is the most superior aspect of the “epicardial” LVOT. Hence VAs originating from this region exhibit the classic slower spread of activation from a focus on the epicardial surface relative to the endocardium and delayed global ventricular activation resulting from later engagement of the His-Purkinje network. Several ECG characteristics can help distinguish epicardial idiopathic VAs from endocardial arrhythmias, including (1) slurring of the initial portion of the QRS complex (pseudo-delta wave ≥ 34 milliseconds), (2) long R-wave peak time (i.e., the interval from the beginning of the QRS complex to the time of initial downstroke of the R wave after it has peaked [previously known as the intrinsicoid deflection] ≥ 85 milliseconds) in lead V_2 , and (3) shortest precordial RS complex of greater than 120 milliseconds. The degree of initial QRS slurring, as measured by the *maximal deflection index* (defined as the quotient of the time from QRS onset to maximal deflection [i.e., the largest positive or negative amplitude deflection] in precordial leads divided by the total QRS duration), can help identify epicardial LV summit VAs. A delayed shortest precordial maximal deflection index (≥ 0.55) discriminates LV summit VAs from those originating within the aortic cusps.¹⁴ Similarly, a peak deflection index (determined in the inferior lead presenting the tallest R wave by dividing the time from the QRS onset to the peak QRS deflection by a total QRS duration) of greater than 0.6 predicts an epicardial LV summit origin.⁷³

VAs arising from the LV summit exhibit either LBBB or, less frequently, RBBB pattern in lead V_1 . As noted, VAs arising from the aortomitral continuity display a characteristic qR pattern, whereas VAs originating from more posterior and lateral structures (e.g., proximal segment of the great cardiac vein, superior/lateral mitral annulus) generally exhibit an RBBB pattern (see Fig. 23.8). As the site of origin moves toward the distal part of the great cardiac vein, closer to the antero-septal myocardium (near junction of the great cardiac and anterior interventricular veins), the initial vector is directed away from V_1 , resulting in RBBB morphology. However, the precordial transition of the arrhythmia will invariably be earlier than that of the sinus rhythm QRS. VAs originating more distally along the anterior interventricular vein as it courses apically within the interventricular groove exhibit an LBBB pattern with a later precordial transition (generally after V_2).¹⁴

Because of its superior location in the LV, VAs originating from the LV summit uniformly exhibit larger R wave amplitudes in the inferior leads. However, R wave amplitude ratio in leads III/II can vary according to the location of VT focus within the LV summit. As the site of origin shifts progressively more laterally (from the superior region of the summit toward the inferior region then toward the lateral mitral annulus), R wave amplitude becomes progressively larger in lead III as compared to lead II (concurrent with progressively more steeply negative complexes in lead I). R wave amplitude ratio in leads III/II ratio of greater than 1.25 can predict the requirement of a pericardial approach for VT ablation (i.e., origins from the inferior aspect of the LV summit).^{14,74}

Similarly, the aVL/aVR Q-wave ratio was strongly correlated with the anatomical distance between the successful ablation site and the apex of the LV summit; the longer distance away from the apex of the LV summit, the larger the aVL/aVR Q-wave ratio. This indicates that the ECG vectors would shift laterally and inferiorly if the distance between the VT and the apex of the LV summit increased. Also, the aVL/aVR Q-wave ratio was found to predict the approach to successful ablation; the aVL/aVR Q-wave ratio was significantly higher for VAs requiring an epicardial approach, followed by VAs arising from the coronary venous system, subvalvular area, and aortic cusp. An aVL/aVR Q-wave ratio of less than 1.45 predicted successful ablation from

Fig. 23.8 Surface Electrocardiogram (ECG) QRS Morphology of Premature Ventricular Complexes (PVCs) Originating from the Perivalvular Regions. aortic sinus of Valsalva or subvalvular approaches, whereas an aVL/aVR Q-wave ratio of greater than 1.75 indicated the need for a pericardial approach (see [Fig. 23.8](#)).^{28,75}

Because of its superior location in the LV, VAs originating from the superior region of the LV summit (the “inaccessible region” close to the apex of the summit) typically exhibit an LBBB pattern, larger R wave amplitudes in the inferior leads, and absence of an S wave in leads V₅ to V₆.¹⁴ When LV summit VAs exhibit an RBBB pattern, a transition zone earlier than lead V₁, aVL/aVR amplitude ratio of greater than 1.1, and S waves in V₅ to V₆, those VAs are likely to be cured by catheter ablation within the great cardiac or anterior interventricular veins. When LV summit VAs exhibit a lead III/II amplitude ratio of greater than

1.25 and lead aVL/aVR amplitude ratio of greater than 1.75, those VAs are likely to require a pericardial approach for ablation.^{22,74,76}

Left Ventricular Papillary Muscle Tachycardias

VAs can arise from the posterior or, less commonly, anterior LV papillary muscles. VAs from the papillary muscles exhibit a RBBB pattern in lead V₁ and RS transition at leads V₃ to V₅. VAs from the anterior papillary muscle demonstrate a rightward inferior axis (negative in leads I and aVL, positive in lead aVR) and frequently inferior lead discordance (negative in lead II, positive in lead III), whereas VAs from the posterior papillary muscle demonstrate left superior axis (negative in leads II and III).³¹

Of note, the ECG morphology of VAs originating from the LV papillary muscle can mimic that of fascicular VAs. Nonetheless, papillary muscle VT has a broader QRS complex than that of fascicular VT (150 ± 15 milliseconds vs. 127 ± 11 milliseconds). In addition, the presence of an rsR' pattern in lead V_1 (with r smaller than R') favors fascicular over papillary muscle foci; papillary muscle VAs typically exhibit qR or R in lead V_1 . The shorter QRS duration and lead V_1 morphology (mimicking typical RBBB pattern) likely reflect the proximal exit of fascicular VAs from the His-Purkinje system (HPS) and early engagement of the Purkinje system in the depolarization of the LV. Furthermore, spontaneous variations in QRS morphology occur relatively frequently during VAs originating from the LV papillary muscles, a feature that can help distinguish these VAs from fascicular VT, the latter being a reentrant tachycardia with a consistent QRS morphology. Unlike fascicular VTs, papillary muscle foci are less likely to present as sustained VT.^{34,77}

Compared with papillary muscle and fascicular foci, VAs originating close to the mitral annulus exhibit positive precordial concordance because of the more basal location of those foci. An R/S ratio ≤ 1 in lead V_6 for VAs in the LV anterolateral region also suggests papillary muscle VT.⁷⁷

Cardiac Crux Ventricular Tachycardias

Cardiac crux VAs exhibit a left superior axis and QS pattern in the inferior leads. A prominent R wave ($R > S$) in lead V_2 is observed in the majority of cases. Additional ECG features include those of other “epicardial” VAs, including a pseudo-delta wave ≥ 34 milliseconds and precordial maximum deflection index (i.e., the interval from QRS onset to the peak of the largest amplitude deflection in each precordial lead, taking the lead with the shortest time, divided by QRS duration) of ≥ 0.55 .³³

Basal crux VAs exhibit a left superior axis and an LBBB pattern with either negative or isoelectric pattern in lead V_1 and $R > S$ in lead V_6 . In contrast, apical crux VAs exhibit a deep S or rS wave in lead V_6 , $R > S$ in lead aVR , and either an RBBB or an LBBB pattern in lead V_1 . Those with an RBBB pattern display a prominent R wave in lead V_1 with transition to rS or qS in lead V_6 . VAs with an LBBB pattern exhibit early precordial transition (in lead V_2) with late transition to rS or qS in lead V_6 , (resulting in a characteristic R wave in lead V_2 that is taller than in leads V_1 or V_3). Occasionally, the QRS morphology in lead V_1 changes spontaneously and abruptly from RBBB to LBBB pattern.³³

Basal crux VT should be distinguished from VAs originating from posteroseptal tricuspid or mitral annular regions. While basal crux VT exhibits a QS pattern in lead II, tricuspid annular VT shows an rS or RS wave in lead II. In addition, the R wave in lead V_2 is taller, and QRS duration is longer in basal crux VT as compared with tricuspid annular VT. On the other hand, mitral annular VT shows an rS wave in lead II and a variable pattern including (R , qR , and rS) in lead V_1 , in contrast with the QS pattern in lead V_1 characteristic of basal crux VT.³³

Apical crux VAs exhibiting an RBBB pattern can mimic VAs originating from the LV papillary muscle or left posterior fascicle. The apical crux is located more inferiorly compared with other LV posteroseptal locations such as papillary muscle or left posterior fascicle, and a combination of QS pattern or R/S ratio of less than 0.15 in lead V_6 , and a monophasic R in lead aVR can distinguish apical crux VAs from other adjacent sites. Of note, patients with arrhythmias originating from apical crux or left posterior fascicle are more likely to present with sustained or nonsustained VT rather than only PVCs compared with those with papillary muscle VAs. Also, patients with apical crux VAs more frequently present with syncope or cardiac arrest compared with patients with other VT origins.³⁴

Right Ventricular Papillary Muscle Tachycardias

RV papillary muscle VAs display an LBBB pattern with a QS or rS pattern in lead V_1 and a wider QRS complex and more prevalent notching than in RVOT VA. VAs arising from the anterior and posterior papillary muscles are frequently associated with a superior axis and a late R wave transition in the precordial leads (later than lead V_4), whereas septal papillary muscle VAs more often display an earlier precordial transition (in lead V_4 or earlier) and an inferior axis (due to the more basal insertion of the septal compared with the anterior and posterior papillary muscles). More than one PVC or VT morphology can be present in a significant proportion of patients with papillary muscle VAs. Compared with origins from the septum, VAs from the free wall exhibit longer QRS duration and deeper S waves in leads V_2 and V_3 .

Focal Purkinje Ventricular Tachycardias

Idiopathic focal VAs can arise from the Purkinje system in either ventricle. Focal Purkinje VTs (classified as “propranolol-sensitive automatic VTs”) can present as an accelerated idioventricular rhythm or VT and display chronotropic properties. Importantly, PVCs arising from the Purkinje system are particularly prone to induce polymorphic VT and VF (due to unclear mechanism). Hence patients presented with idiopathic VF can benefit from special attention to recording PVCs that suggest a Purkinje origin as a potential ablation target.³

Focal Purkinje VAs arising from the left HPS exhibit an RBBB pattern with either left- or right-axis deviation, and can be difficult to distinguish from fascicular VT (Fig. 23.9).

VTs originating from the right bundle (RB) and RV moderator band have been recently reported. The moderator band is a muscular structure that crosses from the septum to the RV free wall and supports the anterior papillary muscle of the tricuspid valve. The moderator band contains bundles of Purkinje fibers that cross subendocardially from the interventricular septum, through the moderator band (with no connection to the surrounding myocardium), and spread after the moderator band joins the anterior papillary muscle to the RV free wall, supplying the subendocardial ventricular plexus. VAs originating from the RB exhibit a classic LBBB morphology with sharp downstroke of the S wave and short rS duration (<70 milliseconds) in leads V_1 and V_2 , and late precordial transition (typically after V_4 or V_5).⁷⁸ VAs originating from the moderator band exhibit an LBBB pattern in lead V_1 with a late precordial transition pattern (typically after V_4) that is always later than that during NSR (see Fig. 23.9). Other ECG characteristics include a left superior frontal plane axis, a sharp downstroke of the QRS in the precordial leads, and a relatively narrow QRS width (due to the proximity to the right bundle and early incorporation of the HPS). Nonetheless, wide variations exist in the morphology and insertion sites of the moderator band, which results in a variety of ECG morphologies of VT originating from this structure. Within the RV, the late precordial transition and superior axis differentiate moderator band VAs from those originating in the RV base or septum, although moderator band VAs tend to display a later precordial transition than VAs originating from the septal RV papillary muscle. However, discrimination of anterior papillary muscle origin VAs is challenging, likely because of the similar insertion on the RV free wall and highly variable anatomy.³

Tricuspid Annular Ventricular Tachycardias

VAs arising from the tricuspid annulus demonstrate LBBB morphology and positive QRS polarity in leads V_5 and V_6 (see Fig. 23.8). Septal annular VAs exhibit early precordial transition (at lead V_3), narrower QRS complexes, and Qs in lead V_1 , whereas lateral annular foci have later precordial transition. Also, as the site of origin moves from medial/septal to lateral locations along the tricuspid annulus, the precordial

Fig. 23.9 Surface Electrocardiogram (ECG) QRS Morphology of Intracavitary Premature Ventricular Complexes (PVCs). Representative surface 12-lead ECG of QRS morphology during PVCs originating from the left ventricular (LV) anterolateral papillary muscle (A and B), posteromedial papillary muscle (C and D), left anterior fascicle (LAF, E), and left posterior fascicle (LPF, F), and right ventricular (RV) moderator band (G and H).

transition becomes later (at lead V_3 in septal locations, and after lead V_3 in free wall locations), the QRS becomes wider, Q wave amplitude becomes larger in anterior precordial leads (V_1 to V_3), and notching in the inferior leads becomes more prevalent and prominent.

VAs arising from the tricuspid annulus have an rS or QS pattern in lead aVR, just as those arising from the RVOT; however, the QRS polarity in lead aVL is positive in almost all VAs arising from the annulus (89%), unlike those arising from the RVOT. In addition, annular VAs typically display a large R wave (with no negative component) in lead I. QRS polarity in the inferior leads is positive in anterior annular VAs, and negative in posterior and posteroseptal annular VAs.⁷⁹

VAs originating in the vicinity of the HB share many of the same ECG features as those originating from the RVOT (including an LBBB pattern in lead V_1 with an inferior axis and an R wave in lead I), the right or noncoronary aortic sinuses adjacent to the membranous septum, or the subaortic LV septum. However, para-Hisian VAs are characterized by a narrower QRS width (due to the rapid ventricular activation caused by early engagement of the HPS), a higher R wave amplitude in lead I, a lower R wave amplitude in the inferior leads, and a higher R wave amplitude ratio in leads II/III. In addition, a prominent R wave in lead aVL is observed in VAs arising from the RV para-Hisian region.

Given its rightward and inferior location, this is the only site of origin in the RVOT that does not exhibit a completely negative deflection in lead aVL.^{59,80}

Discrimination between LV versus RV septal para-Hisian VAs can be difficult, given the close anatomical relationship and rapid transseptal conduction from both locations. Although an early QRS transition (before lead V_3) predicts VAs with an origin in the subvalvular LVOT or aortic root, and a late QRS transition (after lead V_3) predicts those with an origin in the RV para-Hisian region, the sensitivity of these ECG features is limited.

ELECTROPHYSIOLOGICAL TESTING

Induction of Tachycardia

Not infrequently, idiopathic VAs foci can become inactive in the EP laboratory environment, likely due to sedative medications or deviation from daily routine activities (e.g., exercise or caffeine intake) that can affect VT activity. Thus, in preparation for the ablation procedure, antiarrhythmic drugs should be withheld for at least five half-lives before the EP study and minimal sedation should be used throughout the procedure, if possible. In addition, it may be appropriate to monitor

the patient in the EP laboratory initially without sedation. If no spontaneous tachycardia is observed, isoproterenol is administered. If no VAs could be induced during isoproterenol administration or during the washout phase, a single quadripolar catheter may be placed in the RV, and programmed electrical stimulation is performed. If VT focus remains quiescent, the procedure may be aborted and retried at a future date. If the clinical VAs are inducible at any step, the full EP catheter arrangement and EP study are undertaken.

Several pharmacological agents may be used to enhance inducibility of idiopathic VAs. Isoproterenol infusion (targeting a 20% to 30% increment in heart rate) is the first choice. Importantly, VAs may develop (with and without programmed electrical stimulation) only during the washout phase after discontinuation of isoproterenol (analogous to VAs occurring during the recovery phase postexercise). If needed, IV atropine and aminophylline may be sequentially administered (with and without programmed electrical stimulation) to attenuate the potential antiarrhythmic effects of endogenous acetylcholine and adenosine, which inhibit cAMP. Calcium infusion can also facilitate arrhythmia induction. Occasionally, epinephrine or phenylephrine can be more effective than isoproterenol.

Ventricular stimulation can initiate the VAs in less than 65% of patients and, in contrast to reentrant VT, rapid ventricular pacing is usually more effective than VES. Induction of sustained VT is less common in patients with repetitive monomorphic VT than in those with paroxysmal sustained VT. In one report, sustained VT was inducible during EP testing in 78% of patients who presented clinically with sustained VT, in 48% of patients who presented with nonsustained VT, and in 4% of those with PVCs only. Most episodes of triggered activity VT induced by ventricular stimulation are usually nonsustained. Reproducibility of VT induction using all methods is less than 50%, whereas reproducibility of induction with single or double VESs is approximately 25%. Induction with atrial pacing is not uncommon. Of note, in contrast to reentrant VT, initiation of OT VAs does not require associated ventricular conduction delay or block for initiation.

Typically the initial cycle of the VT bears a direct relationship to the PCL (whether or not VESs are delivered following the pacing drive). Thus the shorter the initiating PCL, the shorter the interval to the first VT beat and the shorter the initial VT CL. Similarly, the initial cycle of the VT bears a direct relationship to the coupling interval of the VES initiating the VT. Occasionally, with the addition of very early VESs or with very rapid ventricular pacing (PCL <300 milliseconds), a sudden jump in the interval to the first VT complex may be observed, such that it is approximately twice the interval to the onset of the VT initiated by later coupled VESs. This can be caused by failure of the initial DAD to reach threshold, whereas the second DAD reaches threshold. Thus in triggered activity VAs caused by DADs, the coupling interval of the initial VT complex either shortens or suddenly increases in response to progressively premature VES; it usually does not demonstrate an inverse or gradually increasing relationship (in contrast to reentrant VT).

Of note, successful induction of VAs can be linked to a critical window of heart rates. Ventricular PCLs longer or shorter than the critical CL window may fail to induce VT. This critical window can shift with changing autonomic tone. Therefore it is important to perform ventricular pacing at a wide spectrum of CLs to define the range of CLs most successful in inducing the VAs. The site of ventricular stimulation has no effect on the initiation of triggered activity VT as long as the paced impulse reaches the focus of the VT (in contrast to reentrant VT).

VT induction can be inconsistent. Induction is exquisitely sensitive to the immediate autonomic status of the patient. Therefore noninducibility during a single EP study is not enough evidence to attribute the arrhythmia to a nontriggered activity mechanism.

Tachycardia Features

Idiopathic focal VAs can manifest in the form of sustained VT or, more commonly, frequent monomorphic PVCs, couplets, and salvos of non-sustained VT. When sustained, the VT rate is frequently rapid (CL <300 milliseconds) but can be highly variable.

During VT, the His potential follows the onset of the QRS (i.e., negative HV interval) and is usually buried inside the local ventricular electrogram. Ventriculoatrial conduction may or may not be present. The VT is very sensitive to adenosine, Valsalva maneuvers, carotid sinus massage, edrophonium, verapamil, and beta-blockers.

Diagnostic Maneuvers During Tachycardia

Idiopathic focal VT cannot be entrained by overdrive ventricular pacing (i.e., no QRS fusion demonstrable). Notably, rapid ventricular pacing during the VT can result in acceleration of the VT. In addition, a direct relationship exists between the overdrive PCL and the coupling interval and CL of the VT resuming after cessation of pacing, characteristic of DAD-related triggered activity. VES results in a decreasing resetting response curve characteristic of DAD-related triggered activity.

MAPPING

The prediction of the precise origin of OT VAs based on surface ECG can be challenging, given the close anatomical relationship of the different compartments of the OT region. Therefore it is important to be prepared for mapping and ablation in the different cardiac compartments, including the CS, the aortic retrograde approach, and occasionally, the percutaneous pericardial approach. In addition, angiography of the CS and coronary arteries might be necessary for ablation in specific regions, and the required equipment for these procedures needs to be readily available.

In general, a multielectrode catheter positioned as far as possible in the CS (into the great cardiac vein) and a catheter positioned at the HB region in the RV can be very useful in mapping of OT VAs.

When the ECG QRS morphology strongly suggests a site of origin (e.g., RVOT, LVOT, LV summit, papillary muscle), that region is the initial target for mapping. On the other hand, when the ECG does not provide conclusive criteria to guide localization of the VT focus in the OT region, a stepwise mapping procedure has been proposed. Because most VAs originate from the RVOT, mapping is started there, and if that fails to identify the origin of the VT, mapping is extended to involve the pulmonary artery. If activation mapping and pace mapping suggest a focus outside the RVOT, mapping the CS can add useful information as to whether a left-sided epicardial origin is present. When the transvenous approach is unsuccessful, mapping the LVOT and aortic cusps via a retrograde arterial access is usually the next step. Finally, if all previous anatomical accesses are unsuccessful, epicardial mapping via a percutaneous pericardial access can be considered.

Activation Mapping

Activation mapping can be performed by point-by-point mapping with a standard mapping/ablation catheter, a high-density multielectrode mapping catheter (e.g., PentaRay, Biosense Webster, Diamond Bar, CA, United States), or multielectrode arrays. In idiopathic focal VAs, activation mapping is typically performed in conjunction of electroanatomic mapping.

The goal of activation mapping is to identify the site of origin (focus) of VT/PVCs, defined as the site with the earliest bipolar recording preceding the surface QRs (typically more than 20 to 25 milliseconds presystolic) in which the distal tip shows the earliest intrinsic deflection and QS unipolar electrogram configuration.

Initially, one should seek the general region of the origin of VAs as indicated by the surface ECG. All 12 leads should be inspected, and the lead showing the earliest and most discernible onset of the QRS during VT or PVCs should be selected as the reference point for subsequent mapping. Subsequently, the mapping catheter is moved under the guidance of fluoroscopy into the RVOT, and the bipolar signals are sampled from several endocardial sites. It is important to record examples of VT or PVCs prior to inserting catheters because the catheters can cause ectopic complexes that resemble the target VT or PVCs (Fig. 23.10).

Activation times are generally measured from the onset or the first rapid deflection of the bipolar electrogram to the earliest onset of the QRS on the surface ECG during VT or PVCs. The distal pole of the mapping catheter should be used to search for the earliest activation site, because it is the pole through which RF energy is delivered. Once an area of relatively early local activation is found, small movements of the catheter tip in that region are undertaken until the site is identified with the earliest possible local activation relative to the tachycardia complex.

Bipolar electrograms at the site of origin are modestly early (preceding the surface QRS by 10 to 45 milliseconds) and have high-amplitude and rapid slew rates. Fractionated complex electrograms and mid-diastolic potentials are not typically observed at sites of origin of idiopathic VAs.

Once the site with the earliest bipolar signal is identified, the unipolar signal from the distal ablation electrode should be used to supplement

conventional bipolar mapping (Fig. 23.11). The unfiltered (0.05 to >300 Hz) unipolar electrogram morphology should show a monophasic QS complex with a rapid negative deflection. Although this electrogram configuration is very sensitive for successful ablation sites, it is not specific (70% of unsuccessful ablation sites also manifest a QS complex). In fact, a QS configuration can be observed with unipolar recordings from a relatively large area (exceeding 10 mm in diameter and significantly larger than the VT focus), since the entirety of the heart is directed away from most locations in the ventricular OT region. The timing of the unipolar electrograms recorded at those sites distant from the VT focus, however, is later than that at the site of origin of the VT. Thus a QS complex should not be the only mapping finding used to guide ablation (see Fig. 23.11). Nonetheless, successful ablation is unusual at sites with an RS complex because these are generally distant from the VT focus.

The timing of the unipolar electrograms is also important. Concordance of the timing of the onset of the bipolar electrogram with that of the filtered or unfiltered unipolar electrogram, with the rapid downslope of the S wave of the unipolar QS complex coinciding with the initial peak of the bipolar signal, helps ensure that the tip electrode, which is the ablation electrode, is responsible for the early component of the bipolar electrogram (see Fig. 23.11). In addition, the presence of slight ST elevation on the unipolar recording and the ability to capture the site with unipolar pacing are used to indicate good electrode contact.

Fig. 23.10 Catheter-Induced Premature Ventricular Complexes (PVCs) Versus Target Spontaneous PVCs. Three complexes of catheter-induced PVCs are seen at left, during which both unipolar and bipolar signals are very early (as would be expected, because catheter tip irritation is causing these complexes). During the actual target PVC, however, this site is not early at all. This illustrates the need to be certain of the characteristics of the target PVC or ventricular tachycardia complex before beginning mapping. *Abl_{uni}*, Unipolar ablation; *His_{dist}*, distal His bundle; *His_{prox}*, proximal His bundle; *RVA*, right ventricular apex.

Fig. 23.11 Activation Mapping of Idiopathic Ventricular Tachycardia (VT). Activation mapping results from five sites are shown with 12 leads of a single VT complex, as well as intracardiac recordings from the right ventricular apex, proximal and distal ablation electrode bipolar recordings, and unipolar recordings from the tip electrode (*uni-d*) and the second electrode (*uni-p*). A vertical dashed line denotes QRS onset. Sites A to D are suboptimal ablation sites for the reasons noted. Site E was where ablation terminated VT. *Abl_{dist}*, Distal ablation; *Abl_{prox}*, proximal ablation; *RVA*, right ventricular apex.

In addition to the electrogram temporal relationship assessment, a negative concordance in the initial forces (first 20 milliseconds) of both unipolar and bipolar electrograms further improves the accuracy of conventional mapping to localize the site of origin of PVCs. In a recent report, the presence of this criterion (at sites fulfilling other conventional criteria used to guide focal PVC ablation) highly predicted the acute success rate of RF ablation with a sensitivity and specificity of 94% and 95%, respectively. Furthermore, its positive predictive value was significantly superior to the those of all other conventional criteria (76% vs. 33% to 43%).⁸¹

Careful catheter manipulation during mapping should seek to avoid mechanical trauma that can transiently abolish the arrhythmia. Importantly, catheter manipulation frequently induces PVCs that can closely mimic target PVCs. The findings on the mapping catheter during these catheter-induced PVCs are invariably excellent (e.g., substantial presystolic activation time, sharp QS on the unipolar recording). These complexes must be analyzed and carefully compared with prerecorded VT or PVC complexes to avoid the delivery of RF energy to sites with no relevance to actual VT.

It is important to recognize that some myocardial fibers in the RVOT can potentially be in continuity with those in the LVOT. Consequently,

when mapping is confined to the RVOT, the endocardial site with the earliest presystolic activation time does not necessarily indicate the focus of the tachycardia. This can be observed especially in tachycardias originating in the supraaortic sinuses of Valsalva, whereby the activation wavefront after leaving the focus exits both to the infravalvular LVOT myocardium and to the posterolateral subpulmonic RVOT. Then, mapping in the RVOT merely localizes the breakthrough site, where ablation would not eliminate the arrhythmia.

When mapping above the aortic or pulmonic valve, near- and far-field potentials are typically recorded. The exact nature and cause of these spikes are unknown but are thought to be analogous to PV potentials—that is, they represent electrical activation of myocardial sleeves distal to valve attachment. Because of the overlapping nature of the OT and supraaortic region, when two potentials are seen, only the near-field potential should be used for activation timing. In addition to noting the actual timing of activation, the timing of the near-field electrogram relative to the far-field electrogram should be evaluated. Typically, in sinus rhythm, the near-field potential (representing local supraaortic myocardial activation) is recorded after the far-field ventricular electrogram (likely representing OT activation) separated by an isoelectric period (presumably from conduction delay across the

site of valve insertion). If the sequence of activation is reversed during VT or PVC—that is, the near-field electrogram precedes the far-field electrogram by a similar or greater isoelectric period duration—an etiological role for the supraventricular myocardium can be inferred. This finding alone, however, does not suggest that ablation at this particular site will be successful because other supraventricular locations may show earlier activation than the site being mapped. On the other hand, if the near-field electrogram still succeeds the far-field ventricular electrogram during VT or PVC, then the supraventricular tissue, although present, is a bystander being passively activated during arrhythmia originating in the OT myocardium below the valve. In some cases, the near-field electrogram is fused with the far-field electrogram during tachycardia. This suggests an origin of arrhythmia exactly at the sinus of Valsalva or passive activation from a true distant site of origin to both the supraventricular and infraventricular myocardium.⁸

Pace Mapping

Given the focal nature of idiopathic VAs, comparing the paced QRS configuration with that of VT/PVC is particularly useful for locating the arrhythmia focus in a structurally normal heart. Pace mapping is used to confirm the results of activation mapping, but also can be of great value as the primary mapping technique when the VAs are scarcely inducible. Although there are some limitations to this technique, several studies have demonstrated efficacy using pace mapping to choose ablation target sites for idiopathic VT. However, the spatial resolution of pace mapping remains inferior to that of activation mapping.

Technique

Pace mapping during VT (at PCL 20 to 40 milliseconds shorter than the PCL) is preferable whenever possible because it facilitates rapid comparison of VT and paced QRS complexes at the end of a pacing train in simultaneously displayed 12-lead ECGs. If only nonsustained VT or PVCs are inducible, pacing is performed during NSR. In this setting, the PCL and coupling intervals of the VES should match those of spontaneous ectopy. Pace mapping is preferably performed with unipolar stimuli (≤ 10 mA, 2 milliseconds) from the distal electrode of the mapping catheter (cathode) and an electrode in the inferior vena cava (IVC) (anode). Unipolar pacing, however, causes a large stimulus artifact in the surface ECG. Bipolar pacing from the closely spaced distal electrodes of the mapping catheter is more commonly used. Although the possibility for capture at either the distal or proximal bipolar electrodes can reduce spatial accuracy, this does not appear to be a major limitation. Using the minimum stimulus amplitude required for consistent capture should improve accuracy by limiting the size of the virtual electrode in the tissue and preventing capture of myocardium distant from the pacing site. Pacing thresholds exceeding 5 to 10 mA typically indicate insufficient electrode-tissue contact or electrically inexcitable tissue.¹⁴

Interpretation

The greater the degree of concordance between the morphology during pacing and that during VT/PVC, the closer the catheter will be to the site of origin of the tachycardia. Pace maps with identical or nearly identical matches of the tachycardia morphology in all 12 surface ECG leads can be indicative of the site of origin of the tachycardia or breakout site to the myocardium (see Fig. 5.24).

ECG recordings should be reviewed at the same gain and filter settings and at a paper-sweep speed of 100 mm/s. It is often helpful to have a split-screen display of the target VT in one panel, comparing this with all 12 leads of the paced QRS complexes brought into another panel, as well as with printed regular 12-lead ECGs for side-by-side

comparison on paper. Differences in the QRS morphology between pacing and spontaneous VT in a single lead can be critical. Pacing at a site 5 mm from the index pacing site can result in minor differences in QRS configuration (notching, new small component, change in amplitude of individual component, or overall change in QRS shape) in at least one lead in most patients. In contrast, if only major changes in QRS morphology are considered, pacing sites separated by as much as 15 mm can appear similar.

Although qualitative comparison of the 12-lead ECG morphology between a pace map and VT is frequently performed, there are few objective criteria for quantifying the similarity between two 12-lead ECG waveform morphologies. Such comparisons are frequently completely subjective or semiquantitative, such as a “10/12 lead match.” Discrepancies in ablation outcome can result, in part, from subjective differences in opinion regarding the closeness of a pace map match to the clinical VT. In addition, a common human error in analyzing a pace map is not appreciating subtle amplitude or precordial lead transition differences between two ECG patterns. To overcome these limitations, template matching software is currently available and integrated into some EP recording systems (e.g., LabSystem PRO™ EP recording system, Boston Scientific, Boston, MA, United States; see Fig. 5.25) or 3-D mapping systems (e.g., CARTO, PaSo, Biosense Webster; see Fig. 5.26). This software processes digital images to match the target QRS complex (template signal) and the paced QRS complex (test signal), and provides a score according to the similarity between the two QRS morphologies. The software “slides” the reference over the incoming data until the best local match is found by using a correlation calculation. For each lead-to-lead comparison, both the polarity and the amplitude of the QRS complexes play an important role as to the resulting value of the percentage of correlation calculated by the software. The site that yields the highest average correlation (value toward 99% to 100%) across all of ECG leads means a perfect match between two 12-lead ECG morphologies. In general, an average template-matching score above 90% is considered sensitive for the identification of successful versus unsuccessful ablation sites.^{82,83}

Pitfalls

Current strengths up to 10 mA have little effect on unipolar-paced ECG configuration. In contrast, bipolar pacing can introduce some variability in the paced ECG; a significantly large amount of local myocardium is captured, which, combined with varying degrees of anodal capture, can be detrimental to mapping accuracy. This can be minimized by low pacing outputs and small interelectrode distance (≤ 5 mm). In addition, the morphology of single-paced QRS complexes can vary depending on coupling interval, and the QRS morphology during overdrive pacing is affected by the PCL. Therefore the coupling interval or CL of the template arrhythmia should be matched during pace mapping; otherwise, rate-dependent changes in QRS morphology independent of the pacing site can confound mapping results. Similarly, spontaneous couplets from the same focus may have slight variations in QRS morphology that must be considered when seeking a pace match. Of note, isoproterenol infusion has no significant effect on the QRS configuration.¹⁴ More rapid tachycardias (and sometimes relatively slower ones) can potentially show slight beat-to-beat variations in QRS morphology; depending on which beat is chosen for a template, achieving a perfect “match” to that one with pacing may not be feasible, and yet the paced QRS matches a different VT beat. Similarly, rapid pacing can result in slight changes in QRS morphology from beat to beat.

Importantly, the rapid electrical propagation within the RVOT limits the spatial resolution of pace mapping. In one report, the spatial resolution of a good pace map for targeting RVOT VAs was about 1.8 cm² and was inferior to that of an activation map.⁸⁴

Pace mapping can be particularly difficult to perform above the semilunar valves (in the aortic sinuses of Valsalva or pulmonary artery) and can require high pacing current strengths. Because of the close anatomical proximity of the various structures in the supraventricular region, high-output pacing may reproduce the ECG of clinical arrhythmia, even when the origin is in a different cardiac chamber. For example, high-output pace mapping from the right aortic sinus of Valsalva may reproduce the ECG morphology of VAs originating from the posterior RVOT or subvalvular anterior LVOT. On the other hand, supraventricular arrhythmia origin may exit to the ventricular myocardium below the valve, and pacing at the exit site can potentially produce perfect pace maps. For example, if pace mapping is performed at a breakthrough site on the posterior RVOT to try to match VT that originate in an aortic sinus of Valsalva VT, a perfect result (despite supraaortic origin) will be obtained. Yet ablation energy delivered there typically fails to terminate the arrhythmia and may result in a change in VT morphology, resulting now from a different exit of the sinus of Valsalva arrhythmogenic focus.¹⁷

It is also important to recognize that in a significant minority of patients, pace mapping at the successful ablation site produced a poor pace map, likely due to an intramural site of origin or secondary to conduction through preferential fibers connecting the site of origin to the myocardium.

Electroanatomic Mapping

Centrifugal propagation of activation during RVOT VAs is very rapid, with $3.0 \pm 1.6 \text{ cm}^2$ of the endocardium being activated within the first 10 milliseconds (ranging up to 6.4 cm^2). Therefore minor differences between adjacent sites become difficult to detect, leading to a large number of sites with clinically indistinguishable activation times when examined on a site-by-site basis. However, when displayed simultaneously on a spatially precise electroanatomical reconstruction, the centers of the early activation area and the presumed site of VT origin become easy to identify (Fig. 23.12). Electroanatomic 3-D mapping (CARTO mapping system [Biosense Webster], EnSite NavX system [St. Jude Medical, St. Paul, MN, United States], or Rhythmia [Boston Scientific, Cambridge, MA, United States]) permits spatial discrimination between sites separated by less than 1 mm.

Initially, a stable reference electrogram is selected. This is the fiducial marker on which the entire mapping procedure is based. Preferably, a QRS on the surface ECG (with a well-defined narrow R wave peak) is selected as the reference signal. Alternatively, an intracardiac electrogram (e.g., RV apex) can be selected as the reference point, in which case care must be taken to avoid dislodging this catheter, because if it moves, timing of mapping catheter activations will not be comparable to previously mapped sites. Following selection of the reference electrogram, positioning of the anatomical reference, and determination of the window of interest, the mapping catheter is positioned in the RVOT under fluoroscopic guidance.

At the outset, the plane of the HB location and pulmonic valve are defined and tagged to outline the superior and inferior limits of the RVOT. The mapping catheter is advanced superiorly in the RVOT until no discrete bipolar electrograms are seen in the distal electrode pair. The catheter then is retracted until electrograms in the distal electrode pair reappear and pacing results in capture of the RVOT endocardium. This marks the level of the pulmonic valve. At least three points are acquired and tagged to construct the pulmonic valve. Next, a detailed electroanatomic activation map of the RVOT is constructed by acquiring multiple points during PVCs or VT. The local activation time at each site is determined from the intracardiac bipolar electrogram and is measured in relation to the fixed reference electrogram (surface QRS or intracardiac electrogram). Points are added to the map only if

Fig. 23.12 Electroanatomic Activation Mapping of Ventricular Ectopy Originating From the Right Ventricular Outflow Tract (RVOT). CARTO 3 activation map (posterior view) is shown. The site of impulse origin during ectopy was in the posterolateral aspect of the RVOT (red area), at which point ablation eliminated the ventricular tachycardia (red dot). PA, Pulmonic valve annulus; TA, tricuspid annulus.

stability criteria in space and local activation time are met. The end-diastolic location stability criterion is less than 2 mm, and the local activation time stability criterion is less than 2 milliseconds. Activation maps display the local activation time by a color-coded overlay on the reconstructed 3-D geometry (see Fig. 23.12). The electroanatomic maps of focal VT demonstrate radial spreading of activation, from the earliest local activation site in all directions (a well-defined early activation site surrounded by later activation sites).

The principles used for conventional activation mapping discussed above are also used here to define the site of origin of VT. Although the traditional single-catheter mapping of the region of interest is still required, the ability to use the catheter localization system to steer precisely back to previously obtained sites of earliest activation greatly facilitates the ablation process. Display of activation times facilitates comparison of data from nearby sites, overcoming the imprecision of assigned activation times at single points, and permits rapid identification of a putative site of origin. The activation map can also be used to catalog sites at which pacing maneuvers are performed during assessment of the tachycardia (e.g., sites with a good pace map).

Current iterations of electroanatomic mapping systems allow the construction of high-resolution electroanatomic maps through catheters with multiple electrodes, as well as automated data acquisition. The EnSite NavX system can utilize any multielectrode catheter for data acquisition. The multipolar Lasso, PentaRay, DecaNav catheters (Biosense Webster) are equipped with the electromagnetic sensor and can be used with the CARTO system. The Rhythmia system utilizes a minibasket catheter (Orion; see Fig. 6.7). These techniques can significantly facilitate

the mapping procedure, especially in the presence of infrequent or scarcely inducible VAs.

The CARTO system incorporates an automated template-matching software (PaSo). The ECG waveform of each paced signal is compared to the VT waveform, and correlation is scored between 0 and 1. An automated isochronal pace map is collected by pacing at different sites. This helps eliminate operator subjectivity and provide a visual reference of all the sites visited on the map.⁸²

In addition, ICE imaging can facilitate mapping by visualization of the ablation catheter in the context of the complex anatomy of the OT region. ICE imaging can be coupled with electroanatomic mapping (CARTOSound), which can facilitate tagging anatomic landmarks (on the anatomical model).⁸⁵

When using a 3-D electroanatomic mapping system, it is important to understand that a change in rhythm during the mapping procedure can alter cardiac geometry to the extent that anatomical points acquired during one rhythm cannot be relied on after a change in rhythm. This is relevant during mapping of isolated PVCs or nonsustained VT, because locations assigned to early activation sites during the PVC on the electroanatomic map can potentially be spatially displaced (up to 10 mm) from the same anatomical locations when assigned during normal rhythm (e.g., at the time of RF delivery after tachycardia termination; see Fig. 6.19). Therefore, after termination of the arrhythmia, “revisiting” the site of early activation tagged during PVCs may not be feasible or even misleading as a target for ablation. To mitigate this problem, it might be helpful to assign the location of the identified site of origin of the tachycardia during the PVC (or the location of best pace map acquired during ventricular pacing) and also during sinus beats, while the mapping catheter is maintained at the same location (tagged as “location only” during sinus beats). This technique allows navigating to the site of interest, whether during tachycardia or during NSR.⁸⁶

Noncontact Mapping

The spatial and temporal resolution of point-by-point activation mapping is limited by the number of contact electrodes and the time required. When VT is hard to induce or the PVCs are infrequent, simultaneous multisite data acquisition can help map the VT focus. The biggest advantage of noncontact endocardial mapping is its ability to recreate the endocardial activation sequence from simultaneously acquired multiple data points over a few (theoretically one) tachycardia beats, without requiring sequential point-to-point acquisitions. More detailed mapping, however, is necessary to find the precise site to ablate.⁸⁷

The EnSite 3000 noncontact mapping system (St. Jude Medical) consists of a noncontact catheter (9 Fr) with a multielectrode array surrounding a 7.5-mL balloon mounted at the distal end. To create a map, the balloon catheter is advanced over a 0.035-inch guidewire under fluoroscopic guidance and positioned in the RVOT. The balloon is then deployed; it may be filled with contrast dye, permitting it to be visualized fluoroscopically (eFig. 23.8). The balloon is positioned in the center of the RVOT and does not come in contact with the endocardial walls being mapped. Systemic anticoagulation is critical to prevent thromboembolic complications; intravenous heparin is usually administered to maintain the ACT at 250 to 300 seconds.

A conventional (roving) deflectable mapping catheter is also positioned in the RVOT and used to collect geometry information. The tricuspid annulus, HB, and pulmonic valve are initially tagged, and a detailed 3-D geometry of the RVOT (“virtual” endocardium) is reconstructed by moving the mapping catheter around the RVOT.

The multielectrode array simultaneously acquires multiple data points over a few tachycardia beats or PVCs. The system then reconstructs more than 3360 unipolar electrograms simultaneously and superimposes

them onto the computer-generated model of the RVOT, producing isopotential maps with a color range representing voltage amplitude. The highest chamber voltage is at the site of origin of the electrical impulse. Color settings are adjusted so that the color range matches 1 to 1 with the millivolt range of the electrogram deflection of interest. The color scale for each isopotential map is set so that white indicates the most negative potential and blue indicates the least negative potential. Activation can be tracked on the isopotential map throughout the cycle to the onset of the tachycardia beat. Wavefront propagation can be displayed as a user-controlled 3-D movie (eFig. 23.9).

In addition, the system can simultaneously display as many as 32 electrograms as waveforms. Unipolar or bipolar electrograms (virtual electrograms) are then reconstructed at sites of earliest activation on the isopotential maps to look for a unipolar QS pattern (see Fig. 6.20). The origin of VT is defined as the earliest site showing a single spot of isopotential mapping and a QS pattern of the noncontact unipolar electrogram. Isochronal maps can also be created, which represent the progression of activation throughout the chamber relative to a user-defined electrical reference timing point.

Contact mapping using the conventional ablation catheter is then performed at sites of interest to supplement noncontact mapping findings, and color-coded contact activation maps can be displayed on the same 3-D geometry. Once the earliest activation is identified, the site is labeled on the 3-D map and the locator signal is used to navigate the ablation catheter to it in real time during tachycardia or during normal rhythm when sustained tachycardia is not inducible.

When analyzing noncontact activation map data to locate the site of origin of RVOT VAs, two distinct sites can be marked at the onset of electrical activity: earliest activation and breakout sites. The earliest activation site is defined as the site with the earliest unipolar deflection from baseline during VT/PVCs, forming a single spot on the isopotential map, as well as characterized by a QS pattern of noncontact unipolar electrogram. The breakout site is marked as the site along the depolarization pathway identified by the color-coded activation map where rapid centrifugal electrical propagation originated from and local unipolar electrograms exhibited the maximum negative dV/dt. For the identification of earliest activation and breakout sites, a broad color band setting is used with color high (defined as unipolar electrogram baseline) at -0.1 mV and color low at -2 mV. The virtual unipolar high-pass filter is set to 4 Hz. While earliest activation and breakout sites appear to be associated with similar pace map scores and endocardial bipolar activation prematurity in relation to QRS onset, one study found that the earliest activation site was a more sensitive marker for the true site of origin of the VT/PVC, as evident by the greater likelihood of achieving acute ablative success.⁸⁴

It was speculated that the distance between earliest activation and breakout sites could be affected by the subendocardial depth of the foci and/or the presence of preferential routes of conduction. Electrical propagation from deeper foci results in a larger endocardial area being activated simultaneously. By using unipolar mapping, this would appear like a wide earliest activation and breakout area (with r waves on unipolar signals, rather than QS complexes), and by using bipolar mapping, this would appear like a wide area of early activation. Within the earliest activation and breakout area, small differences in local activation time would result in the earliest activation site appearing to activate milliseconds earlier than breakout sites. The alternative explanation is that there are preferential routes of activation from these subendocardial sites to the endocardial surface, resulting in variable distances between earliest activation and breakout sites.⁸⁴

The EnSite 3000 noncontact mapping system is not commonly used because of several limitations. Manipulation of the array into the RVOT can be difficult, and contact of some portions of the area with

eFig. 23.8 Noncontact Mapping of Idiopathic Right Ventricular Outflow Tract (RVOT) Ventricular Tachycardia. Upper panel, Fluoroscopic (right anterior oblique [RAO] and left anterior oblique [LAO]) views of the EnSite balloon catheter positioned in the RVOT. Middle panel, Color-coded isopotential map of RVOT activation during a single premature ventricular complex (PVC). The inset shows a virtual electrogram at the site of earliest activation (note the QS pattern). Red dots indicate radiofrequency applications. Further detailed mapping using a standard mapping catheter localized the PVC focus to a site adjacent to the site, with the earliest local activation identified by the balloon catheter. Lower panel, Surface electrocardiogram and intracardiac contact (ABL) and virtual noncontact (green) electrograms are shown during mapping of PVCs. His, His bundle; RA, right atrium; RV, right ventricle.

eFig. 23.9 Noncontact Isopotential Maps During a Premature Ventricular Complex (PVC) Originating From the Right Ventricular Outflow Tract. Wavefront propagation spreads radially from a small focus (from *left to right*). The insets show a virtual electrogram with the bar indicating the timing of activation during the PVC.

myocardium may induce PVCs that appear similar to clinical PVCs or VT and confuse mapping efforts. In addition, this mapping tool is appropriate mostly for idiopathic VAs originating from the RVOT. Since the exact site of origin cannot be accurately predicted based on ECG morphology, there will be a significant proportion of patients who will require mapping outside the RVOT (e.g., aortic root or CS) utilizing conventional mapping techniques, in which setting the multielectrode array would not be beneficial.

Basket Catheter Mapping

Basket catheters have been used successfully to guide ablation of idiopathic VAs arising from the RVOT, and are of particular interest in patients with infrequent arrhythmia that limits mapping. This mapping catheter consists of an open-lumen catheter shaft with a collapsible, basket-shaped distal end, which is composed of 64 electrodes mounted on eight flexible, self-expanding, equidistant metallic splines (each spline carrying eight ring electrodes; see Fig. 4.3). The electrodes are equally spaced 4 or 5 mm apart, depending on the size of the basket catheter used (with diameters of 48 or 60 mm, respectively). Each spline is identified by a letter (from A to H) and each electrode by a number (from 1 to 8), with electrode 1 having the distal position on the splines. The size of the RV is initially evaluated (usually with echocardiography) to help select the appropriate size of the basket catheter. The collapsed basket catheter is advanced under fluoroscopic guidance through an 11 Fr long sheath into the RV; the basket is then expanded. After basket catheter deployment, the conventional catheters are introduced and positioned in standard positions (eFig. 23.10). Several observations can help determine electrical-anatomical relations of the basket catheter electrodes, including fluoroscopically identifiable markers (spline A has one marker and spline B has two markers located near the shaft of the basket catheter) and electrical signals recorded from certain electrodes (e.g., ventricular, atrial, or HB electrograms), which can help identify the location of those particular splines.

From the 64 electrodes, 64 unipolar signals and 32 to 56 bipolar signals can be recorded, by combining 1–2, 3–4, 5–6, 7–8, or by combining 1–2, 2–3, until 7–8 electrodes are on each spline. The color-coded animation images simplify the analysis of multielectrode recordings and help establish the relation between activation patterns and anatomical structures. The degree of resolution is lower than that in 3-D mapping systems but appears satisfactory for clinical purposes.

The concepts of conventional activation mapping discussed above are then used to determine the site of origin of the tachycardia. The ablation catheter is placed in the region of earliest activity and is used for more detailed mapping of the site of origin of the VT. The Astronomer navigation system (Boston Scientific, Natick, MA) permits precise and reproducible guidance of the ablation catheter tip electrode to targets identified by the basket catheter. Without the use of this navigation system, it can be difficult to identify the alphabetical order of the splines by fluoroscopic guidance. The capacity of pacing from most basket electrodes allows the evaluation of activation patterns and pace mapping.

Basket catheter mapping is not commonly used because of several limitations. Most basket catheters are difficult, if not impossible, to steer; thus positioning in the RVOT can be challenging. In addition, firm contact with the tip of the basket and RVOT myocardium can induce ectopic complexes that mimic spontaneous VT or PVCs. Spatial sampling is limited by the interspline and interelectrode distances, and endocardial contact is often limited because of the complex geometry of the ventricles. A second catheter is still required to be manipulated to the site identified for more precise localization of the target for ablation, as well as RF energy delivery.

ABLATION

Target of Ablation

The ablation target site is defined as the site where the earliest local activation time during VT or PVCs (bipolar recording preceding the surface QRS typically by more than 20 to 25 milliseconds, and the distal tip recoding the earliest intrinsic deflection and QS unipolar electrogram configuration) and exact or best pace map matches can be obtained. Activation mapping and pace mapping are highly correlated techniques, and both methods are typically used in conjunction to select ablation sites (see Fig. 23.11).

RF delivery at successful ablation sites often results in an early “flurry” of PVCs or acceleration of VT (likely due to stimulatory effect of RF energy in proximity to the arrhythmia focus), followed by gradual slowing and complete resolution of the arrhythmia within 10 to 15 seconds (Fig. 23.13). At these sites, RF application is usually continued for 30 to 60 seconds. The inability to eliminate the PVCs or terminate VT after 20 seconds of RF application should prompt cessation of RF energy delivery and additional mapping to look for a better target site. Of note, late arrhythmia suppression during RF is more commonly seen with ablation of LVOT and LV summit VAs, and likely suggest a site of origin remote from the site of ablation (most commonly seen with intramural foci).¹⁴

Occasionally, following several RF applications, the first VT/PVC morphology is no longer seen, but a second, slightly different one is now observed. This can be caused by an actual second focus near the first or, more likely, by modification of the exit site from the first focus (Fig. 23.14). In this situation, ablation within 1 to 2 cm of the first site frequently eliminates the second VT morphology.

Ablation Technique

Ventricular Tachycardias Originating in the Right Ventricular Outflow Tract

To map the RVOT via the femoral vein, the mapping catheter is advanced into the mid-RV. From there, a sharp clockwise torque directs the catheter toward the anterior portion of the RVOT. The mapping catheter is then advanced into the proximal pulmonary artery and slowly withdrawn into the RVOT until the first local endocardial electrogram is recorded. This site is just below the pulmonic valve, and is at the level where most RVOT VAs originate. It is important to avoid trying to advance the catheter when its tip is perpendicular to the RVOT because this can result in perforation and cardiac tamponade. Torque is applied to the catheter for circumferential mapping of the RVOT within 1 cm of the pulmonic valve. The plane of the septum in the left anterior oblique (LAO) view is nearly perpendicular to the imaging plane. Delineating the boundaries within which mapping will be carried out is useful, rather than discovering after several minutes of mapping that more tissue lies in one direction or another from where efforts had previously been concentrated.

For mapping of the posterior portion of the RVOT, the catheter needs to be flexed posteriorly and counterclockwise torque applied. Such application of counterclockwise torque, however, will tend to pull the electrodes back into the RV inflow portion. Using a long guiding sheath in the RV may offer adequate catheter stability. In addition, mapping of the posterior RVOT wall can be facilitated by advancing the mapping catheter retrogradely into the right aortic sinus (see below), which lies immediately anterior to the RVOT (see eFig. 23.1).

VAs originating from the RVOT typically have local presystolic activation of more than 20 milliseconds and produce a near perfect pace map match. If very thorough mapping in the RVOT fails to localize the VT focus, mapping is extended into the pulmonary artery. It is important to resist the temptation to ablate the earliest site in a given chamber

eFig. 23.10 Basket Catheter Mapping During a Premature Ventricular Complex Originating From the Right Ventricular Outflow Tract (RVOT). Fluoroscopic (right anterior oblique and left anterior oblique) views of a basket catheter positioned in the RVOT. A second catheter is used for further mapping and ablation.

Fig. 23.13 Ablation (ABL) of Idiopathic Ventricular Tachycardia (VT). Radiofrequency (RF) energy delivery is started during sustained VT originating from the right ventricular outflow tract (RVOT). Acceleration of the VT is observed within a few seconds, followed by slowing and termination of the VT.

unless all of the different chambers have been mapped or unless the unipolar electrogram displays a QS morphology concordant with the earliest bipolar electrogram and the pace map at the site of earliest activation matches perfectly.

In some VAs originating from the aortic sinuses of Valsalva, a preferential conduction to the RVOT can render activation and pace mapping misleading. In fact, in one report, 27% of patients with VAs with an aortic sinus of Valsalva origin had the local ventricular activation in the RVOT preceding the QRS onset during VT/PVCs. Therefore it is important to carefully analyze the electrogram at the site of early activation on the RVOT to investigate whether the early electrogram recorded represents a far-field signal. Mapping the supra-ventricular aortic sinus of Valsalva should be considered if the earliest signal is far field in character near the posterior portion of the pulmonic valve. Also, when early presystolic activation from the RVOT is accompanied with a poor pace map match or when RF ablation at a seemingly good RVOT target site fails to permanently suppress the arrhythmia, mapping should be extended to the right aortic sinus of Valsalva. Similarly, RVOT sites displaying good pace maps but not particularly early local activation should prompt consideration for aortic sinus of Valsalva mapping.¹⁴

For catheter ablation in the RVOT, a nonirrigated 4-mm-tip ablation catheter is usually used. Idiopathic VAs are focal in nature and usually superficial toward the RVOT endocardium; therefore, extensive tissue injury is usually not necessary for successful ablation. RF applications at moderate temperatures (target temperature, 55°C) and a maximal power output of 30 to 40 W seem to be safe and effective. The high flow within the RVOT enhances the cooling effect and facilitates adequate RF power delivery. The duration of energy application should not exceed 30 to 60 seconds. Rarely, if ever, does one need more than 50 W or use of irrigated or large-tip electrodes to ablate RVOT VAs successfully, and

it is preferable to avoid those ablation approaches to prevent perforation of the thin free wall of the RVOT.

Ventricular Tachycardias Originating in the Pulmonary Cusps

The pulmonic valve can be defined on electroanatomic mapping by using ICE or by voltage mapping. A cutoff value of 1.9 mV likely discriminates between subvalvular and supra-ventricular positions with 90% sensitivity and 96% specificity. Therefore the level of pulmonic valve may be defined by color-coded voltage map adjustment of the lower and upper thresholds at 1.9 and 1.91 mV, respectively.¹⁵

The ablation target within the pulmonary artery is typically identified by the earliest ventricular activation, with simultaneous activation in bipolar and unipolar recordings. Discrete potentials, representing myocardial extensions into the pulmonary artery, are useful in guiding ablation of VAs arising from pulmonary cusps. Two components at the site with the earliest local activation can be observed: During NSR, the first potential is far-field (representing subvalvular RVOT myocardial activation), and the second potential is near-field (representing local supra-ventricular activation). During VT/PVC originating from the supra-ventricular RVOT, reversal of the two potentials is observed. Of note, RF application during VAs originating from the pulmonary cusps can occasionally lead to a change in QRS morphology, likely caused by interruption of conduction from the PVC focus over one of the myocardial extensions to the subvalvular myocardium, resulting in detouring the activation impulse.¹⁹

Ventricular Tachycardias Originating in the Left Ventricular Outflow Tract

Anatomically, successful catheter ablation sites of LVOT VAs include the aortic root, endocardium underneath the aortic valve (the aorto-mitral continuity), and epicardial surface of the LV (LV summit).²⁹

Fig. 23.14 Ablation of Premature Ventricular Complexes (PVCs) Originating From the Right Ventricular Outflow Tract (RVOT). Electroanatomic (CARTO) activation map (posterior views) of PVCs originating from the RVOT. Left panels show (in order from top to bottom) surface electrocardiogram (ECG) leads (I, II, III, V₁) and bipolar and unipolar recording of the distal ablation electrodes during the PVCs. (A) The site of impulse origin during ectopy is in the posterolateral aspect of the RVOT (red area, arrow), at which intracardiac recordings show early bipolar electrogram concordant with a QS-unipolar electrogram; ablation (red dots) at this site eliminated VT. (B) PVCs with slightly different QRS morphology (note the notching in the QRS in ECG leads II and III) emerged after initial ablation. Mapping revealed the focus of the latter PVCs (note intracardiac recordings) at a close but different location from the site targeted by initial ablation, at which ablation (red area, arrow) eliminated all PVCs.

Mapping is initially performed at the medial (“septal”) aspect of the RVOT and via the coronary venous system. LV and aortic root mapping is performed when the surface ECG strongly suggest an LV origin (e.g., VAs with RBBB configuration), when very thorough mapping and ablation in the RVOT and pulmonary artery fail to localize or terminate the tachycardia, or when recordings from distal CS or great cardiac or anterior interventricular veins suggest an LV origin.

LV and aortic root mapping is performed retrogradely via the femoral artery. Anticoagulation (IV heparin) should be started once the LV is accessed to maintain the ACT above 250 seconds. Importantly, catheter stability in the LVOT below the aortic valve is often challenging using the retrograde transaortic approach. The moving aortic valve leaflets can limit catheter manipulation and prevent stable tissue contact. The use of a long sheath (e.g., SL0 or SL1; 81 cm; St. Jude Medical), with the tip of the sheath placed through the aortic valve into the LV, can facilitate catheter stability and limit catheter dislodgement out of the LV.²⁹

Also, the catheter tip may be looped within the LV and then withdrawn so that the tip of the mapping catheter points upward underneath the aortic valve. The catheter loop may be rotated and partially released to optimized tissue contact while avoiding the disturbance from the movements of the aortic leaflets.²²

Mapping and ablation of the subaortic LVOT endocardium is performed to identify the arrhythmia focus as described for RVOT mapping. Standard or irrigated ablation catheters may be used for LVOT VAs. Some operators prefer irrigated ablation for left-sided idiopathic focal VT because of perceived higher risk of coagulum formation and thromboembolic complications compared with ablation in the RV.

Ventricular Tachycardias Originating in the Aortic Sinuses of Valsalva

Mapping and ablation are generally performed under the guidance of fluoroscopy and 3-D mapping. ICE imaging or contrast aortography can be required to facilitate comprehensive mapping of the supraventricular region (Fig. 23.15). ICE allows direct visualization of the ablation catheter tip, aortic sinuses of Valsalva, left and right coronary artery ostia, and surrounding anatomy, and can potentially eliminate the need for angiography. For catheter ablation in the aortic sinuses of Valsalva, the ICE catheter is positioned in the RV inflow region, just past the tricuspid valve. Longitudinal views are best to appreciate the relationship of the RVOT and LVOT and for identifying the ostia of the coronary arteries. A cross-sectional view is of most value in identifying the sinuses themselves (Fig. 23.16). Once the three sinuses are visualized, the interatrial septum will be seen in immediate relationship to the noncoronary sinus. Rightward and anterior to the noncoronary sinus and immediately behind the RVOT lies the right sinus of Valsalva. Another landmark for the right sinus is that the septal and anterior leaflets of the tricuspid valve will meet at the junction between the right and noncoronary sinuses. The left sinus of Valsalva is identified as being leftward and anterior to the noncoronary sinus and in close relation to the anterior leaflet of the mitral valve. In addition, integration of 3-D electroanatomic mapping and ICE (CARTOSound, Biosense Webster) can facilitate tagging anatomical landmarks (coronary ostia) on the anatomical model. Doppler color flow can be used to determine the degree of aortic regurgitation before and after ablation.^{14,85}

Relative positions among each sinus of Valsalva are viewed in the right anterior oblique (RAO) 30-degree, left anterior oblique (LAO) 60-degree projections. Ant., Anterior; LCC, left sinus of Valsalva; LMT, left main trunk; NCC, noncoronary sinus of Valsalva; Post., posterior; RCA, right coronary artery; RCC, right sinus of Valsalva. (From Sasaki T, Hachiya H, Hirao K, et al. Utility of distinctive local electrogram pattern and aortographic anatomical position in catheter manipulation at coronary cusps. *J Cardiovasc Electrophysiol*. 2011;22:521–529.)

Fig. 23.16 Catheter Ablation in the Aortic Root. Top, Intracardiac echocardiography (ICE) images (*top row*) and left anterior oblique (LAO) and right anterior oblique (RAO) fluoroscopic views (*middle and bottom rows*, respectively). Bottom, Intracardiac recordings. Images and recordings were obtained during mapping in the noncoronary cusp (NCC, *left panels*), right coronary cusp (RCC, *middle panels*), and left coronary cusp (LCC, *left panels*). The ablation catheter tip on ICE and fluoroscopic images is marked by yellow arrows. Cross-sectional ICE images of the aortic valve were obtained with the ICE catheter (*arrowheads*) positioned at the His bundle region of the right ventricular (RV) septum. Right atrial (RA) and RV leads of an implantable cardioverter-defibrillator and a decapolar catheter positioned in the coronary sinus (CS) are marked. In the NCC, large near-field atrial and small far-field ventricular electrograms are recorded by the ablation (ABL) catheter tip. The recorded electrograms from the RCC show a large ventricular electrogram and far-field atrial electrogram. In the LCC, large ventricular and small, far-field atrial electrograms are recorded.

When mapping the aortic sinuses of Valsalva, it is important to consider the entire surface of each of the sinus regions (at the valve level and up to 2 cm above the valve), as well as the corresponding area just beneath the valve, as distinct activation times and pace maps might be obtained from each point. The aortic sinuses of Valsalva are not flat surfaces, and mapping the floor of each sinus often requires rotation

as well bending of the catheter tip. Also, moving the mapping catheter from one sinus to another typically requires withdrawing the catheter tip back toward the ascending aorta out of the recess of the sinus and then reorienting the catheter tip before advancing it into the recess of a neighboring sinus.¹⁴ In addition, myocardial extensions can exist between the right and left sinuses, and mapping and ablation of these

sites usually require the catheter prolapsed below the valve and flexed onto the aortic wall for contact and then gently pulled up into this commissural region.⁸⁸

The earliest endocardial activation time during VT or PVCs should be sought. In a subset (26%) of patients, meticulous mapping within the aortic root can uncover a discrete prepotential with an activation time preceding the QRS onset by more than 50 milliseconds, separated from the ventricular electrogram by an isoelectric interval. Such finding can predict a successful ablation site.⁸⁹

Notably, pace mapping may not be feasible within the aortic sinuses of Valsalva due to the inability to capture the ventricle. Pacing at high output can result in “remote” capture of ventricular myocardium with or without capture of local myocardial sleeves. Therefore pace mapping from the aortic sinuses of Valsalva can potentially produce a poor pace map, even when pacing from the site of origin of the VT, and hence it

is often of limited value to determine the site of origin of VAs arising in the aortic root.¹⁴ Pacing at the junction of left and right sinuses of Valsalva may produce different QRS configurations, due to varying exits from the site (Fig. 23.17). Multiple QRS configurations of VT or PVCs from this site, with multiple exits from a focus, have been described that can be eliminated with a single RF application.

A catheter positioned at the HB region in the RV can be very useful in mapping and ablation of aortic sinus of Valsalva VAs. The HB catheter can be used as a landmark for mapping within the noncoronary and right sinuses, where the proximity to the HB should be kept in mind to avoid inadvertent damage to the AV conduction system. Not infrequently, early far-field ventricular electrograms (reflecting aortic sinus activation) can be recorded preceding the later near-field electrograms reflecting activity of the RV HB region.²⁴ In addition, the local ventricular activation time relative to the QRS onset at the HB region

Fig. 23.17 Multiple Electrocardiogram (ECG) Configurations When Pacing From Left-Right Aortic Leaflet Commissure. All 12 ECG leads are shown during continuous pacing at a consistent site and output. Note wide differences in QRS configurations (left vs. right axis [lead I]; degrees of inferior axis [lead aVF]; left vs. right bundle branch block [lead V₁]). Diagram at bottom right is a cartoon of the aortic root showing possible paths of activation from the same source in the root, spreading in different directions around the right ventricular outflow tract to yield the ECG patterns shown.

Fig. 23.18 Recordings From a Patient With Premature Ventricular Complexes (PVCs) Originating From the Right Aortic Sinus of Valsalva. A sinus rhythm complex as well as the PVC is shown; the vertical line denotes the onset of the PVC QRS. The blue arrow shows that the His bundle ventricular electrogram is slightly presystolic, whereas the red arrow shows the electrogram at the site of origin of the PVC in the sinus of Valsalva, occurring about 100 milliseconds prior to the QRS onset. *Abl_{dist}*, Distal ablation; *Abl_{prox}*, proximal ablation; *Abl_{uni}*, unipolar ablation; *His_{dist}*, distal His bundle; *HRA*, high right atrium; *RV*, right ventricle.

in the RV can be an important clue for differentiating VT origins in the aortic root. The activation time in the HB region is usually significantly earlier during PVCs originating from the right versus the left aortic sinus, suggesting that the activation from the right sinus of Valsalva may propagate to the ventricular septum and RV before the LV free wall, whereas that from the left sinus may do so after part of the LV free wall activates (Fig. 23.18). The local ventricular activation time relative to the QRS onset at the RV HB region typically is significantly later for the VAs with origins from the left sinus of Valsalva and the junction of the right and left sinuses than for those from the noncoronary and right sinuses. Not infrequently, early far-field ventricular electrograms

(reflecting aortic sinus of Valsalva activation) can be recorded preceding the later near-field electrograms reflecting activity of the RV HB region.²⁴

Before performing catheter ablation within the aortic sinuses of Valsalva, it is critical to ensure a safe distance (more than 5 to 10 mm) between the ablation target site and the ostia of the coronary arteries. This can be accomplished by aortic root angiography or selective angiography of the coronary arteries, performed with the ablation catheter positioned at the desired location (via separate arterial access). If the origin of VT is in the left sinus of Valsalva, cannulation the left main coronary artery with a 4 to 5 Fr left Judkin catheter can be utilized as

a marker and for protection of the left main coronary artery in case of ablation catheter dislodgment during RF application. Alternatively, a combination of electroanatomic mapping and ICE imaging (usually appreciated in the longitudinal view of the LVOT) can be used to confirm anatomical location, catheter tip position and contact, and distance to coronary vasculature and to monitor RF delivery. Longitudinal views are best to appreciate the relationship of the RVOT and LVOT and for identifying the ostia of the coronary arteries. For ablation performed in the left sinus of Valsalva or at the left-right sinus junction, the left main coronary ostium is easily visualized at approximately 6 o'clock of the cross-sectional view of the aortic root. Once the left main ostium is visualized, the catheter is rotated or advanced to locate the catheter tip to determine the distance from the coronary ostium. If the catheter tip is seen in the same plane as the coronary ostia, or the catheter tip cannot be clearly visualized, coronary angiography is performed. For ablation performed in the right sinus of Valsalva, a long-axis view of the aortic root is obtained. If the catheter tip is located at the level of the aortic cusp leaflets, a safe distance from the right coronary ostium can be assumed. If the catheter tip is at a level higher than the aortic sinus of Valsalva, above the sinotubular junction, aortic or coronary angiography is performed.⁸⁵

Irrigated or nonirrigated RF ablation catheters may be used for ablation of VAs arising in the aortic root. RF energy delivery in the aortic sinuses is preferably started at a low power output. Using a standard 4-mm-tip catheter, RF power is typically started at 15 to 20 W and then slowly titrated up to achieve a target temperature of 50°C to 55°C and an impedance drop of approximately 10 Ω . For irrigated ablation, RF energy delivery is preferably started at a 15 to 20 W and gradually increased to no more than 30 to 35 W. Occasionally powers of up to 50 W may be used for intramyocardial or epicardial foci targeted from the aortic root. The impedance drop should be carefully observed and power discontinued at any sign of a rise in impedance. It is advisable to apply RF energy during continuous fluoroscopy to observe for catheter dislodgment; RF application should be discontinued in case of even minimal dislodgment from the site showing the best mapping findings. When an acceleration or reduction in the frequency of the VT or PVCs is observed during the first 10 seconds of the application, RF delivery is continued for 30 to 60 seconds. Otherwise, RF delivery is terminated, and additional mapping is performed.²⁴ Coronary angiography is often performed immediately after the ablative procedure to exclude coronary artery spasm, dissection, or thrombus.

Right aortic sinus of Valsalva. Analysis of the electrogram is helpful for identifying the correct positioning of the mapping-ablation catheter at the aortic sinuses of Valsalva during the ablation procedure. The recorded electrogram from the right sinus of Valsalva typically shows a large ventricular electrogram, which represents activation of the overlying relatively thick posterior wall of the RVOT infundibulum (see Fig. 23.16). Because this tissue is immediately adjacent to the anterior portion of the right sinus, the electrogram may appear near field, and the site of early activation can be difficult to distinguish between arrhythmia origination from the myocardium extending above this cusp. Nonetheless, during PVCs originating from the right sinus of Valsalva itself, a smaller and relatively fragmented but near-field electrogram will be observed to precede the large ventricular electrogram and results from activation of the small myocardial sleeve extending into the sinus.

A far-field atrial electrogram may also be recorded in the right sinus of Valsalva, particularly at more posterior locations (closer to the noncoronary sinus), and it usually represents atrial activation of the antero-septal tricuspid annulus or the RA appendage.¹⁴

On fluoroscopy, a catheter positioned in the right sinus of Valsalva (using the retrograde approach) will point rightward in the LAO projection and anterior in the right anterior oblique (RAO) projection.

When the fluoroscopic view appears to suggest right sinus position but a large atrial electrogram is noted, the catheter should be manipulated with clockwise torque to see whether the atrial electrogram becomes larger. If so, the catheter is likely to be in the noncoronary sinus and the fluoroscopic images are misleading, perhaps because of atrial enlargement or counterclockwise rotation of the heart. In this setting, withdrawal of the catheter followed by application of counterclockwise torque and then advancing the catheter again will move the catheter from the noncoronary sinus to the right sinus of Valsalva.

Left aortic sinus of Valsalva. Electrograms obtained in the left sinus of Valsalva are the most variable of the aortic sinuses of Valsalva, but typically the ventricular electrogram amplitude is larger than that of the atrial electrogram. More anteriorly close to the commissure with the right sinus, a large ventricular electrogram, again originating in the posterior RVOT, can be recorded (see Fig. 23.16). More leftward and posteriorly, however, because of the aortomitral continuity, recorded ventricular electrograms are small and far field in nature. In the RAO fluoroscopic view, as the catheter is rotated counterclockwise in the left sinus, a relatively larger but usually far-field atrial electrogram is located representing LA activation close to the antero-septal mitral annulus.

A distinct potential preceding the QRS complex (prepotential) is often recorded at successful ablation sites during VAs originating from the left sinus of Valsalva. When the left sinus site appears early but ablation is unsuccessful, mapping should be extended to the posterior supraventricular pulmonary artery region and the transitional zone from the great cardiac vein to the anterior interventricular vein (LV summit).

Noncoronary aortic sinus of Valsalva. A large near-field atrial electrogram (much larger than the ventricular electrogram amplitude) is typically recorded in the noncoronary sinus of Valsalva, which represents activation of the thick myocardium of the interatrial septum located immediately posterior to the midportion of the noncoronary sinus (see Fig. 23.16). When the catheter is rotated leftward and rightward from the interatrial septum, electrograms from the LA and RA, respectively, are recorded. A far-field ventricular electrogram may also be recorded from the noncoronary sinus, and depending on the exact catheter location, this smaller electrogram may reflect ventricular activation of the posterior LVOT, antero-septal tricuspid annulus, or supraventricular myocardial activation.

On fluoroscopy, a catheter positioned in the noncoronary sinus of Valsalva will point posteriorly in the RAO projection. In the LAO projection, however, the noncoronary sinus can be difficult to distinguish from the left sinus of Valsalva because both appear to be somewhat leftward. When counterclockwise torque is applied and a large near-field atrial electrogram is seen, catheter location in the noncoronary sinus is verified.

The most inferior portions of the noncoronary and right sinuses of Valsalva are in contact with the membranous portion of the inter-ventricular septum, where it comes in close apposition to the penetrating HB. Because of this close proximity, a catheter recording HB activation across the tricuspid annulus typically records an early ventricular activation during VAs originating from the noncoronary and right sinuses of Valsalva. However, as compared with right sinus origins, noncoronary sinus VAs tend to have earlier ventricular activation in the HB region (typically preceding QRS onset by >25 milliseconds), and a larger atrial to ventricular electrogram amplitude ratio, as well as a narrower QRS duration (typically <150 milliseconds), and a smaller lead III/II ratio (typically <0.65).²⁴

In addition, because of the anatomical proximity to the HB, ablation within the noncoronary sinus of Valsalva can result in injury to the HB and AVN. Therefore, before RF energy application, it is important to carefully investigate the presence of His potential during sinus beats at the ablation target site. In addition, monitoring AV conduction and

applying RF energy output in an incremental fashion may help avoid such a complication.

Epicardial Idiopathic Ventricular Tachycardias

Idiopathic focal VAs requiring epicardial ablation (via the coronary venous system or transpericardial approach) are observed in up to 14% of patients. These VAs typically arise in close proximity to the coronary venous system in the LV summit and cardiac crux, including the anterior interventricular vein (which runs in the anterior interventricular sulcus parallel to the left anterior descending coronary artery), the great cardiac vein (which runs in the left AV groove parallel to the left circumflex coronary artery and forms the CS once it is joined by the left atrial oblique vein of Marshall and the posterolateral vein of the LV), the junction of the anterior interventricular and great cardiac veins (near the bifurcation of the left coronary artery), and less commonly the middle cardiac vein (which runs with the posterior descending coronary artery in the posterior interventricular groove).

An epicardial approach typically is not required for VAs originating in the RVOT. The anterior and lateral portions of the RVOT are fairly thin; thus ablation from the endocardium is usually effective, even when VT foci occur on the epicardial surface. The posterior RVOT (infundibulum) is much thicker, but the epicardial surface of the posterior infundibulum is the LVOT, and thus ablation may be effective from either the LVOT or the RVOT for arrhythmias arising deep in the myocardium of the posterior RVOT. For the supraaortic region there is no true epicardial location because the RVOT lies anterior to the right and left sinuses of Valsalva and the atria lie posterior to the noncoronary sinus.

Mapping findings suggestive of epicardial origin include suboptimal pace maps generated from the ventricular endocardial surface, absence of sharp potentials earlier than 15 milliseconds prior to QRS onset, low-amplitude far-field potentials at the earliest endocardial sites, the occurrence of a very slurred upstroke and wide QS complex, and a large area of equally (and minimally) presystolic sites on the activation map.

Ventricular Tachycardias Originating in the Left Ventricular Summit

The LV summit is the most common site of idiopathic epicardial LV arrhythmias. LV summit VAs are most commonly ablated within the great cardiac or anterior interventricular veins. CS venography can help delineate coronary venous anatomy and evaluate feasibility of access to the target area via the CS. Mapping can be facilitated by using small (2.5 Fr), flexible, multipolar electrode catheters introduced through a guiding catheter positioned at the coronary sinus ostium (CS os). Once the ablation catheter is positioned at the target site, and before RF energy delivery, coronary arteriography is performed to outline the spatial relationship between the target vein and the adjacent coronary artery (Fig. 23.19). Although the minimal safe distance between ablation sites and coronary arteries is not clear, ablation is not performed within 5 mm of a coronary artery. Coronary arteriography is also performed after ablation to rule out damage to coronary arteries. In addition, pacing from the distal ablation electrode should be performed at an output of 20 mA. If diaphragmatic capture can be demonstrated, then ablation should not be attempted to avoid phrenic nerve injury.

Although the coronary venous approach can be successful in more than half of patients with LV summit VAs, it is often technically limited. Currently available ablation catheters often are difficult to advance beyond the distal great cardiac vein or the proximal portions of the middle cardiac vein because of the tortuosity, sharp angulation, and small caliber of the distal veins. Also, the coronary veins offer only a limited access to parts of LV summit immediately adjacent to those

veins. In addition, proximity to within 5 mm of a coronary artery (as defined by coronary angiography) can be observed in about three quarters of patients, prohibiting RF ablation because of the potential risk of coronary injury. Furthermore, RF energy delivery is often limited because of impedance and temperature rise (due to limited cooling from surrounding blood flow). It is recommended to use irrigated catheters when ablating within the coronary veins. Cryoablation may also be considered because it is not limited by high impedance and is likely facilitated by low blood flow. Freezing also seems less likely to damage adjacent coronary arteries. However, the cryocatheter can be difficult to maneuver in the coronary venous system.^{14,75,90-92}

When the great cardiac vein is of sufficient size to allow adequate RF energy applications, the elimination of VT can be achieved in most patients. When this approach is not feasible or is unsuccessful, ablation can be attempted at the best identifiable endocardial sites in the LV (immediately below the aortic valve) or in the left aortic sinus. Not infrequently, RF application at the site closest to the early great cardiac vein site can produce a lesion of sufficient transmural to suppress VAs originating from the LV summit, despite a later local activation time (~10 milliseconds) and a poorer pace map at the successful ablation site compared with the best coronary venous site. A close anatomical distance (<13.5 mm) and a Q wave ratio of less than 1.45 in leads aVL/aVR may help identify the most appropriate cases for an ablation attempt from the left sinus of Valsalva or the adjacent LV endocardium in this setting. Also, a recent report found that all successful ablation sites had VAs with an initial r wave in lead I and local activation time within 7 milliseconds of the earliest activation site within the great cardiac vein.^{14,90,91}

When endocardial ablation and ablation from within the coronary venous system is not feasible or unsuccessful, the percutaneous trans-thoracic epicardial approach needs to be considered. The percutaneous epicardial approach, required in about 20% to 30% of patients with LV summit VAs, provides access to the entire epicardial surface and allows the deployment of a greater range of ablation catheters and energy sources (see Chapter 27 for a detailed discussion). However, in addition to the increased risk of complications, the transthoracic epicardial approach has significant limitations. Sedation and anesthesia as is generally used for transpericardial procedures can suppress arrhythmias. In addition, the close proximity of the coronary arteries and the thick layer of epicardial fat that overlies the proximal portion of these vessels ("the inaccessible area" in the superior aspect of the LV summit) often prohibit successful ablation in a significant proportion of these patients. In fact, LV summit foci account for the majority of ablation failures for OT VAs in the present era.^{14,74,75,90,91}

When epicardial ablation within the coronary veins or via the transpericardial approach is anticipated, an irrigated ablation catheter is preferred, giving the frequent occurrence of high tip temperatures limiting power delivery via nonirrigated catheters. Power output is typically started at 20 W with an irrigation flow rate of 30 mL/min. RF power output is increased gradually (up to 30 W within the coronary venous system, and 50 W within the pericardium), with a goal of impedance drop of impedance of 8 to 10 Ω . Precautions should be undertaken to avoid injuring the coronary arteries during ablation, as discussed above for ablation within the aortic root. RF ablation should never be performed within 5 mm of a coronary artery.

Ventricular Tachycardias Arising From the Cardiac Crux

VAs originating from the basal crux of the heart can be ablated via the middle cardiac vein, whereas ablation of apical crux VAs often requires the percutaneous subxiphoid epicardial approach. The use of thin multielectrode catheters can facilitate mapping distally in the middle cardiac vein.^{33,34}

Fig. 23.19 Recordings From a Patient With Premature Ventricular Complexes (PVCs) Originating on the Left Ventricular (LV) Summit. The dashed line denotes the onset of the PVC QRS complex. Note that the distal coronary sinus electrogram (CS_{dist}) (blue arrow) occurs well before the onset of the QRS, similar to the ablation catheter recording in the pericardial space (red arrow); the location is shown in the fluoroscopic views at right (Abl). Abl_{dist}, Distal ablation; Abl_{prox}, proximal ablation; Abl_{uni}, unipolar ablation; Cx, circumflex coronary artery; CS_{prox}, proximal coronary sinus; His_{dist}, distal His bundle; His_{prox}, proximal His bundle; LAD, left anterior descending artery; LAO, left anterior oblique; LM, left main coronary artery; RAO, right anterior oblique; RV, right ventricle.

Ventricular Tachycardias Originating From the Left Ventricular Papillary Muscles

RF catheter ablation of these VAs is particularly challenging, likely secondary to the complex structure of the papillary muscles as well as the relatively deep intramural VT origins within the thick muscle. In addition, maintaining an adequate and stable catheter tip contact with the papillary muscle during ablation can be challenging because of the vigorous motion associated with normal papillary muscle contraction. Furthermore, induction of mechanical and thermally provoked ectopy can complicate catheter stability and hinder activation mapping.

While the retrograde transaortic approach to the LV usually is adequate for mapping and ablation of VAs originating from the posterior papillary muscle, the transseptal approach often provides added advantage for access and catheter stability to the anterior papillary muscle. The use of a long sheath can enhance catheter manipulation and stability. With the retrograde transaortic approach, a long SL0 or SL1 sheath (81 cm, St. Jude Medical) is often used with the tip of the sheath placed through the aortic valve into the LV. With the transseptal approach, a deflectable sheath with a large curve (Agilis, St. Jude Medical) is preferred with the tip positioned near the mitral annulus. In addition, ICE can help facilitate catheter navigation and positioning

and visualize direct contact with the papillary muscle (Fig. 23.20).⁹³ Ablation catheters with contact force capabilities can be of significant benefit in these procedures.^{30,31}

Sites with the earliest endocardial activation and matching pace maps are targeted by ablation. Purkinje potentials often (in 40% of patients) can be observed at successful ablation sites. Importantly, pace mapping alone is usually insufficient to guide successful ablation. The site of origin of VT can be located deep within the muscle and away from the exit site at the base of the papillary muscle. The latter sites can exhibit perfect pace maps but are not good targets for ablation.³¹

Use of high RF power delivered from an irrigated ablation catheter and RF lesions in a relatively wide area and, not infrequently, on both sides of the papillary muscle often are required to achieve successful ablation. For deep intramural arrhythmia sources, circumferential ablation at the base of the targeted papillary muscle (aiming for exit block) can overcome the anatomical limitations and improve the ablation outcome.^{31,34,94}

Of note, in up to 50% of patients, LV papillary muscle VAs exhibit variable QRS morphologies spontaneously or after the initial RF ablation lesions, likely related to different directions of propagation of the wavefront exiting the papillary muscle.

Fig. 23.20 Intracardiac Echocardiography (ICE) for Ablation of Arrhythmias Rising From Left Papillary Muscles. The ICE transducer is positioned in the right ventricle, across the tricuspid valve, abutting the interventricular septum (IVS). (A) The left posteromedial papillary muscle is visualized (white arrows). (B) The left anterolateral papillary muscle is visualized (white arrows) as well as the ablation catheters (yellow arrowheads) which was advanced across the mitral valve (via the atrial transseptal approach). ICE allows confirmation of catheter contact with the anterolateral muscles. MV, Mitral valve.

When catheter stability remains an issue, cryoablation can be considered. Cryoadhesion helps ensure constant contact of the ablation catheter to the target tissue on the mobile papillary muscle during ablation. The lack of catheter motion (as well as the lack of tissue heating) also limits mechanical and thermally induced ectopy, which can impede catheter stability. However, cryoablation may not result in sufficiently deep lesions to eliminate foci within the papillary muscle.³⁰

Para-Hisian Ventricular Tachycardias

If the earliest ventricular activation was observed close to the HB region (i.e., the area near the HB and within 10 mm of the largest His potential recording site) in the RV during the VT or PVCs, mapping should be extended to the aortic root and subaortic LV septum before attempting ablation in the RV His region. The most inferior portion of the non-coronary and right sinuses of Valsalva are in contact with the membranous portion of the interventricular septum where it comes in close apposition to the penetrating HB (see Fig. 9.1). Because of this close proximity, VAs originating from those two sinuses can be associated with early activation recorded from a catheter in the para-Hisian position across the tricuspid annulus, which likely represents a breakout point into the RV myocardium.

Ablation at the para-Hisian region carries a risk of AV block. To minimize this risk, it is recommended to use a standard, nonirrigated 4-mm tip ablation catheter and start RF energy application at low power output (10 to 20 W) with gradual titration up to the target output. RF application should be discontinued immediately if accelerated junctional rhythm or AV block is observed. It is also advisable to avoid ablation immediately over the proximal HB (as indicated by an A:V electrogram amplitude ratio above 1:1 with His potential).⁵⁹ Cryoablation can also potentially limit the risk of injury to the AV conduction system.

When ablation at the RV para-Hisian region causes a change in the QRS morphology during VT/PVCs, an aortic sinus of Valsalva focus should be suspected, since ablation in the RV region can potentially alter the connection from the sinus of Valsalva to the RV myocardium, which in turn precipitates the change in ventricular activation pattern.¹⁷

Intramural Ventricular Tachycardias

Diagnosis of an intramural VT/PVC foci is challenging and is often made only after extensive mapping of the left and RVs and related endocardial and epicardial anatomical areas. Clues for an intramural site of origin include (1) the earliest local activation sites on both sides of ventricular wall share a similar activation timing (within less than 10 milliseconds) and neither produce a satisfactory pace map; (2) far-field ventricular potentials preceding near-field local electrograms can be recorded in the endocardial and epicardial sites during VAs; (3) RF ablation at the site of the earliest local ventricular activation or best pace map (from the endocardial or epicardial side) results in either only transient suppression or no effect on the arrhythmia.^{29,95}

For intramural LVOT foci, RF ablation can be performed in a sequential manner from the endocardium followed by the epicardium (via the coronary venous system), or vice versa. For refractory cases, RF ablation can be performed simultaneously from two ablation catheters positioned on the endocardial and epicardial LVOT. The latter approach typically entails the application of irrigated unipolar RF current to the distal electrodes of two ablation catheters using two RF generators at the same sites. In intramural LVOT foci, this ablation approach was most successful when the distance between the endocardial and epicardial ablation sites was more than 8 mm and the local ventricular activation time relative to the QRS onset during the VAs earlier than -30 milliseconds was recorded in the aortomitral continuity or great cardiac vein. RF current can also be applied in a bipolar configuration from the distal electrode of the two ablation catheters. However, bipolar RFCA may not be effective when there is an impedance mismatch between the aortomitral continuity and coronary venous system, as the higher impedance of either electrode will limit the current that can be applied to both electrodes. An intramural needle ablation catheter has been developed to create an intramural RF lesion, but this catheter is not yet commercially available.^{29,95}

The region of the interventricular septum between the RVOT and LVOT can be mapped by using thinner multielectrode catheters advanced via the septal perforating venous tributaries of the great cardiac vein

that give direct access to intramural locations.⁹⁶ When this is not feasible, a recent report described the utility of infusing cold saline into those veins for the diagnosis of intramural foci. An irrigated-tip catheter is positioned in the distally in the great cardiac vein close to the origin of the anterior interventricular vein. During ongoing ventricular ectopy, cold saline is infused via catheter the ablation catheter at a rate of 60 mL/min for 10 seconds. Reproducible suppression of PVCs by cold saline infusion suggests an intramural PVC site of origin in the territory of the anterior interventricular vein. For intramural septal foci, several reports described the value of sequential or simultaneous irrigated RF ablation at the sites directly across the myocardial wall (right and left sides of the interventricular septum).^{97,98}

Endpoints of Ablation

Successful ablation is defined as the lack of spontaneous or inducible PVCs and VT, with and without isoproterenol administration (using the best method for induction documented before ablation), at least 30 minutes after ablation.

Outcome

The acute success rate of ablation of idiopathic VAs ranges from 75% to more than 90%.¹¹ The recurrence rate after an acutely successful ablation is approximately 15%. Of these, 40% recur during the first 24 to 48 hours after the ablation procedure. Recurrence of VT beyond the first year post ablation is rare. The acute success of ablation largely depends on the presence of spontaneous or inducible VT or PVCs at the time of the procedure, as well as on the anatomical site of origin of the arrhythmia. Predictors of recurrences include poor pace map, late activation at target sites, reliance on pace mapping alone, and termination of VT inducibility with mechanical trauma by the mapping-ablation catheter before RF delivery. Success rates are highest for RVOT VAs, but are more modest for VAs arising from the LV summit, papillary muscles, and intramural foci. Late (after few months of initially successful ablation) recurrences of PVCs can also be observed, especially in patients who had pleomorphic PVCs at baseline. Successful ablation of the dominant PVC focus can be followed by increasing frequency of previously nondominant foci.^{57,99}

Complications are very infrequent. RBBB develops in 2%, and cardiac tamponade is rare. Systemic thromboembolism and damage to the aortic valve (causing aortic regurgitation) can occur during ablation of LVOT or aortic sinus of Valsalva VAs.

The potential for acute coronary artery occlusion is a major risk consideration with catheter ablation within the aortic cusps. Damage to the coronary arteries can result from catheter manipulation and ablation in the aortic root, secondary to RF energy delivery in close proximity to the ostia of the right or left coronary arteries, as well as inadvertent catheter engagement of the left main coronary artery when ablating in the left aortic sinus of Valsalva. Damage to the left coronary artery and its branches can also complicate epicardial ablation via the coronary venous system or the percutaneous pericardial approach. It is also important to recognize the potential risk of coronary artery damage when ablating in the RVOT and pulmonary artery. The right coronary artery is typically 4 to 5 mm away from the proximal part of the RVOT near the free wall, and is separated by a variable amount of fat. In addition, the cephalocaudal separation of the pulmonic and aortic valve results in close proximity of the pulmonic valve to the origin of the right coronary artery, and the left main coronary artery lies in immediate posterior proximity to the subvalvular RVOT near the pulmonic valve as well as the supra-ventricular pulmonary artery; in fact, an ablation catheter at this site is closer to the left main coronary artery than a catheter at the floor of the left aortic sinus of Valsalva. Thus when concern exists about possibly damaging the artery, the

ablation catheter should be kept where energy delivery is to be given, and a root aortogram, coronary angiography, or careful ICE imaging should be performed.

Catheter ablation at the right or left para-Hisian region can cause AV block. Furthermore, the penetrating HB lies at the membranous septum formed in part by the commissure between the right and non-coronary sinuses, and ablation at this region can potentially damage the HB. Typically the HB electrogram can be recorded from the right sinus of Valsalva posteriorly, the noncoronary sinus anteriorly, and when the electrode has been prolapsed below the plane of the semilunar valve in between these two sinuses. However, during VT, the His potential can be inscribed within the ventricular electrogram because of retrograde activation to the HB, and hence may not be easily recognizable. Therefore, when ablating in the depths of the noncoronary sinus of Valsalva, particularly toward the junction with the right sinus, monitoring for fast pathway damage (AH interval prolongation, junctional beats) is advisable.²⁴

Cryoablation

Focal ablation of idiopathic VAs can be performed using an 8-mm cryoablation catheter (Freezor MAX 3, Medtronic, Minneapolis, MN, United States). A major advantage of cryoablation is the virtual absence of pain, which makes the use of analgesia unnecessary. Moreover, reasonable fluoroscopy and procedure times can be achieved by an experienced investigator. Stability of the catheter during cryoablation can be advantageous because monitoring of catheter position by fluoroscopy is not necessary. Adhesion of the catheter, however, requires precise positioning before the start of cryoablation. Slight dislocations, as may easily occur with breathing, can delay ablation success. Furthermore, brushing of the catheter within a small, defined area, as often observed with RF ablations, cannot occur; therefore repositioning of the catheter to adjust for a dislocation is not possible during cryoablation. The cryocatheter differs substantially in size and rigidity from standard RF catheters and requires some experience in handling.

Complete disappearance of the arrhythmia is typically observed within 20 seconds of freezing. Therefore cryoablation is stopped after 60 seconds if no positive effect is observed.

Given the high success rate and low risk of RF ablation of idiopathic VAs, it may be difficult to demonstrate a clinical advantage of cryoablation over RF ablation. Nonetheless, cryoablation can be of value in difficult or atypical sites when a maximal stability of the catheter is necessary—for example, to avoid dislodgment of the catheter into the coronary arteries during ablation of idiopathic VAs originating from the aortic sinuses of Valsalva. In addition, cryoablation may be considered for elimination of epicardial VAs from within the coronary venous system, when RF energy delivery is limited. Cryoablation may have a role in para-Hisian PVCs to reduce the risk of AV block. Also, the absence of pain during ablation may render the procedure more comfortable for the patient, especially when the use of sedative medications suppresses inducibility of the VT.¹⁰⁰

Video 23.1 Ablation of Ventricular Tachycardia Originating From the Aortic Root: Guided by Intracardiac Echocardiography. *Part 1:* Intracardiac echocardiography (ICE) of the aortic valve. A cross-section image of the aortic valve is obtained with the ICE catheter positioned in the mid right atrium (RA) with slight anterior deflection. Clockwise torque of the ICE catheter brings its tip closer to the aortic root (His bundle region) and better visualizes the interatrial septum and left atrium (LA). *Part 2:* With the ICE catheter in the mid RA, anterior and clockwise deflection of the catheter tip to the medial aspect of the tricuspid annulus allows a long-axis view of the left ventricle (LV), LV outflow region and mitral valve (MV), and LA. From that position, counterclockwise torque of the catheter brings more of the RA in view as well as the TV, RV, and cross-section of the aortic valve. *Part 3:* A cross-sectional view of the aortic valve with the tip of the ablation catheter (Abl) visualized in the NCC. *Part 4:* A cross-sectional view of the aortic valve with the tip of the ablation catheter visualized in the RCC. *Part 5:* A cross-sectional view of the aortic valve with the tip of the ablation catheter visualized in the LCC. *Part 6:* A long-axis view of the aortic root with the tip of the ablation catheter visualized in the LCC. LCC, Left coronary cusp; NCC, noncoronary cusp; RCC, right coronary cusp; RV, right ventricle; TV, tricuspid valve.

Video 23.2 Epicardial Ablation of Focal Ventricular Tachycardia Originating From the Left Ventricular Summit. Right anterior oblique (RAO) and left anterior oblique (LAO) fluoroscopic views during selective left coronary angiography with the ablation catheter positioned at the site of origin of focal ventricular tachycardia (VT) originating from the left ventricle (LV) summit. The ablation catheter is positioned epicardially via the subxiphoid percutaneous approach. Note the proximity of the ablation catheter to the left anterior descending coronary artery. CS, Coronary sinus.

PATHOPHYSIOLOGY

The His-Purkinje system plays an important role in the genesis of cardiac arrhythmias. The mechanisms of several types of monomorphic ventricular tachycardias (VTs) have been directly linked to the Purkinje system, including bundle branch reentrant VT, interfascicular reentrant VT, fascicular VT, and focal Purkinje VT. A subset of polymorphic VTs and ventricular fibrillation has also been linked to triggers originating from the Purkinje system. Most of those arrhythmias occur in patients with underlying structural heart disease; however, fascicular VT and a subset of focal Purkinje VTs are idiopathic, occurring in the absence of apparent cardiac disease.^{1,2}

Idiopathic fascicular VT is a reentrant tachycardia involving the left fascicular Purkinje system. The reentry circuit is most commonly (90%) located in the territory of the left posterior fascicle (LPF), infrequently (5% to 10%) in the region of the left anterior fascicle (LAF), and rarely arise from fascicular locations high in the septum. Fascicular VT is also referred to as “verapamil-sensitive” VT, given its tendency to slow or terminate with intravenous verapamil.^{3,4}

Tachycardia Circuit

In the most common form (LPF-VT), the tachycardia circuit incorporates the LPF serving as one limb and abnormal Purkinje tissue with slow, decremental conduction serving as the other limb. The anterograde limb may be associated with longitudinal dissociation within the LPF or contiguous tissue that is directly coupled to the LPF (such as a false tendon) or, alternatively, has ventricular myocardium interposed. The zone of slow conduction appears to depend on the slow inward calcium current because the degree of slowing of tachycardia cycle length (TCL) in response to verapamil is entirely attributed to its negative dromotropic effects on the area of slow conduction.^{5,6}

The entrance site to the slow conduction zone is thought to be located closer to the base of the left ventricle (LV) septum. From there,

activation propagates anterogradely (from basal to apical segments along the LV septum) over the abnormal Purkinje tissue with decremental conduction properties and verapamil sensitivity, which serves as the anterograde limb of the circuit and appears to be insulated from the nearby ventricular myocardium. The lower turnaround point of the reentrant circuit is located in the lower third of the septum, where the wavefront captures the fast conduction Purkinje tissue from or contiguous to the LPF, and retrograde activation occurs over the LPF from the apical to basal septum forming the retrograde limb of the reentrant circuit. In addition, at the lower turnaround point, anterograde activation occurs down the septum to break through (at the exit of the tachycardia circuit) in the posterior septal myocardium. The upper turnaround point of the reentrant circuit occurs over a zone of slow conduction located close to the main trunk of the left bundle branch (LB) in the basal interventricular septum (Fig. 24.1). The estimated distance between the entrance and exit of the circuit is approximately 2 cm.^{5,6}

Anatomy of the Left Fascicular System

The LB arises from the His bundle (HB) as numerous fine, intermingling fascicles that leave the left margin of the branching HB through most of its course along the crest of the muscular ventricular septum. The predivisional portion of the LB penetrates the membranous portion of the interventricular septum under the aortic ring and then divides under the septal endocardium into two branches: the LAF and the LPF. An estimated 65% of individuals have a third fascicle of the LB, the left median fascicle (LMF). The fascicles cascade down the LV septum in a fan-like configuration with extensive interconnections. Unlike the cord-like right bundle branch, the LB and its divisions are diffuse, fan-like structures that quickly arborize just beyond their origin. The LAF represents the superior (anterior) division of the LB, the LPF represents the inferior (posterior) division, and the LMF represents the septal (median) division.

Fig. 24.1 Schematic Illustration of the Reentrant Circuit in Fascicular Ventricular Tachycardia (VT). A block of the LV septum is depicted with the left posterior fascicle (LPF) and diastolic pathway (DP) running in parallel until they intersect at the bottom. A 10-pole catheter is shown recording between pathways; electrograms from each pair are shown along with surface electrocardiogram leads and His bundle recordings. (A) Activation sequence is shown during normal sinus rhythm (NSR), the dashed line denotes QRS onset. Note the direction and speed of propagation over the LPF while the DP is activated after the QRS and in both directions (arrows). (B) During VT complex, the DP is activated anterogradely and the LPF retrogradely (arrows). See text for discussion.

The LB subdivisions extend to the midportion of the septum before they detach from the underlying endocardium and form free-running false tendons that traverse the ventricular chamber, projecting predominantly toward the papillary muscles. The fascicles become ramified in the ventricular apex and extend back along the ventricular walls toward the cardiac base.⁷

The thin LAF crosses the anterobasal LV region toward the anterolateral papillary muscle and terminates in the Purkinje system of the anterolateral LV wall. The LPF appears as an extension of the main LB and is broad in its initial course. It then fans out extensively toward the posterior papillary muscle and terminates in the Purkinje system of the posteroinferior LV wall. The LMF runs to the interventricular septum; it arises in most cases from the LPF, less frequently from the LAF, or from both fascicles, and in a few cases it has an independent origin from the central part of the main LB at the site of its bifurcation.²

EPIDEMIOLOGY

Fascicular VT accounts for 10% to 15% of all idiopathic VTs. Age at presentation is typically 15 to 40 years (unusual after 55 years). Males are more commonly affected (60% to 80%). The clinical course is generally benign, and the prognosis is excellent. Sudden cardiac death is very rare. Tachycardia-induced cardiomyopathy precipitated by incessant

VT can be observed in 6% of patients. Spontaneous remission of the VT can occur with time.⁸

CLINICAL PRESENTATION

Most patients present with mild to moderate symptoms of palpitations and lightheadedness. Occasionally, symptoms are debilitating and include fatigue, dyspnea, and presyncope. Syncope and cardiac arrest are rare. The VT is typically paroxysmal and can last for minutes to hours. Although fascicular VT can occur at rest, it is sensitive to catecholamines and often occurs during physical or emotional stress. Rarely, the VT can become incessant, sustained for a long period (days) and does not revert spontaneously to normal sinus rhythm (NSR). When incessant, fascicular VT can precipitate tachycardia-induced cardiomyopathy and heart failure.⁸

INITIAL EVALUATION

The diagnosis of fascicular VT is based on: (1) VT morphology on the surface electrocardiogram (ECG) (right bundle branch block [RBBB] with left or, less commonly, right axis deviation); (2) VT sensitivity to verapamil; and (3) absence of structural heart disease. Invasive electrophysiology (EP) testing is required to confirm the diagnosis. Evaluation

to exclude structural heart disease is necessary and typically includes echocardiographic examination (that may show one or more prominent false tendons), stress testing, and coronary arteriography, depending on patient age and risk factors.⁸

PRINCIPLES OF MANAGEMENT

Acute Management

Electrical cardioversion is required for VT termination in hemodynamically unstable patients. For stable patients with an established diagnosis of verapamil-sensitive fascicular VT, intravenous verapamil is the first-line treatment and is very successful in acutely terminating the VT. Intravenous verapamil slows the rate of VT progressively and then terminates it. Diltiazem is equally effective. Nonsustained VT may continue to occur for a while after termination.³

Response of VT to lidocaine, procainamide, amiodarone, sotalol, and beta-blockers is less consistent, and these drugs are usually ineffective. Carotid sinus massage and Valsalva maneuvers have no effect on the VT. Fascicular VT is generally unresponsive to adenosine; however, when catecholamine stimulation (isoproterenol infusion) is required for the initiation of VT (in the EP laboratory), the VT can become adenosine sensitive.^{8,9}

Chronic Management

Oral verapamil or diltiazem is useful in mild cases; however, long-term efficacy is variable and the benefit of these drugs in management of patients with severe symptoms is often limited. Catheter ablation is highly effective (success rate of 85% to 90%) and is recommended for patients in whom drug therapy is not successful, not tolerated, or not preferred.^{3,8,9}

ELECTROCARDIOGRAPHIC FEATURES

Electrocardiogram During Normal Sinus Rhythm

The resting ECG is usually normal. Symmetrical inferolateral T wave inversion can be observed after termination of the VT (cardiac memory).

Electrocardiogram During Ventricular Tachycardia

Fascicular VT is characterized by relatively narrow QRS duration (127 ± 11 milliseconds) and short RS interval (the duration from the beginning of the QRS to the nadir of the S wave) in the precordial leads (60 to 80 milliseconds). The shorter QRS duration reflects the proximal exit of fascicular VTs from the His-Purkinje system (HPS). In addition, during fascicular VT, the interventricular septum is activated early with a left-to-right direction, resulting in an initial “r” waves in lead V_1 and small “q” waves in leads I and aV_L (similar to classic RBBB pattern). In addition, the rapid activation of the LV via the Purkinje system results in unopposed late activation of the right ventricular outflow tract (RVOT), leading to a large R' amplitude in lead V_1 (and $r < R'$).^{8,10}

The VT rate is approximately 150 to 200 beats/min (range, 120 to 250 beats/min). Alternans in the TCL is frequently noted; otherwise, the VT rate is stable.

According to the fascicular territory involved and, consequently, the QRS morphology, fascicular VTs are classified into three subtypes: (1) LPF VT (with the reentrant circuit exit in the inferoposterior septum) exhibits an RBBB and superior axis configuration (most common form); (2) LAF VT (with the reentrant circuit exit in the anterolateral wall of the LV) exhibits RBBB and right-axis deviation configuration; and (3) upper septal fascicular VT with a narrow QRS and normal axis configuration (rare form). In the most common form (LPF-VT), the QRS during VT typically has RBBB with LAF block configuration. The R/S ratio is less than 1 in leads V_5 and V_6 (Fig. 24.2). VTs arising more toward the middle at the region of the posterior papillary muscle have a left superior axis and RS in leads V_5 and V_6 , whereas those arising closer to the apex have a right superior axis with a small “r” and deep S (or even QS) in leads V_5 and V_6 .^{1,8}

ELECTROPHYSIOLOGICAL TESTING

Induction of Tachycardia

Given the reentrant mechanism of fascicular VT, the arrhythmia is usually inducible by programmed electrical stimulation. In fact, fascicular

Fig. 24.2 Surface Electrocardiogram of Fascicular Ventricular Tachycardia (VT). Note the right bundle branch block and left anterior fascicle block pattern characteristic of these VTs.

VT is characterized by its reproducible initiation and termination not just by ventricular stimulation but also by atrial pacing. Often, isoproterenol infusion facilitates VT induction. Consistent with a reentry mechanism, an inverse relationship is observed between the coupling interval of the initiating ventricular extrastimulation (VES) or ventricular pacing cycle length (PCL) and the first VT beat.⁶

Diagnostic Maneuvers During Tachycardia

Entrainment

Entrainment of fascicular VT can usually be demonstrated with ventricular pacing at a PCL approximately 10 to 30 milliseconds shorter than the TCL. Manifest entrainment is more frequently achieved when pacing is performed from the RVOT because the RVOT is closer to the entrance site of the area of slow conduction in the reentrant circuit, located near the base of the LV septum. On the other hand, pacing from the RV apex is less likely to demonstrate entrainment and, when it does, it is unlikely to demonstrate manifest fusion because of the larger distance from the entrance site of the circuit and because of the narrow excitable gap of the reentrant circuit.

Resetting

Fascicular VT can be reset by VES, with an increasing or mixed resetting response (characteristic of reentrant circuit with an excitable gap).

Termination

VT can be reproducibly terminated with programmed atrial or ventricular stimulation.

Exclusion of Other Arrhythmia Mechanisms

The differential diagnosis of fascicular VT includes interfascicular VT, supraventricular tachycardia (SVT) with aberrant conduction, and VT originating from the LV papillary muscles.

Interfascicular Ventricular Tachycardia

Interfascicular VT has several characteristic features (see Chapter 26): (1) bifascicular block QRS morphology during VT, which is identical to that during NSR; (2) reversal of activation sequence of the HB and LB during VT; and (3) spontaneous oscillations in the TCL caused by changes in the LB-LB interval that precede and drive the TCL. Interfascicular VT terminates with VES or radiofrequency (RF) ablation that produces block in LAF or LPF.

Supraventricular Tachycardia

When fascicular VT is associated with a 1:1 VA conduction and because of its responsiveness to verapamil and inducibility by atrial pacing, it can be misdiagnosed as SVT with bifascicular block aberrancy. During SVT (similar to NSR), the HB is activated in an anterograde direction with sequential activation of the HB and ventricles (see Chapter 21). In contrast, during fascicular VT, the HB is activated retrogradely, with parallel activation of the HB and ventricle. Thus the HV interval during SVT with aberrancy is equal to or slightly longer than that during NSR. On the other hand, the HV interval during fascicular VT is frequently negative (i.e., His potential is recorded after onset of the QRS). The His potential can also precede the QRS onset during fascicular VT (especially during upper septal fascicular VT); however, the HV interval during VT will be shorter than that during NSR. In addition, unlike fascicular VT, aberrantly conducted SVTs are typically responsive to adenosine, beta-blockers, and Valsalva maneuvers.

Papillary Muscle Ventricular Tachycardia

Papillary muscle VTs typically manifest as premature ventricular complexes (PVCs) rather than sustained monomorphic VT and are more

likely to occur in older patients with structural heart disease. VTs arising from the LV papillary muscles exhibit a QRS morphology that can mimic fascicular VT. However, compared with fascicular VT, papillary muscle VTs have a broader QRS complex (150 ± 15 milliseconds vs. 127 ± 11 milliseconds). In addition, VTs originating from the papillary muscles (which are farther away from the septum) lack the rsR' pattern in lead V₁; rather, those VTs often have a qR pattern (or, less commonly, a monophasic R wave) in lead V₁. Furthermore, spontaneous variations in QRS morphology occur relatively frequently during VTs originating from the LV papillary muscles, a feature that can help distinguish these VTs from LV fascicular VT; the latter being a reentrant tachycardia with a consistent QRS morphology.^{8,10} Unlike patients with fascicular VAs, papillary muscle VAs are typically not inducible with programmed electrical stimulation, which is consistent with a nonreentrant mechanism of papillary muscle VTs.

Focal Purkinje Ventricular Tachycardia

Idiopathic focal VTs can arise from the Purkinje system in either ventricle and can present as PVCs, accelerated idioventricular rhythm, or VT. Focal Purkinje VTs arising from the left Purkinje network exhibit an RBBB pattern with either left- or right-axis deviation and can be difficult to distinguish from fascicular VT. In contrast to the reentrant idiopathic fascicular VT, focal Purkinje VTs are most likely related to abnormal automaticity. These VTs are sensitive to autonomic tone and frequently display chronotropic properties. Focal Purkinje VTs are typically induced by exercise and catecholamines and slowed or terminated by beta-blockers (and hence classified as "propranolol-sensitive" VTs) and lidocaine. Unlike fascicular VT, focal Purkinje VTs are not responsive to verapamil and cannot be induced or terminated by programmed electrical stimulation. In addition, these VTs are transiently suppressed by adenosine and with overdrive pacing.¹¹

MAPPING

Activation Mapping

Activation mapping is performed during sustained VT and is specifically directed toward sites with His or Purkinje potentials (PPs) extending from LV basal septal sites with HB recordings to most apical sites with presystolic PPs. Activation mapping is used to identify sites with the earliest ventricular activation and earliest presystolic PPs, as well as late diastolic potentials (LDPs).^{6,8} Mapping is performed along the LV inferior septum (for LPF VT), along the anterolateral LV (for LAF VT), or the basal LV septum (for left upper septal VT). Strategies for mapping and ablation of LPF VT, the most common type of fascicular VT, are discussed here in detail. The same principles can be applied for the two other types of fascicular VT.

When the VT is not inducible or not sustained, mapping can be performed during NSR to record the PPs along the posterior aspect of the LV septum, identifying the course of the LPF.

Site of Earliest Ventricular Activation

The site of earliest ventricular activation during VT (which represents the exit of the reentrant circuit) is in the region of the LPF (inferoposterior LV septum) in 90% of fascicular VTs (explaining the RBBB–superior axis configuration of the QRS), and in the region of the LAF (anterosuperior LV septum) in 5% to 10% of fascicular VTs (explaining the RBBB–right axis configuration of the QRS). In most cases, ventricular electrograms at the site of earliest activation are discrete during both NSR and VT. The HB is not a component of the reentrant circuit; in fact, a retrograde His potential is often recorded 20 to 40 milliseconds after the earliest ventricular activation (Fig. 24.3).¹²

Fig. 24.3 Idiopathic Fascicular Ventricular Tachycardia. The blue arrow shows late diastolic small potential, 45 milliseconds prior to QRS onset. Distinct Purkinje-like potentials (*blue arrow*) are evident before the dotted line denoting QRS onset, as well as in the proximal ablation electrogram. The red arrow indicates retrograde His potential. Note the unipolar QS configuration just coinciding with QRS onset. *Abl_{dist}*, Distal ablation; *Abl_{prox}*, proximal ablation; *Abl_{uni}*, unipolar ablation; *His_{dist}*, distal His bundle; *RVA*, right ventricular apex; *RVOT*, right ventricular outflow tract.

Fig. 24.4 Sinus Rhythm Recordings at a Successful Ablation Site for Fascicular Ventricular Tachycardia. The left arrow points to a Purkinje-like potential just prior to the local electrogram (also slightly preceding the onset of the QRS); the right arrow shows a sharp, delayed diastolic potential, purportedly from the slow-conducting limb of the circuit. *Abl_{dist}*, Distal ablation; *His_{dist}*, distal His bundle; *His_{prox}*, proximal His bundle; *HRA*, high right atrium; *RVA*, right ventricular apex.

Purkinje Potential

The PP (also referred to as “P2” in literature) is a discrete, high-frequency potential that precedes the site of earliest ventricular activation by 15 to 42 milliseconds and is recorded in the posterior third of the IV septum during VT, as well as during NSR (see Figs. 24.3 and 24.4). Because this

potential also precedes ventricular activation during NSR, it is believed to originate from activation of a segment of the LPF and to represent the lower turnaround point in the reentrant circuit. The earliest ventricular activation site (exit) during VT is identified more distally (apically) in the septum than the region with the earliest recorded PP.¹²

Late Diastolic Potential

The LDP, also referred to as “P₁” or “pre-PP,” is a discrete potential that precedes the PP during VT and is recorded at the basal, middle, or apical LV septum. During NSR, the LDP is inscribed after the QRS. The LDP is thought to originate from activation at the entrance to the abnormal Purkinje tissue (the specialized, verapamil-sensitive zone), which is thought to serve as the anterograde limb of the reentrant circuit and is isolated from surrounding muscle (allowing it to have a discrete diastolic activation time). The LDP differs in morphology from the PP and has a relatively small amplitude and low-frequency component. The area with LDP recording is confined to a small region (0.5 to 1.0 cm²) and is included in the larger area where the PP is recorded (2 to 3 cm²); hence the LDP often is recorded simultaneously with the PP by the same electrode. The LDP is recorded within an area proximal to the earliest PP recording site and is activated from the basal to apical septum toward the earliest PP site. The relative activation times of the LDP, PP, and local ventricular potential at the LDP recording site to the onset of QRS complex are -50.4 ± 18.9 , -15.2 ± 9.6 , and 3.0 ± 13.3 milliseconds, respectively (see Fig. 24.3). The earliest ventricular activation site (exit) during VT is identified at the posteroapical septum and is more apical in the septum than the region with LDP.¹²

Ventricular Activation Sequence

During NSR, conduction propagates anterogradely (proximal to distal or basal to apical) and rapidly down the LPF, generating an anterograde PP followed by ventricular activation (see Fig. 24.1). In parallel, the impulse slowly conducts anterogradely over the abnormal Purkinje tissue, and such slow conduction (or block) in the proximal segment allows the anterograde wavefront traveling rapidly over the LPF to conduct retrogradely up the slow pathway, resulting in fusion of delayed (late) ascending and descending potentials that follow (or are buried in) local ventricular depolarization, which likely represent the LDPs recorded during VT (see Fig. 24.4). Those late potentials have been found only in patients with fascicular VT but not in control subjects and have been recorded in the midinferior septum within or contiguous to the LPF.

During ventricular pacing, the LPF is activated retrogradely, generating a retrograde PP. In parallel, the impulse produces bidirectional activation of the abnormal Purkinje pathway in a manner similar but in reverse direction to that during NSR.

During VT, activation propagates anterogradely (from the basal to the apical site of the LV septum) over the abnormal Purkinje tissue, giving rise to an anterograde LDP; hence the earliest LDP is seen in the basal septum and the latest LDP is seen in the apical septum. The reentrant wavefront then turns around in the lower third of the septum and activates the fast conduction Purkinje fibers along the LPF, generating a retrograde PP. From the lower turnaround point, the wavefront propagates anterogradely down the septum to exit the reentrant circuit and activate the posterior septal myocardium, and retrogradely over the LPF from apical to basal septum, forming the retrograde limb of the tachycardia, with an upper turnaround point of the reentrant wavefront occurring over a zone of slow conduction (between LDP and PP areas) located close to the main trunk of the LB (see Fig. 24.1).

For a VES to initiate VT, retrograde block must occur in the abnormal Purkinje tissue, and the paced wavefront is retrogradely conducted up the LPF (generating a retrograde PP) with some delay and then down the abnormal Purkinje tissue (generating an anterograde LDP) to initiate reentry. Thus, during VT, the LDP precedes PP, which in turn precedes ventricular activation.

Verapamil significantly prolongs the TCL, LDP-PP interval, and PP-LDP interval during VT. However, the interval from PP to the onset of the QRS complex remains unchanged.

Entrainment Mapping

Analysis of entrainment from different ventricular sites helps to identify the relationship of those sites to the VT circuit (Box 24.1). Entrainment with concealed fusion and a PPI that approximates the TCL helps to identify the diastolic slow zone (isthmus) of the reentrant circuit. Notably, because of the overlap between the fascicular tissue and the ventricular myocardium, pacing from the isthmus of the VT circuit may not produce concealed fusion, because pacing frequently results in local myocardial capture outside that region, producing manifest fusion.¹³

During entrainment, the LDP (representing the entrance of the circuit) is orthodromically captured and, as the pacing rate is increased, the LDP-PP interval (representing an area of decremental Purkinje tissue) prolongs, whereas the stimulus-to-LDP and PP-QRS intervals typically remain constant.¹²

Pace Mapping

Pace mapping is not very reliable in identifying the optimal target site for ablation of fascicular VT. Pace mapping during NSR that matches the QRS morphology during VT can help to identify the exit site (i.e., the myocardial breakthrough site) of the VT circuit, but the exit site does not represent an effective ablation target. Pacing at successful ablation sites (within the slow diastolic zone of the VT circuit) often captures both the Purkinje fiber system and adjacent local myocardial tissue (away from the exit of the reentrant circuit) and also result in antidromic

BOX 24.1 Entrainment Mapping of Verapamil-Sensitive Left Ventricle Ventricular Tachycardia

Pacing From Sites Outside VT Circuit (RV Apex or RVOT)

- Manifest ventricular fusion on the surface ECG (fixed fusion at a single PCL and progressive fusion on progressively shorter PCLs) or fully paced QRS morphology
- PPI – TCL > 30 ms
- Interval between stimulus artifact to onset of QRS on surface ECG is greater than the interval between local ventricular electrogram on pacing lead to onset of QRS on surface ECG

Pacing From Sites Inside VT Circuit (Posteroinferior LV Septum)

- Manifest ventricular fusion on the surface ECG (fixed fusion at a single PCL and progressive fusion on progressively shorter PCLs)
- PPI – TCL < 30 ms
- Interval between stimulus artifact to onset of QRS on surface ECG equals the interval between local ventricular electrogram on pacing lead to onset of QRS on surface ECG (± 20 ms)

Pacing From Protected Isthmus Inside VT Circuit (Site Where Both PP and LDP Are Recorded)

- Concealed ventricular fusion (i.e., paced QRS is identical to the VT QRS)
- PPI – TCL < 30 ms
- Interval between stimulus artifact to onset of QRS on surface ECG equals the interval between PP to onset of QRS on surface ECG (± 20 ms)
- Stimulus-to-LDP interval is long, and LDP is orthodromically captured from proximal to distal sites during activation

CL, Cycle length; ECG, electrocardiogram; LDP, late diastolic potential; LV, left ventricle; PP, Purkinje potential; PPI, post-pacing interval; RV, right ventricle; RVOT, right ventricular outflow tract; VT, ventricular tachycardia.

activation of the isthmus of the VT circuit, generating a QRS morphology that can be significantly different from the VT morphology.^{1,8}

Electroanatomic Mapping

Electroanatomic three-dimensional (3-D) mapping (CARTO mapping system [Biosense Webster, Diamond Bar, CA, United States] or EnSite NavX system [St. Jude Medical, St. Paul, MN, United States]) can facilitate mapping of the left fascicular system and is of particular value when mapping is performed during NSR. After the LV geometry is created, activation mapping is performed during NSR along the LV septum to trace the conduction system from the site of recording of His potential just under the aortic valve and moving progressively distally (apically) until no fascicular/PP can be recorded. These sites, as well as the sinus breakout point, are tagged as special landmarks on the electroanatomic map to help identify ablation targets (Fig. 24.5). Once sustained VT is induced, activation mapping is performed during VT, with particular attention to sites with earliest ventricular activation, sites with presystolic PPs, as well as sites with LDPs. These sites are tagged on the electroanatomic map to identify the different components of the reentry circuit in relation to the fascicular system identified during NSR.^{14,15}

Noncontact Mapping

The EnSite 3000 noncontact mapping system (St. Jude Medical) may be used to identify the sinus breakout point (i.e., the LV site with the earliest local activation during NSR), and that point has been used to guide linear ablation perpendicular to the conduction direction of LPE. Particular attention is paid to the geometric detail in the areas of the HB, septum, and apex of the LV. After the ventricular geometry has been generated, the system can then calculate electrograms from more than 3000 endocardial points simultaneously by reconstructing far-field

signals to create the isopotential map of sinus rhythm using a single cardiac cycle. The HB, LB, fascicles, and sinus breakout point are tagged as special landmarks in the geometry. The sinus breakout point is located in the midposterior septum and the local virtual electrogram presents with QS morphology (Fig. 24.6). Virtual electrograms at points from the HB down to the sinus breakout point show a sharp, low-amplitude potential preceding the ventricular potential. The interval between these two potentials becomes progressively shorter as the activation propagates from the HB to the sinus breakout point, until the two potentials finally fuse together at the sinus breakout point.¹⁶

ABLATION

Target of Ablation

Definition of the appropriate ablation target has evolved with better understanding of the anatomical substrate of fascicular VT. Initially, the ablation target site was defined as the site where the earliest endocardial ventricular activation time and the best pace map could be obtained during VT (which represents the exit of the reentrant circuit). Subsequently, in combination with pace mapping, the earliest PP preceding QRS onset during VT (considered to be the lower turnaround point of the reentrant circuit) in the posterior third of the LV septum was reported to be a marker for successful ablation. Successful ablation is achieved at sites where PP is recorded 30 to 40 milliseconds before QRS onset (Fig. 24.7). Entrainment mapping at this location helps to confirm the relationship to the reentrant circuit. Of note, this area is located more basally than the LV area that shows the earliest ventricular activation during VT (the exit point of the circuit into the ventricular septum), suggesting that the location of the earliest ventricular activation during tachycardia is not an ideal site for ablation of this arrhythmia. Later on, the LDP recorded during VT, which likely reflects

Fig. 24.5 Three-dimensional Electroanatomic (ESI NavX) Map of the Left Ventricle With Its Conduction System Obtained During Sinus Rhythm. Green markers denote His bundle and left bundle branch (LB) recording site; red markers denote posterior fascicle and Purkinje potential recording site; white marker denotes target for radiofrequency (RF) catheter ablation. (From Kataria V, Yaduvanshi A, Kumar M, Nair M. Demonstration of posterior fascicle to myocardial conduction block during ablation of idiopathic left ventricular tachycardia: an electrophysiological predictor of long-term success. *Heart Rhythm*. 2013;10:638–645.)

Fig. 24.6 Noncontact Mapping During Normal Sinus Rhythm (NSR). Shown is an animated propagation map of the left ventricle (LV) from frames A to G in the right anterior oblique view during NSR. Note that the sinus activation propagates down from the His bundle (AV) to the left bundle branch (LB) and then bifurcates into left anterior and left posterior fascicles before the entire LV is finally activated. The activation breakout point is at the midposterior septum and marked sinus breakout point (SBO) on the map. The thick black line indicates the propagation direction of the wavefronts from AV down to SBO. (H) Right anterior oblique orientation of the images. Ant., Anterior; Inf., inferior; Sep., septal. (From Chen M, Yang B, Zou J, et al. Non-contact mapping and linear ablation of the left posterior fascicle during sinus rhythm in the treatment of idiopathic left ventricular tachycardia. *Europace*. 2005;7:138.)

Fig. 24.7 Ablation of Idiopathic Fascicular Ventricular Tachycardia. Radiofrequency (RF) delivery is begun (blue arrow) at the site of the diastolic Purkinje potential during fascicular ventricular tachycardia. Within less than 1 second, the tachycardia terminates. The red arrow indicates probable Purkinje potentials. the excitation within the critical slow conduction area participating in the reentry circuit, was reported to be a useful marker in guiding successful ablation.

Currently, ablation is targeted to a site over the middle or inferoapical portion of the LV septum where the earliest PP and LDP are recorded (Fig. 24.8). Verification of these sites can be achieved with entrainment mapping demonstrating concealed fusion and progressive prolongation of the LDP-PP interval with increasing pacing rate. In addition, pressure applied to the catheter tip at the LDP region occasionally results in VT termination with conduction block between LDP and PP. Pace mapping can also be used as an adjunct to verify this site but, because of poor sensitivity, is less helpful than in focal VTs. It is important to recognize that successful ablation is not necessarily predicted by targeting the earliest (most proximal) LDP. Success can be achieved by ablating an LDP distal to the earliest potential (within the apical third of the septum). This approach is preferred to help reduce the risk of damaging the trunk of the LB. If such an LDP cannot be detected, the site with the earliest PP may then be targeted by ablation.^{1,6}

One report showed a high success rate of an ablation strategy targeting the distal most fascicular potentials of the LPF, close to the Purkinje-myocardial interface, as guided by electroanatomic mapping of the left fascicular system. Ablation is extended progressively distal linearly to the surrounding myocardium until conduction block is achieved between the LV myocardium and the distal posterior fascicle/Purkinje network. At successful ablation sites, the fascicular potential typically preceded the local ventricular electrogram by an interval of 12 ± 1.7 milliseconds, which is less presystolic than the earliest PP targeted in other ablation

strategies. Myocardium-fascicular conduction block during NSR was defined as the prolongation of the interval between the local ventricular electrogram and the fascicular/PP just proximal to the ablation site (duration of >100 milliseconds) or a higher degree of myocardium-fascicular block is recorded. Notably, this ablation approach did not result in LPF block or left axis deviation given the site of ablation being distal to LPF itself.¹⁴

Ablation Technique

Ablation is usually performed through the retrograde transaortic approach using a standard 4-mm-tip catheter. The catheter is advanced by prolapsing into the LV and directed to the LV septum. Mapping is initially concentrated at the inferoapical septum. If an ideal site is not found in this area, the ablation catheter is moved upward to the mid-septal area. It is important to move the catheter slowly and carefully to avoid mechanical trauma to the circuit. Endocardial activation mapping and entrainment mapping are performed to define the target site of ablation.¹

Once the target site is identified, a test RF current is applied during VT for 20 seconds with an initial power of 20 to 35 W, targeting a temperature of 60°C. If the VT is terminated or slowed within 15 seconds, additional current is applied for another 60 to 120 seconds and power is increased up to 40 W to reach the target temperature if necessary. If the test RF current is ineffective despite adequate catheter contact, ablation is directed to another site after additional mapping, usually targeting a more proximal site with the earlier LDP. This approach helps to limit RF damage to the area of LPF and LB. Rarely, if ever, does one need

Fig. 24.8 Ablation of Fascicular Ventricular Tachycardia (VT). Shown are recordings during VT (left) and normal sinus rhythm (NSR; right) from a successful ablation site for idiopathic left ventricular tachycardia. Red arrows indicate probable Purkinje potentials, activated distal-to-proximal during VT and proximal-to-distal during sinus. Blue arrows show His potentials, occurring after QRS onset during VT. *Abl_{dist}*, Distal ablation; *Abl_{prox}*, proximal ablation; *Abl_{uni}*, unipolar ablation; *His_{dist}*, distal His bundle; *His_{prox}*, proximal His bundle; *HRA*, high right atrium; *RVA*, right ventricular apex.

more than 50 W or the use of irrigated or large-tip electrodes to ablate these VTs successfully.¹

During the RF application, successful ablation sites often display progressive prolongation of the LDP-PP interval, with termination of VT coincident with conduction block between the two potentials. After successful ablation, the LDP can no longer be recorded during NSR.

Endpoints of Ablation

Successful ablation is defined as the lack of inducibility of VT, with and without isoproterenol administration (using the best method for induction documented before ablation), at least 30 minutes after ablation. Importantly, creation of LPF block is not an effective endpoint for ablation and does not prevent arrhythmia recurrence.

Outcome

The acute success rate is more than 90%, even when different mapping methods and ablation strategies are used. The recurrence rate is approximately 7% to 15%, with most recurrences occurring in the first 24 to 48 hours after the ablation procedure. Arrhythmia recurrences after an initially successful ablation are caused most commonly by recurrent fascicular VT involving the same fascicle and by new onset of upper septal VT in one third of patients. Of note, the development of new LPF block after fascicular VT ablation was associated with more basal ablations and did not protect against VT recurrence.⁶

Complications are rare and include different degrees of fascicular block (most likely because of inadvertent collateral damage to the LPF, particularly when ablation is delivered more basally), LBBB, cardiac tamponade, aortic regurgitation, and mitral regurgitation caused by torn chordae that may result from entrapment of the ablation catheter in a chorda of the mitral leaflet.¹⁷

Empirical Ablation of Noninducible Ventricular Tachycardia

Conventional activation mapping, guided by either the earliest PP or the LDP, although effective, depends on the inducibility of sustained and hemodynamically stable fascicular VT. However, the VT may not be inducible in the EP laboratory. In addition, the critical substrate of

fascicular VT is vulnerable to mechanical injury because of catheter manipulation, which can render the tachycardia noninducible. In these cases, substrate mapping and ablation during NSR have been suggested to eradicate fascicular VT.^{1,8}

Three approaches have been used for substrate-based ablation during sinus rhythm: (1) ablation of the slow conduction zone adjacent to the LPF; (2) anatomical linear ablation to transect the middle to distal portion of the LPF; and (3) ablation of the most distal LPF fibers at the Purkinje-myocardial interface.¹⁸

The first approach involves identifying areas of the slow conduction zone that is adjacent to the LPF, which might represent the anterograde limb of the VT reentry circuit. The location of this region is suggested by recording low-amplitude electrograms visible after the sinus QRS complex (presumably resulting from delayed retrograde activation of abnormal Purkinje fibers) in conjunction with more prominent PP (which is generated by anterograde conduction down the LPF). At these locations the low-amplitude signals occur 15 to 45 milliseconds after the PP, and the PP precedes the QRS onset by a relatively short interval (13 ± 8 milliseconds). A major limitation of this ablation strategy is the inability to identify the low-amplitude signals in a sizable proportion of patients. In addition, in another subset of patients, similar non-specific low-amplitude signals are recorded over a sizeable area of the septum; targeting all those regions would increase the risk of injury to the conducting system.⁸

The second approach involves creation of an ablation line perpendicular to the activation direction of LPF and 1 cm above the sinus breakout point, as defined by electroanatomic or noncontact mapping during NSR (Fig. 24.9). The ablation line typically extends for approximately 2.0 ± 0.4 cm in the region of the mid to midinferior LV septum and is guided by recording a small PP preceding the ventricular activation at its starting and ending points. A significant rightward shift of the QRS axis in the surface limb leads can be observed after the ablation procedure.¹⁶

The third approach involves targeting the distal most fascicular potentials of the LPF, close to the Purkinje-myocardial junction, as described previously. This approach can be used both for inducible or noninducible VT cases.¹⁴

Fig. 24.9 Noncontact Mapping of Fascicular Ventricular Tachycardia During Normal Sinus Rhythm. A linear ablation lesion was created perpendicular to the wavefront propagation direction and 1 cm above the sinus breakout point (SBO). Both the starting and ending lesion points have a small Purkinje potential preceding the ventricular activation. Ant., Anterior; AV, His recording area; Inf., inferior; LB, left bundle branch; Sep., septal. (From Chen M, Yang B, Zou J, et al. Non-contact mapping and linear ablation of the left posterior fascicle during sinus rhythm in the treatment of idiopathic left ventricular tachycardia. *Europace*. 2005;7:138.)

PATHOPHYSIOLOGY

Cardiomyopathies are traditionally defined on the basis of structural and functional phenotypes, notably dilated, hypertrophic, and restrictive. The dilated cardiomyopathy (DCM) phenotype is the most common and is often viewed as a “final common pathway” of numerous types of cardiac injuries.¹

The diagnosis of nonischemic DCM is established by the absence of significant (greater than 75% stenosis) coronary artery disease and prior myocardial infarction (MI). Nonischemic DCM is not a single disease entity. Valvular heart disease, hypertension, Chagas disease, sarcoidosis, amyloidosis, infections, hypothyroidism, thiamine deficiency, pregnancy (postpartum cardiomyopathy), vasculitides (e.g., Kawasaki disease and Churg-Strauss syndrome), and toxins (e.g., alcohol, anthracyclines, tyrosine kinase inhibitors), among others, need to be considered as possible etiologies. An underlying etiology for adult DCM is found in only 50% of patients. The remaining 50% are considered idiopathic. Idiopathic DCM is characterized by an increase in myocardial mass and a reduction in ventricular wall thickness. The heart assumes a

globular shape, and there is a pronounced ventricular chamber dilation and atrial enlargement.

Molecular Genetics

There is increasing evidence that a significant portion (30% to 50%) of idiopathic DCM is familial. Familial DCM is clinically and genetically heterogeneous and exhibits various patterns of hereditary transmission, including autosomal dominant with variable penetrance (the predominant pattern of transmission, accounting for about 90% of cases), X-linked (5% to 10%), autosomal recessive (rare), and maternal transmission through mitochondrial DNA (rare). It is also likely that many sporadic DCM cases can be due to genetic mutations. Although usually nonsyndromic, DCM can be included in syndromic disease involving various organ systems, most commonly skeletal muscle disease (muscular dystrophies).

To date, more than 40 genes have been linked to nonsyndromic familial DCM. Notably the frequencies of DCM mutations in any one gene are low (less than 1% to 8%), and a genetic cause is identified in only 35% to 40% of familial DCM cases. Most patients with familial

TABLE 25.1 Associated Clinical Features Which Are Present in a Minority of Patients With Familial Dilated Cardiomyopathy

Associated Phenotype	Clinical Features	Comment	Associated Gene ^a
Conduction disease	Sinus arrest Atrioventricular block Interventricular block	May precede DCM	<i>DES</i> <i>DMD</i> <i>EMD</i> <i>LMNA</i> <i>SCN5A</i>
Supraventricular arrhythmia prior to DCM	Premature atrial contraction Atrial fibrillation	Often with slow ventricular response	<i>EMD</i> <i>LMNA</i> <i>SCN5A</i>
Skeletal myopathy	Limb girdle Emery-Dreifuss Myotonic dystrophy Duchenne/Becker Myofibrillar myopathy	Proximal muscle weakness Contractures, skeletal myopathy and wasting Myotonia, weakness, baldness and cataracts Progressive X-linked proximal myopathy Slowly progressive proximal and distal weakness	<i>LMNA</i> <i>EMD</i> , <i>LMNA</i> <i>ZNF9</i> , <i>DMPK1</i> <i>DMD</i> <i>DES</i>
Hearing loss	Sensorineural hearing loss	Hearing loss typically occurs in the 1st and 2nd decade of life	<i>EVA</i>
Palmoplantar keratoderma	Increased thickness of the palms and soles with woolly or excessively curly hair	May precede cardiac involvement	<i>DSP</i>

DCM, Dilated cardiomyopathy.

From Lakdawala NK, Winterfield JR, Funke BH. Dilated cardiomyopathy. *Circ Arrhythmia Electrophysiol.* 2013;6:228–237.

DCM have isolated heart muscle disease; however, a minority of patients also manifest extracardiomyopathic phenotypes, including conduction system disease, supraventricular arrhythmias, sensorineural hearing loss, and skeletal myopathy (Table 25.1).¹ Clinical phenotypes and outcome in patients with DCM often vary according to the disease gene, penetrance, age, and type of mutation. At least four phenotypes are generally recognized: isolated DCM, DCM with cardiac conduction disease, DCM with concomitant skeletal myopathy (with or without conduction disease), and DCM with sensorineural deafness.

Familial forms of DCM can be due to mutations in cytoskeletal, sarcomeric, Z-disk, nuclear envelope, sarcolemmal, and intercalated disc protein genes. Several gene mutations have been identified in the autosomal form of familial DCM, including those encoding Z-disc proteins (alpha-actin-2, muscle LIM protein, titin-cap), costameres, adherens junctions, desmosomes, intermediate filaments, sarcomere proteins (cardiac alpha-actin, beta-myosin heavy chain, cardiac troponin T, alpha-tropomyosin, titin), sarcoplasmic reticulum proteins (phospholamban), and ion channel (SUR2A). Of note, different mutations in the sarcomere genes can cause hypertrophic cardiomyopathy (HCM). Mutations in the *LMNA* gene (which encodes Lamin A/C, a nuclear envelope protein) are involved in 8% of familial DCM and in 2% of sporadic DCM. Mutations in Lamin A/C also cause Emery-Dreifuss muscular dystrophy. Autosomal dominant DCM can exhibit either a pure DCM phenotype or DCM with cardiac conduction system disease. X-linked familial DCM is usually caused by mutations in the dystrophin gene and is typically associated with skeletal muscle involvement (Duchenne and Becker muscular dystrophy). The infantile form of X-linked DCM or Barth syndrome typically affects male infants (characterized by neutropenia and growth retardation). Mitochondrial cytopathies and inherited metabolic disorders such as hemochromatosis can also be associated with DCM.¹

Compared with sporadic cases of idiopathic DCM, familial DCM patients are younger and tend to have higher left ventricular ejection fraction (LVEF) and more significant myocardial fibrosis. In patients with idiopathic DCM, the proposed diagnostic criteria for the familial

form of the disease are the existence of two or more affected family members, or of one first-degree relative with a documented history of unexplained sudden death before 35 years of age. In most cases, proof of a genetic cause of a cardiomyopathy has limited impact on the treatment of the index patient, but can have important implications in regard to family screening and genetic counseling. DCM in patients who do not have a known family history may also have a genetic basis.¹

A new nomenclature system (the MOGE[S]) was recently developed for the description of familial DCM. This system proposes a nosology that addresses five attributes of cardiomyopathies, including morpho-functional characteristic (M), organ involvement (O), genetic or familial inheritance pattern (G), and an explicit etiological annotation (E) with details of the genetic defect or underlying disease/cause, allowing complete description of the disease and precise communication among physicians.²

Ventricular Arrhythmias

Patients with DCM can develop any variety of ventricular arrhythmias, including premature ventricular complexes (PVCs), nonsustained ventricular tachycardia (VT), sustained monomorphic VT, polymorphic VT, and ventricular fibrillation (VF). Cardiac arrest is usually precipitated by polymorphic VT or monomorphic VT degenerating to VF. Nonetheless, asystolic arrest and pulseless electric activity are common modes of death, particularly in patients with end-stage heart failure (HF).

Sustained monomorphic VT is less common in DCM than in patients with prior MI. In contrast to ischemic heart disease, the electrophysiological (EP) substrate for sustained monomorphic VT in patients with nonischemic DCM is not clearly defined. Although bundle branch reentry (BBR) VT is identified as the VT mechanism in a significant percentage of patients with monomorphic VT in the setting of nonischemic DCM, the majority (80%) of VTs appear to originate from the myocardium and are due to scar-related reentry rather than BBR. BBR VT is discussed separately in Chapter 26.

On the other hand, PVCs and nonsustained VTs induced by programmed electrical stimulation or occurring spontaneously in patients

with idiopathic DCM initiate primarily in the subendocardium by a focal mechanism without evidence of macroreentry. The nature of the focal mechanism remains unknown; triggered activity arising from early or delayed afterdepolarizations seems to be more likely than microreentry.

Myocardial fibrosis, myocyte disarray, and membrane abnormalities are important factors in the substrate, causing VT in patients with DCM. Sustained VT is associated with more extensive myocardial fibrosis and nonuniform anisotropy involving both the endocardium and epicardium, compared with patients without sustained reentry. The reentry circuits are typically associated with regions of low-voltage electrograms, consistent with scar. Catheter mapping studies of patients with nonischemic DCM point to reentry around scar deep in the myocardium, near the ventricular base and in the perivalvular region, as the underlying mechanism for VT. Studies of explanted hearts with nonischemic DCM have found unexcitable fibrosis creating regions of conduction block and surviving myocardium, providing the substrate for potential reentry circuits. Slow conduction through muscle bundles separated by interstitial fibrosis can cause a zigzag path and promote reentry. Furthermore, patients with nonischemic DCM who have predominance of scar distribution involving 26% to 75% of wall thickness (as quantified by cardiac magnetic resonance [CMR]) are more likely to have inducible VT. Delayed-enhancement CMR typically reveals nontransmural scar areas often distributed in the basal portion of the ventricular free wall or basal to midportion of the septum. Sustained VTs are observed more frequently in patients having a greater extent of fibrosis detected on CMR, and nontransmural scar tissue is observed at the VT circuit exit site in the majority of patients.

The cause of fibrosis in nonischemic DCM is not well defined. Scattered foci of myocyte necrosis and replacement fibrosis are commonly seen at autopsy (evident histologically in 35% of sections of the right ventricle [RV] and in 57% of sections of the left ventricle [LV]), but grossly visible confluent regions of scar are not common (observed in only 14% of subjects). The unique propensity for abnormal basal endocardial voltage and VT site of origin in patients with nonischemic DCM remains unexplained. Low-voltage areas have also been observed during electroanatomic mapping in patients with focal VT and BBR VT, although the scar areas appeared to be smaller.

The scar and fibrosis resulting from nonischemic etiologies are distinctly different from post-MI scar; hence the reentrant circuit may have different anatomical and functional properties that affect propagation. Compared with post-MI VT, the scar in DCM tends to be smaller and less confluent, the total number of the transmural scar segments is significantly smaller, and there is less endocardial involvement. Whereas ischemia produces a predictable wavefront of necrosis progressing from subendocardium to epicardium (and scar areas larger endocardially than epicardially), usually confined to a specific coronary vascular territory, scars in nonischemic DCM have been shown to have a predilection for the midmyocardium and epicardium. In contrast to the dense post-MI scar with isolated surviving myocardial bundles, scar in nonischemic DCM is patchy with fewer fixed boundaries and protected channels or isthmuses. In addition, the myopathic process in DCM can be dynamic and progressive over time, resulting in increasing myocardial fibrosis and, as a result, progressively worsening LV dilatation and systolic dysfunction, as well as the development of new VTs.^{3,4}

Nonetheless, several similarities of the arrhythmia substrate exist in myocardial reentry VT in patients with nonischemic DCM compared with that in post-MI patients. Low-voltage areas are observed in all patients, and the regions of scar are frequently adjacent to a valve annulus, as is often the case in VT after inferior wall MI. The annulus often seems to form a border for an isthmus in the reentry path, which suggests the formation of a long channel, or isthmus, along an annulus contributing to the formation of reentry circuits that can support VT.

Other factors may serve as triggers for ventricular arrhythmias, including electrolyte abnormalities (e.g., hypokalemia, hypomagnesemia), ischemia caused by small vessel disease, inflammation, heightened sympathetic tone, and stretch-induced shortening of the ventricular refractory period.

EPIDEMIOLOGY AND NATURAL HISTORY

The incidence of nonischemic DCM in adults in Western countries varies from 5 to 8 per 100,000 person-years, with a prevalence of 36 to 40 per 100,000 individuals. DCM accounts for 30% to 40% of all HF cases and is the most common indication for heart transplantation.

Although nonischemic DCM is regarded as a largely progressive disorder, the natural history of individual patients is highly variable. The 5-year mortality for DCM has been estimated at 20%, with sudden cardiac death (SCD) accounting for approximately one-third (8% to 51%) of deaths. Among all cardiomyopathy patients, nonischemic DCM patients likely represent a relatively low arrhythmic death risk subgroup. While the likelihood of death from progressive pump failure rather than SCD increases with the severity of HF symptoms, the absolute likelihood of SCD (presumed arrhythmic death) increases with the severity of HF.³

Ventricular arrhythmias, both symptomatic and asymptomatic, are common in patients with nonischemic DCM, and the frequency of arrhythmias increases with the severity of HF. PVCs (often multifocal) are observed in up to 90% of patients. In addition, nonsustained VT can be observed in 40% to 60% of patients, but its incidence decreases significantly after the optimization of HF medical treatment. Sustained monomorphic VT is less common in DCM than in patients with prior MI; DCM accounts for about one-fifth of patients undergoing catheter ablation for drug-refractory VT because of structural heart disease.⁵

Nonischemic DCM is the second leading cause of SCD in the United States. Syncope and SCD are infrequent initial manifestations of the disease. The incidence of SCD is highest among patients with indicators of more advanced cardiac disease who are also at highest risk of all-cause mortality. Although VT and VF are considered the most common mechanism of SCD, bradycardia, pulmonary embolism, electromechanical dissociation, and other causes account for up to 50% of SCDs in patients with advanced HF.⁵

Initial Evaluation

Transthoracic echocardiography is the usual modality for diagnosis of DCM. Cardiac stress testing or coronary angiography is typically performed in patients with coronary risk factors and those with new-onset ventricular arrhythmias to exclude the presence of obstructive coronary artery disease.

Ambulatory cardiac monitoring is required for patients with symptoms suggestive of arrhythmias (e.g., palpitations, dizziness, syncope), but not for screening purposes.

CMR provides accurate assessment of ventricular chamber size, wall thickness, and systolic function. Furthermore, CMR is a useful tool to detect and assess the characteristics and heterogeneous distribution of scar tissue and its composition of the wall layer, as well as its precise location within the ventricle. CMR can also help determine the underlying etiology of cardiomyopathy in some patients, such as myocarditis, sarcoidosis, and arrhythmogenic right ventricular cardiomyopathy (ARVC). In addition, the findings on CMR can potentially have prognostic implications; the extent of myocardial fibrosis is associated with HF-related hospitalization and death, and is a powerful predictor of VT/VF.^{1,6}

Genetic testing can be considered in selected patients when familial DCM is suspected. This can be of particular value when the clinical

management is influenced by the results of genetic testing (e.g., in patients with suspected cardiac sarcoidosis vs. familial DCM). Also, identification of a causative mutation can facilitate screening of family members. The likelihood of identifying a pathogenic mutation is less likely in older patients (older than 40 years) with nonfamilial disease.¹

RISK STRATIFICATION

Risk stratification in DCM is difficult. Although SCD occurs less frequently in patients with less advanced cardiac disease, the proportion of SCD to all-cause death is higher in this group.

Predictors of overall outcome (such as LVEF, end-diastolic LV volume, older age, hyponatremia, pulmonary capillary wedge pressure, systemic hypotension, atrial fibrillation [AF]) also predict SCD and generally reflect the severity of disease. Unfortunately these findings do not specifically predict arrhythmic death and are not useful in the patient with less severe disease.

Left Ventricular Ejection Fraction

LVEF remains the most studied and the most useful predictor of SCD despite limitations (see below) and is the primary method currently used in clinical decisions for the prevention of SCD in patients with HF. Depressed LVEF is also a powerful predictor of cardiac mortality. On the basis of the results of large studies, in clinical practice an LVEF $\leq 35\%$ has become the primary criterion used for prophylactic implantable cardioverter-defibrillator (ICD) placement.⁷

However, the use of LVEF as the predominant risk stratifier has serious limitations because it lacks both sensitivity and specificity for prediction of SCD. There is no evidence of any direct mechanistic link between low LVEF and mechanisms responsible for ventricular tachyarrhythmias, and no study has demonstrated that reduced LVEF is specifically related to SCD. Although low LVEF predicts total mortality (SCD and heart failure death), its value in predicting benefit from ICD implantation is limited. In these patients, ICD may reduce the risk of SCD but total mortality may not be modified. Even a very low LVEF (less than 20%) may not have a high positive predictive value for SCD. Many DCM patients who die from SCD have only a moderately depressed LVEF. Furthermore, the arrhythmic mechanisms underlying DCM and the risk of SCD can be different in different etiologies and clinical situations. Clinical factors such as functional class, symptomatic HF, nonsustained VT, age, LV conduction abnormalities, inducible sustained VT, and AF influence the risk of arrhythmic death and total mortality, and hence potentially influence the prognostic value of a depressed LVEF. Therefore patients with an LVEF greater than 30% and other risk factors may have a higher mortality and a higher risk of SCD than those with an LVEF less than 30% but no other risk factors.⁸

Another limitation is that methods of LVEF determination lack precision. Different imaging modalities can produce significantly different LVEF values, and the accuracy of techniques varies among laboratories and institutions, and there is evidence that prognosis, and hence risk, depends on the method by which the LVEF is measured. Clinically, when a patient has multiple LVEF measurements over time, it raises the question of which of the many measurements should be used—the most recent, the average, or the lowest.^{5,9} In cases in which frequent atrial or ventricular ectopic complexes or AF is present, sampling of representative contractions for the estimation of LVEF is especially problematic.

Syncope

Syncope has been associated with a higher risk of SCD and mortality (exceeding 30% at 2 years) regardless of the proven etiology of the syncope. Further, ICD recipients with syncope experience a high fre-

quency of appropriate ICD therapy at a rate comparable to a secondary prevention cohort.⁵

Nonsustained Ventricular Tachycardia

PVCs and nonsustained VT correlate with the severity of cardiac disease and occur in the majority of patients with severe LV dysfunction. Although the negative predictive value of these arrhythmias is high (greater than 90%), the positive predictive value is relatively low (20% to 50%), which limits the usefulness of ventricular arrhythmias as risk stratifiers. In addition, the presence and characteristics (frequency, length, and rate) of nonsustained VT do not appear to predict increased risk of subsequent life-threatening ventricular arrhythmias in patients with severe LV impairment receiving optimal medical treatment.¹

Nevertheless, it has been suggested that the presence of nonsustained VT may be more specific in patients with only mild to moderate LV systolic dysfunction. Nonsustained VT significantly increases the risk of malignant ventricular arrhythmias in the subgroup with LVEF greater than 35%. In these patients, even without worsening LV systolic function and symptoms, survival free from malignant ventricular arrhythmias is similar to that of patients with LVEF less than 35% with or without nonsustained VT.¹

Electrophysiological Testing

In contrast to patients with ischemic cardiomyopathy, invasive EP testing with programmed ventricular stimulation to assess inducibility of sustained ventricular arrhythmias did not prove to be useful for SCD risk stratification in patients with DCM. EP testing was found to offer low VT inducibility (13% sustained monomorphic ventricular tachycardia [SMVT], 6% ventricular flutter, 9% polymorphic VT/VF), low reproducibility, and poor predictive value of induced VT. Also, failure to induce SMVT during programmed electrical stimulation can be associated with high rates of arrhythmia recurrence and SCD, although at lower incidence rates than in patients with inducible VT.⁸ A recent study in patients with idiopathic DCM found that, among ICD recipients, induction of sustained ventricular arrhythmias during invasive EP testing was associated with significantly higher rates of appropriate ICD therapies (73% vs. 18%).^{1,10}

Electrocardiographic Markers

DCM patients typically have wide QRS complexes during the baseline rhythm, often with left bundle branch block (LBBB) or nonspecific intraventricular conduction defect. Prolonged QRS duration has been associated with increased mortality in HF patients, but association with SCD has not been proven.

Fragmentation of the QRS complex on the 12-lead surface electrocardiogram (ECG; filter range, 0.15 to 100 Hz; AC filter, 60 Hz, 25 mm/s, 10 mm/mV) has been found to potentially predict increased risk of appropriate ICD therapies as well as a higher combined endpoint of ICD therapy and mortality in nonischemic DCM patients who received an ICD for primary and secondary prevention. The usefulness of this parameter needs further evaluation. During VT, QRS complexes are typically very wide and fragmented; most patients have multiple QRS morphologies of VT (eFig. 25.1).

Prolongation of the QT interval, QT dispersion, and QT variability have had mixed predictive results with limited clinical applicability at present. The role of signal-averaged ECG is controversial.^{8,11}

Autonomic Testing

The prognostic value of autonomic tests, such as heart rate turbulence, heart rate variability, and baroreflex sensitivity, in DCM patients is questionable, and currently those parameters have little clinical application for risk stratification for SCD.¹¹

eFig. 25.1 Surface 12-Lead Electrocardiograms of Two Different Ventricular Tachycardias Configurations in a Patient With Dilated Cardiomyopathy. QRS morphology is suggestive of origin from basal septal left ventricular substrate. (A) Right bundle branch block morphology, positive precordial concordance, and inferior axis. (B) Left bundle branch block morphology, early precordial transition (leads V₂), and inferior axis.

Microvolt T Wave Alternans

Microvolt T wave alternans provides a quantitative assessment of temporal and spatial heterogeneity of repolarization, which are linked to cellular arrhythmia mechanisms. Microvolt T wave alternans was found to have relatively modest (0.22) positive predictive value for SCD in patients with DCM, largely due to the high rates of abnormal results (37% to 51%) and the low event rate within a short follow-up period. Previous studies suggested a high negative predictive value for primary prevention of SCD, and T-wave alternans was hypothesized to be a useful tool to differentiate between patients who would benefit from ICD implantation and those who would not. However, results from subsequent studies failed to support this hypothesis and strongly suggested that a negative microvolt T-wave alternans result should not be used to withhold ICD therapy among patients who meet standard criteria.^{8,11}

Cardiac Magnetic Resonance Imaging

Late gadolinium enhancement on contrast CMR reflects myocardial fibrosis, which represents a potential substrate for ventricular arrhythmias. Fibrosis detected by CMR is evident in 40% to 50% of DCM patients. On average, regions of hyperenhancement indicative of fibrosis account for up to 10% to 12% of the ventricular mass.^{1,6}

The presence of myocardial scar, as assessed by late gadolinium enhancement CMR, has been reported to be an independent predictor of appropriate ICD therapies, SCD, and all-cause mortality in patients with nonischemic DCM. The pattern and extent of myocardial fibrosis was found to be a predictor of both inducible and spontaneous VT, independent of LVEF, and appear to be a stronger predictor of monomorphic VT than of polymorphic VT/VF. In addition, larger scar extent in basal LV segments, higher maximal signal intensity, and increased scar transmural extent further indicate a predisposition for monomorphic VT. On the other hand, the absence of myocardial fibrosis on CMR was associated with a very low risk of arrhythmic events (0% to 3% per year).^{12,13}

It is likely that late gadolinium enhancement on CMR can contribute to risk stratification in patients with DCM. However, its utility for selecting DCM patients to receive an ICD has yet to be demonstrated.^{8,12–14}

Genetic Testing

Some familial forms of DCM are associated with a particularly high risk of arrhythmias and SCD, including LMNA, TNNT2, SGCD, RBM20, and CHRM2 mutations, whereas other forms (such as X-linked DCM related to dystrophin gene mutations) were found to have a high risk of severe HF but a lower risk of malignant ventricular arrhythmias. However, large studies documenting the correlation between individual genotypes and arrhythmogenicity are lacking, and current guidelines do not advise the use of genetic testing for SCD risk stratification in patients with DCM.^{1,7}

PRINCIPLES OF MANAGEMENT

Pharmacological Therapy

Drug therapy, such as beta-blockers, angiotensin-converting enzyme inhibitors, and mineralocorticoid receptor antagonists, improves overall mortality in patients with HF and reduces the risk of SCD. In contrast, the use of antiarrhythmic drugs for primary prevention in patients with nonischemic DCM does not improve survival and is not recommended.¹⁵

In patients with symptomatic ventricular arrhythmias, amiodarone is generally the preferred antiarrhythmic agent because of the absence of significant negative hemodynamic effects and low proarrhythmic potential, but controlled comparative trials of drugs are not available.

Antiarrhythmic drug therapy can help improve quality of life in ICD patients receiving frequent appropriate shocks and those with incessant VT. Although amiodarone can potentially improve mortality and reduce the incidence of SCD in patients with nonischemic DCM, it is inferior to ICD therapy for secondary prevention of VT and VF. Treatment of asymptomatic PVCs or nonsustained VT with antiarrhythmic drug therapy has not been shown to improve survival and is not recommended.¹⁵

Implantable Cardioverter-Defibrillator Secondary Prevention

The benefit of ICD therapy in secondary prevention of SCD in nonischemic DCM has been well established and is superior to amiodarone or any other drug therapy. ICD implantation is recommended in patients with prior cardiac arrest or sustained VT—even in those undergoing catheter ablation of the VT or responding to antiarrhythmic therapy (Table 25.2; Fig. 25.1).^{5,15–17}

Primary Prevention

The benefit of ICD treatment in nonischemic DCM for primary prevention of SCD remains uncertain. Several randomized studies arrived at contradictory conclusions. Whereas prophylactic ICD implantation is of significant benefit in ischemic cardiomyopathy patients, the magnitude of absolute benefit in those with nonischemic DCM is relatively small (1.4% per year; cumulative, 7% over 5 years) at best. Nevertheless, a pooled analysis of six randomized primary prevention trials (2967 patients with nonischemic DCM) demonstrated that the use of prophylactic ICD is associated with a significant 22% reduction in total mortality and 54% reduction in arrhythmia-related death as compared with control (eFig. 25.2). These findings reflect the fact that nonischemic DCM patients have a better prognosis and a lower rate of SCD than patients with ischemic cardiomyopathy.^{5,15,17–21}

Vigorous efforts have been made in developing noninvasive stratification methods to identify the subgroup of nonischemic DCM patients at high risk for SCD. However, the best approach to identifying patients and the value of various risk stratification tools are not entirely clear. Currently there is no coherent strategy for intervention based on data integrating the results of these techniques. Many of the identified risk factors are also associated with increased risk for nonsudden death.^{5,15}

At the present time, LVEF remains the single most important risk stratification tool to identify individuals with a high risk of SCD, again emphasizing that it predicts all-cause mortality and not necessarily arrhythmic risk. Despite some uncertainty regarding ICD benefit for nonischemic DCM patients without HF, regardless of LVEF, the cumulative information available from clinical trials and observational data, in conjunction with opinions of experts in the field, support prophylactic ICD therapy among the subgroup of patients with nonischemic DCM and LVEF $\leq 35\%$ who remain in New York Heart Association (NYHA) functional class II or III HF on optimal medical therapy (provided that a reversible cause of transient LV function has been excluded and their response to optimal medical therapy has been assessed), and for those with a history of syncope and documented significant LV dysfunction (see Table 25.2; Fig. 25.1). Furthermore, cardiac resynchronization with an ICD was found to significantly reduce all-cause mortality compared with pharmacological therapy alone in patients with DCM, QRS prolongation, and mild-to-severe HF symptoms (Box 25.1).^{5,15,17}

The value of ICD therapy in primary prophylaxis in asymptomatic DCM patients with NYHA functional class I has not been adequately tested and remains unanswered. Nevertheless, since this patient population has a relatively low mortality rate, the benefit of ICD therapy probably is modest at best. In addition, ICD therapy is not recommended in DCM with advanced HF and NYHA functional class IV who are not

TABLE 25.2 AHA/ACC/HRS Recommendations for Prevention of SCD in Patients With Nonischemic Cardiomyopathy**Secondary Prevention**

- In patients who either survive SCA due to VT/VF or experience hemodynamically unstable VT or stable VT not due to reversible causes, an ICD is recommended if meaningful survival >1 year is expected. Class I
- In patients who experience syncope presumed to be due to ventricular arrhythmias and who do not meet indications for a primary prevention ICD, an ICD or an electrophysiological study for risk stratification for SCD can be beneficial if meaningful survival >1 year is expected. Class IIa
- In patients who survive a cardiac arrest, have sustained VT, or have symptomatic ventricular arrhythmias who are ineligible for an ICD (due to a limited life expectancy and/or functional status or lack of access to an ICD), amiodarone may be considered for prevention of SCD. Class IIb

Primary Prevention

- In patients with NYHA class II–III symptoms and an LVEF of $\leq 35\%$ despite GDMT, an ICD is recommended if meaningful survival of >1 year is expected. Class I
- In patients with nonischemic cardiomyopathy due to a Lamin A/C mutation who have 2 or more risk factors (NSVT, LVEF <45%, non-missense mutation, and male sex), an ICD can be beneficial if meaningful survival of >1 year is expected. Class IIa
- In patients with Emery-Dreifuss and limb-girdle type IB muscular dystrophies with progressive cardiac involvement, an ICD is reasonable if a meaningful survival of >1 year is expected. Class IIa
- In patients with NYHA class I symptoms and an LVEF of $\leq 35\%$ despite GDMT, an ICD may be considered if meaningful survival of >1 year is expected. Class IIb
- In patients with myotonic dystrophy type 1 with an indication for a permanent pacemaker, an ICD may be considered to minimize the risk of SCA from VT if meaningful survival of >1 year is expected. Class IIb
- In patients with medication-refractory NYHA class IV heart failure who are not also candidates for cardiac transplantation, an LVAD, or a CRT defibrillator that incorporates both pacing and defibrillation capabilities, an ICD should not be implanted. Class III

ACC, American College of Cardiology; AHA, American Heart Association; CRT, cardiac resynchronization therapy; GDMT, guideline-directed management and therapy; HRS, Heart Rhythm Society; ICD, implantable cardioverter-defibrillator; LVAD, left ventricular assist device; LVEF, left ventricular ejection fraction; NSVT, nonsustained ventricular tachycardia; NYHA, New York Heart Association; SCA, sudden cardiac arrest; SCD, sudden cardiac death; VF, ventricular fibrillation; VT, ventricular tachycardia.

From Al-Khatib SM, Stevenson WG, Ackerman MJ, et al. 2017 AHA/ACC/HRS guideline for management of patients with ventricular arrhythmias and the prevention of sudden cardiac death: a report of the American College of Cardiology/American Heart Association Task Force on Clinical Practice Guidelines and the Heart Rhythm Society. *Heart Rhythm*. 2017 Oct 26. [Epub ahead of print]

BOX 25.1 Heart Rhythm Society Recommendations for Cardiac Resynchronization Therapy in Patients With Cardiomyopathy

Class I: CRT is indicated for:

- Patients who have LVEF $\leq 35\%$; sinus rhythm; LBBB with a QRS duration ≥ 150 msec; and NYHA class II, III, or ambulatory IV; symptoms on GDMT

Class IIa: CRT is reasonable for:

- Patients who have LVEF $\leq 35\%$, sinus rhythm; LBBB with a QRS duration 120–149 msec; and NYHA class II, III, or ambulatory IV symptoms on GDMT
- Patients who have LVEF $\leq 35\%$, sinus rhythm; a non-LBBB pattern with a QRS duration ≥ 150 msec; and NYHA class III/ambulatory class IV symptoms on GDMT
- Patients with atrial fibrillation and LVEF $\leq 35\%$ on GDMT if (a) the patient requires ventricular pacing or otherwise meets CRT criteria and (b) AVN ablation or pharmacological rate control will allow near 100% ventricular pacing with CRT
- Patients on GDMT who have LVEF $\leq 35\%$ and are undergoing new or replacement device placement with anticipated requirement for significant (>40%) ventricular pacing

Class IIb: CRT may be considered for:

- Patients who have LVEF $\leq 30\%$, ischemic etiology of heart failure, sinus rhythm, LBBB with a QRS duration ≥ 150 msec, and NYHA class I symptoms on GDMT
- Patients who have LVEF $\leq 35\%$, sinus rhythm, a non-LBBB pattern with QRS duration 120–149 msec, and NYHA class III/ambulatory class IV on GDMT
- Patients who have LVEF $\leq 35\%$, sinus rhythm, a non-LBBB pattern with a QRS duration ≥ 150 msec, and NYHA class II symptoms on GDMT.

Class III: CRT is not recommended for:

- Patients with NYHA class I or II symptoms and non-LBBB pattern with QRS duration <150 msec
- Patients whose comorbidities and/or frailty limit survival with good functional capacity to <1 year

AVN, Atrioventricular node; CRT, cardiac resynchronization therapy; GDMT, guideline-directed medical therapy; LBBB, left bundle branch block; LVEF, left ventricular ejection fraction; NYHA, New York Heart Association.

[Epub ahead of print])

candidates for cardiac resynchronization therapy. This group of patients has a high mortality rate driven mainly by progressive HF, and recurrent VT/VF can be a sign of progression of the impaired LV function. Therefore, in these patients, ICD therapy may shift the mode of death from SCD to HF death rather than reduce total mortality.^{5,8}

The appropriate timing to perform ICD implantation in DCM remains controversial. In general, implantation of an ICD for primary prevention is not recommended within the first 3 months after initial diagnosis of DCM.^{7,15} It is important to understand that medical management with angiotensin-converting enzyme inhibitors and beta-blockers (with or without aldosterone antagonists) has proven mortality benefit in these patients and should be optimized as much as possible before ICD placement. Furthermore, improvements of LVEF have been observed in about 50% of patients with recent onset DCM after a period of 3 to 9 months on guideline-directed medical therapy. Many of these patients may be excluded as candidates for an ICD after optimization of medical treatment.^{22–24} The deleterious effects of residual ventricular scarring, despite improvement in overall LV function, is unknown.

At initial evaluation, predicting the course of LV dysfunction is difficult. In one report, a smaller LV end-diastolic diameter, higher systolic blood pressure, and an acute inflammatory process identified at biopsy were associated with an increased likelihood of recovery of LV function. Conversely, black race and higher NYHA functional class

were associated with a lower LVEF at follow-up. Furthermore, DCM due to cardiac sarcoidosis, giant cell myocarditis, or certain genetic mutations is unlikely to improve with medical therapy. On the other hand, peripartum cardiomyopathy, myocarditis, acute drug-induced cardiomyopathy, tachycardia-, or PVC-induced cardiomyopathy have higher likelihood of improvement with optimal medical therapy and elimination of underlying etiology, if possible.

There is no evidence that early ICD implantation benefits patients with newly diagnosed nonischemic DCM. Data suggest that the impact of defibrillators on reducing SCD in patients during the first 90 days on optimal medical therapy is low, and in most studies, ICD benefit did not become apparent for more than a year. Furthermore, a recent retrospective study reported a low incidence of appropriate ICD shocks in patients who received an ICD before mandated waiting periods were complete.²⁵ Therefore, for patients with a new diagnosis of DCM, it is prudent to treat with optimal HF medications for at least 3 months and reassess for recovery of ventricular function before consideration of prophylactic ICD therapy, unless there are high-risk features such as sarcoidosis, giant cell myocarditis, or familial cardiomyopathy, known to be associated with malignant ventricular arrhythmias.⁷

On the other hand, ICD implantation can be considered in patients with recent (less than 3 months) diagnosis of nonischemic DCM who also require nonelective permanent pacing, develop sustained (or

hemodynamically significant) ventricular tachyarrhythmia, present with syncope that is thought to be due to a ventricular tachyarrhythmia (by clinical history, documented nonsustained ventricular tachycardia [NSVT], or EP study), or are listed for heart transplant or implanted with a LV assist device.^{7,26}

To mitigate the risk of arrhythmic SCD during the 90-day waiting period on optimal medical therapy before reevaluation of LV function, wearable cardioverter defibrillators are frequently prescribed for patients with newly diagnosed nonischemic DCM. However, data to support such a practice are lacking. Observation studies demonstrated that the risk of SCD in this patient population is very low, and the utility of wearable cardioverter defibrillators is very limited and unlikely to be cost effective.²⁵

Catheter Ablation

While ICD therapy reduces the risk of arrhythmic death, it does not prevent the recurrence of symptomatic VT. Further, antiarrhythmic drug therapy has limited success rate for control of VT (approximately 40% of cases), leaving a significant proportion of patients with symptomatic VT or ICD shocks. Catheter ablation of VT in patients with nonischemic DCM is typically considered in those with incessant VT or with frequent ICD discharges (or electrical storm) refractory to antiarrhythmic drug therapy (see Box 22.1). However, because of the future risk of life-threatening VT due to progression of the myopathic process, catheter ablation is not a substitute for an ICD, even when excellent short-term results are achieved.²⁷

In addition, limited data found that catheter ablation (in conjunction with ICD implantation) earlier in the course of treatment of VT or as a primary therapy (i.e., before antiarrhythmic drug therapy), with the goal of avoiding future ICD shocks, was associated with better acute procedural success as compared with delayed ablation. However, evidence for the efficacy and safety of such an approach in patients with nonischemic DCM remains limited.^{28,29}

The success rate for catheter ablation of VT in DCM is lower than that for ischemic VT, and depends on VT substrate location, which can be endocardial, intramural, or epicardial. An epicardial ablation approach is necessary in a large proportion of patients and is associated with higher complication rates. In experienced centers, catheter ablation is associated with acute success rates of up to 71%. VT recurs in 50% to 60% during the first year post ablation, although VT burden can be significantly reduced. Alcohol septal ablation can be particularly useful in patients with intramural septal VTs refractory to catheter ablation.³⁰

Furthermore, catheter ablation also should be considered for patients with BBR VT or interfascicular VT, and those with frequent PVCs, nonsustained VT, or sustained VT that is presumed to cause ventricular dysfunction. Box 22.1 lists the recommendation of ablation for VT in structural heart disease, in accordance with the published guidelines for management of patients with ventricular arrhythmias.^{15,31}

ELECTROCARDIOGRAPHIC FEATURES

The site of origin of VT is the source of electrical activity producing the VT QRS complex. Although this is a discrete site of impulse formation in automatic and triggered (i.e., focal) rhythms, during reentrant VT it represents the exit site from the diastolic pathway (isthmus) to the myocardium giving rise to the QRS.

Although the surface ECG during VT can help predict the location of the arrhythmogenic substrate in patient with DCM, it is important to recognize its limitations. The pattern of ventricular activation and hence the resultant QRS depends on how the wavefront propagates from the site of origin to the remainder of the heart, which (because of scar-related alterations of propagation) can be totally different during

VT than during pacing from the same site in normal sinus rhythm (NSR). Furthermore, the 12-lead ECG provides information about the VT exit site from the scar border and not about the site to be targeted by ablation. Ablation of scar-related VTs targets the critical isthmus of the reentrant circuit, which can be removed from the exit site indicated by the surface ECG. In addition, the overall QRS morphology during scar-related VT is determined not just by the site of origin of the VT, but also by scar extent and distribution in the rest of the ventricle. Therefore the presence of large confluent myocardial scars can limit the accuracy of the 12-lead ECG to localize the VT.³²

Anteroseptal Versus Inferolateral Ventricular Tachycardia

The VT substrate in patients with nonischemic DCM is often located in the basal LV, clustering around the mitral and aortic annuli, with variable extension toward the LV apex. Two predominant scar patterns account for the arrhythmogenic substrate in the majority of these patients: anteroseptal LV scar and inferolateral LV scar. VT morphologies consistent with anteroseptal substrate include (1) right bundle branch block (RBBB) morphology, positive precordial concordance, and inferior axis VTs; and (2) LBBB morphology, early precordial transition (leads V₁ to V₃), and inferior axis (see eFig. 25.1). In contrast, RBBB morphology, late precordial transition, and right (superior or inferior) axis during VT are consistent with an inferolateral scar (Fig. 25.2).²⁷

Apical Ventricular Tachycardia

An apical VT origin is suggested by (1) LBBB morphology with late precordial transition (leads V₅ to V₆) to a dominant positive QRS complex; or (2) RBBB morphology and early precordial transition (leads V₁ to V₃) to a dominant negative QRS complex.

Septal Ventricular Tachycardia

In the setting of isolated septal substrates, VT morphologies can vary but predominantly exhibit RBBB, with either superior or inferior axis. About 40% of those VTs exhibit one of two particular configurations. The first is characterized by a precordial “transition pattern break” in lead V₂ with qR/Rs morphology in leads V₁ and V₃ but reversal of this in lead V₂, usually in the presence of an inferior-axis RBBB configuration. The second is characterized by an inferior limb lead discordance, usually LBBB configuration with a net positive vector in II, negative in III, and positive in aVL.³³

Epicardial Ventricular Tachycardia

For VTs originating from the LV and having RBBB pattern, some findings on the surface ECG suggest an epicardial origin. These ECG characteristics, which generally rely on the late engagement of rapidly conducting His-Purkinje fibers by tachycardia circuit exits on the epicardium, include the following: (1) a pseudo-delta wave (measured from the earliest ventricular activation to the earliest fast deflection in any precordial lead) of 34 milliseconds or more (sensitivity, 83%; specificity, 95%); (2) a QRS duration exceeding 200 milliseconds; (3) a long R-wave peak time in lead V₂ (i.e., an interval from the beginning of the QRS complex to the time of initial downstroke of the R wave after it has peaked [previously known as the *intrinsicoid deflection*]) of at least 85 milliseconds (sensitivity, 87%; specificity, 90%); and (4) a shortest RS complex duration (measured from the earliest ventricular activation to the nadir of the first S wave in any precordial lead) of 121 milliseconds or more (sensitivity, 76%; specificity, 85%).³⁴

Importantly, ECG criteria for identifying an epicardial origin of VT appear to be region and substrate specific. ECG interval criteria that identify slow conduction in the initial portion of the QRS do not appear to be equally accurate among all LV regions and are not as reliable for

Fig. 25.2 Surface Electrocardiogram of Ventricular Tachycardias in a Patient With Dilated Cardiomyopathy. QRS morphology is suggestive of origin from inferolateral left ventricular substrate. Right bundle branch block morphology, late precordial transition (leads V_6), and right inferior axis.

consistently identifying the endocardial versus epicardial origin in the setting of nonischemic DCM, despite their proven value in patients without structural heart disease.^{34,35}

Given the limited predictive value of ECG criteria when applied individually, a multistep algorithm that incorporates several criteria (two morphology criteria and two adjusted interval criteria) was proposed to predict the site of origin of VTs from the basal-superior/lateral epicardium in patients with nonischemic DCM (Fig. 25.3). The criteria included, in a stepwise fashion, (1) the absence of Q waves in inferior leads; (2) a pseudo-delta wave of at least 75 milliseconds; (3) a maximum deflection index of 0.59 or more; and (4) the presence of a Q wave in lead I. The maximum deflection index is defined as the shortest time to maximal deflection in the precordial leads, divided by the total QRS duration—that is, the interval measured from the earliest ventricular activation (or from the stimulation artifact) to the peak of the largest amplitude deflection in each precordial lead (taking the lead with shortest time), divided by the QRS duration.³⁵

This four-step algorithm had a 95% specificity and at least 20% sensitivity for identifying basal-superior/lateral epicardial origin of VTs in nonischemic cardiomyopathy. The morphological criteria (presence of a q wave in lead I and absence of q waves in the inferior leads) appear to be the most specific criteria. In particular, the presence of a q wave in lead I is a very specific (88%) and also a very sensitive criterion (88%) for identifying an epicardial site of origin.³⁵

MAPPING

Scar-related macroreentry is the dominant mechanism of VT in DCM. Therefore mapping techniques for these VT are similar to those used for post-MI VT (see Chapter 22 for detailed discussion).

There are two strategies for VT ablation: (1) identification of the critical isthmus of the tachycardia circuit; and (2) identification of the potential arrhythmogenic substrate. Identification of the critical isthmus of the VT by activation and entrainment mapping techniques is the gold standard for VT mapping. However, this goal may not be achiev-

SN = 96% SP = 93%

Fig. 25.3 Four-Step Algorithm to Identify an Epicardial (EPI) Left Ventricular Ventricular Tachycardia (VT) Site of Origin From the Basal Superior and Lateral Left Ventricle in Patients With Nonischemic Cardiomyopathy. The cutoff values of the pseudo-delta wave and maximum deflection index (MDI) were modified to increase its individual predictive value. The three top steps have a high specificity and the last step is the most accurate. The total sensitivity (SN) and specificity (SP) of the algorithm in the study population for pace map localization reach 96% and 93%, respectively. (From Vallès E, Bazan V, Marchlinski FE. ECG criteria to identify epicardial ventricular tachycardia in nonischemic cardiomyopathy. *Circ Arrhythmia Electrophysiol.* 2010;3:63–71.)

able in patients with noninducible or poorly tolerated VTs. Therefore it is a common practice to utilize substrate mapping during NSR as an initial strategy to delineate the potential arrhythmogenic substrate and refine the area of interest, and then attempt focused activation and entrainment mapping after VT induction, if feasible. When the VT is

unstable or unsustainable, substrate-based mapping becomes the main strategy to guide ablation. Substrate mapping during NSR as the sole strategy to guide ablation has also been employed successfully to guide ablation without attempting mapping during VT, even in patients with inducible VTs (see Fig. 22.30).³⁶

When VT mapping is the goal of the procedure, it is recommended that isthmuses of all mappable VTs be identified and selectively targeted, with an ultimate goal of elimination of all those VTs. On the other hand, when multiple VTs are inducible during EP testing, some investigators recommend targeting only the clinical VT, especially in very ill patients in whom the goal is to decrease the frequency of ICD shocks.³⁶

However, there are several difficulties with selecting a dominant clinical VT for ablation. Often it is not possible to determine which VT is the one that has occurred spontaneously. Only a limited recording of one or a few ECG leads may be available. In patients with an ICD, VT is usually terminated promptly and a 12-lead ECG often is not available. Even if one VT is identified as predominant, other VTs that are inducible can subsequently occur spontaneously. Nonetheless, comparing the tachycardia cycle length (TCL) and ICD electrogram morphology during spontaneous and induced VTs can be helpful, particularly when trying to limit ablation and target only the presumptive clinical VT.

Electroanatomic mapping systems have become an essential tool for mapping and ablation of scar-related VT. Electroanatomic mapping can help in the precise description of VT reentrant circuits, sequence of ventricular activation during the VT, rapid visualization of the activation wavefront, and identification of slow-conducting pathways and appropriate sites for entrainment mapping. These systems also help navigation of the ablation catheter, planning of ablation lines, and cataloging sites of interest (e.g., sites with favorable entrainment or pace mapping findings), which can then be revisited with precision. In addition, the use of electroanatomic mapping systems is essential for substrate-based approaches to mapping and ablation of post-MI VT.

A quadripolar mapping-ablation catheter is typically utilized for point-by-point mapping. High-density mapping can be facilitated by the use of a 20-pole catheter (PentaRay, Biosense-Webster, Diamond Bar, CA, United States) or the Orion minibasket catheter (Boston Scientific, Cambridge, MA, United States).^{37,38} Multielectrode catheters with small and closely spaced electrodes offer improved mapping resolution, especially when mapping in areas of heterogeneous scar distribution, where they allow identification of distinct diastolic activity that may not be seen with standard linear catheters.³⁹

Preprocedural Evaluation

Preprocedural optimization of HF and hemodynamic status is necessary. Echocardiography, computed tomographic (CT), or CMR imaging may be used to identify the size, location, and transmural extent of the myocardial scar that potentially contains the arrhythmogenic substrate. This information can potentially predict the approach required for successful VT ablation (endocardial vs. epicardial) and help focus initial mapping strategies to the area of interest within the ventricle. Furthermore, registration of preacquired CT or CMR images with real-time electroanatomic mapping has successfully been used to facilitate and guide catheter navigation and VT ablation (see eFig. 6.8).^{40,41}

These tests also help exclude the presence of LV thrombus, which can increase the risk of embolization during mapping. Organized thrombus can overlie the area of interest for ablation and prevent effective energy delivery to target sites.⁴

Left Ventricular Access

The LV is accessed through the retrograde transaortic approach, the atrial transseptal approach, the subxiphoid epicardial mapping, or a combination of these approaches.

VT mapping and ablation in patients with DCM often is challenging, more so than post-MI VT, partly because of the frequent intramural and subepicardial location of the arrhythmogenic substrate. Two scar patterns (basal anteroseptal and inferolateral) account for arrhythmogenic substrates in the majority of patients. Basal anteroseptal scars are most effectively approached from the endocardial retrograde transaortic approach, and are usually not well accessible from the epicardium. Mapping and ablation of midseptal circuits requires a biventricular endocardial approach. In patients with inferolateral scars, an epicardial approach is frequently required.⁴

Hemodynamic Support

Not infrequently, hemodynamic instability during sustained VT precludes conventional mapping approaches (entrainment and activation mapping), especially in patients with severe LV dysfunction. In some patients, hemodynamic support can be achieved by the use of intravenous (IV) vasopressors (dopamine, dobutamine, or phenylephrine), partial or complete cardiopulmonary bypass, or percutaneous LV assist devices. In addition, IV procainamide can help slow and stabilize the VT rate.^{42–44}

Percutaneous LV assist devices (Impella microcirculatory axial blood flow pump [Abiomed, Danvers, MA, United States] and TandemHeart [Cardiac Assist, Pittsburgh, PA, United States]) generally provide greater hemodynamic stability during sustained VT than intraaortic balloon pumps. Although the ability to maintain sustained VT without hemodynamic compromise allows for more detailed mapping to identify the critical isthmus of the VT circuit, the use of these devices has not been proven to improve outcome. Therefore the potential benefits of these approaches should be weighed against the risk of vascular and thromboembolic complications in the individual patient.^{44–46}

Importantly, the volume status and intake and output should be closely monitored during the ablation procedure, especially when utilizing open-irrigated ablation catheters. In some patients, administration of diuretics and utilization of decreased irrigation rate or closed-irrigation ablation catheters need to be considered. In addition, when the transseptal approach is utilized for LV access, monitoring left atrial (LA) pressure can help assess volume status.

Induction of Tachycardia

Typically the stimulation protocol applies pacing output at twice the diastolic threshold and a pulse width of 1 to 2 milliseconds. Single ventricular extrastimuli (VESs) during NSR and at pacing drive CLs of 600 and 400 milliseconds are delivered, first from the RV apex and then from the right ventricular outflow tract (RVOT). The prematurity of extrastimuli is increased until refractoriness or induction of sustained VT is achieved. If these measures fail to induce VT, double and then triple VESs are used in the same manner. If VT still cannot be induced, rapid ventricular pacing is started at a pacing cycle length (PCL) of 400 milliseconds, gradually decreasing the PCL until 1:1 ventricular capture is lost or a PCL of 220 milliseconds is reached. Repeating the protocol at other pacing drive CLs, at other RV sites, or after administration of isoproterenol is then attempted.²⁹ Short-long-short coupling intervals may be helpful in initiating BBR-VT.

Substrate Mapping

The majority of VTs in patients with DCM are caused by scar-related macroreentry. Substrate mapping aims at identification of the areas of scar (as identified by low-amplitude electrograms and electrical unexcitability), as well as delineation of conducting channels within or adjacent to the scar regions that can potentially support the VT circuit (as identified by voltage channels and local abnormal ventricular activity [LAVA]).

Substrate mapping during NSR often is employed as an initial mapping strategy to help identify potential isthmuses that support the VT circuit, and narrow the area of interest for further activation and entrainment mapping maneuvers required to confirm the target for ablation. This approach helps minimize the duration spent in sustained VT that can potentially result in exacerbation of cardiac and renal failure. On the other hand, when the VT is not approachable by conventional point-by-point activation mapping and entrainment maneuvers (because of hemodynamic intolerance, inconsistent induction, altering QRS morphology, or nonsustained duration), substrate mapping approaches become the primary strategy to guide VT ablation.

Preprocedural Substrate Imaging

CT or CMR imaging can be used to identify the size, location, and transmural extent of the scar that potentially contains the arrhythmogenic substrate. In addition, registration of those imaging modalities in the three-dimensional (3-D) electroanatomic mapping system can help visualize the LV substrate and focus the mapping procedure to the region of interest. In addition, CMR is able to characterize the transmural extent and intramyocardial location of scar tissue, which can potentially help identify intramural and epicardial arrhythmia substrate, overcoming a limitation of endocardial voltage mapping.⁴⁷

Scar Mapping

While substrate mapping techniques are similar to those describe for post-MI VT, it is important to note that the VT substrate in DCM exhibits more complicated morphology and distribution patterns compared with the substrate in post-MI VT, given the propensity for intramural, epicardial, and patchy scar morphologies characteristic of DCM. In addition, the scar in DCM tends to be smaller and less confluent, and more diffuse, necessitating high-density mapping of the entire ventricular surface.

Electrical scar is defined by low amplitude of local electrograms and tissue unexcitability during high-output pacing. Voltage mapping is performed during sinus rhythm, atrial pacing, or ventricular pacing. During bipolar voltage mapping, endocardial scar is defined as areas with peak-to-peak electrogram amplitude less than 0.5 mV. A low-voltage “border zone” is defined as endocardial bipolar voltages between 0.5 and 1.5 mV. At low-amplitude (less than 0.5 mV) sites, pacing is performed with 10-mA, 2-millisecond pulse width stimuli. A pacing threshold greater than 10 mA has been used to define unexcitable scar, provided electrode-tissue contact is adequate. The use of intracardiac echocardiography (ICE) and contact force catheters can help ensure adequate catheter contact, an essential prerequisite for reliable voltage mapping. The voltage map is displayed in a color-coded manner, with the color range set between 0.5 and 1.5 mV, and superimposed on the on the electroanatomical model.^{45,48}

In general, endocardial sites with evidence of slow conduction (e.g., late potentials, fragmented electrograms, and long S-QRS intervals during pacing) correspond to areas with more than 75% scar transmural or patchy scar.^{45,49}

Because of the predilection of nonischemic scar for the midwall and epicardium, low-voltage areas on endocardial electroanatomic mapping are smaller in patients with nonischemic scar-related VTs compared with patients with post-MI VTs. Frequently the VT substrate can be solely or predominantly intramural or epicardial and hence might not be detected during bipolar voltage mapping. In this setting, unipolar voltage mapping (with threshold of 8.3 mV for detection of LV scar and 5.5 mV for RV scar) can be used effectively to identify substrates deeper to the endocardial recording site, such as intramural, midseptal, and epicardial scar. Low unipolar voltages indicate regions of epicardial involvement with high positive and negative predictive values in patients

with no or minimal endocardial changes evident on bipolar electrogram analysis (Fig. 25.4). In addition, if VT circuits within the interventricular septum are suspected, the RV side of the septum should be mapped.^{45,49,50}

Voltage mapping in patients with DCM typically demonstrates a modest-sized area of endocardial electrogram abnormalities (ranging from 6% to 48% of the LV endocardial surface, but uncommonly involving more than 25% of the total endocardial surface area) located near the LV base and lateral aspect, frequently surrounding the aortic and mitral valve region and then extending apically. The amount of dense scar (electrogram amplitude less than 0.5 mV) accounts for approximately $27\% \pm 20\%$ (range, 0% to 64%) of the overall abnormal low-voltage endocardial substrate. The exit site of a VT circuit corresponds to these basal electrogram abnormalities.

The electroanatomical substrate abnormalities in DCM are often found in the LV basal and perivalvular regions with a predilection for the midmyocardial and epicardial layers (Fig. 25.5). Two predominant scar patterns account for the arrhythmogenic substrate in the majority of these patients: anteroapical LV scar and inferolateral LV scar. VT originating from the inferolateral scar often requires epicardial ablation, in contrast to VT originating from an anteroapical scar that more frequently appear to have an intramural origin requiring ablation from the aortic root or the anteroapical LV endocardium, but not from the epicardium.²⁷

In addition, the interventricular septum is a frequent location for the VT substrate, which can escape detection by bipolar voltage mapping. Unipolar voltage mapping on both sides of the septum and preprocedural CMR, as well as delayed transseptal activation time and patterns, can help identify midseptal scar.²⁷

Identification of Conducting Channels

Diastolic isthmuses during VT are typically composed of relatively small bundles of viable myocardium embedded within or between dense scar regions. Abnormal low-voltage electrograms can be recorded throughout extensive areas of scar that are not sufficiently specific for the components of the reentrant circuit. Therefore identification of the conducting channels within the low voltage zones helps refine the area that potentially supports the VT circuit. Those channels can be identified by voltage channels or, more reliably, as sites with late potentials embedded within dense scar.⁵¹ It is important to recognize, however, that the assessment of the relationship between conducting channels identified in NSR and those detected by entrainment mapping during tachycardia has been limited.⁵²

Voltage channels. Conducting channels can be visualized on the electroanatomic voltage map as corridors of voltage preservation (voltage channels) within denser regions of scar or corridors between a dense scar and a valvular annulus. Careful step-by-step manual adjustment of voltage upper and lower limits on the color-coded electroanatomic voltage map (i.e., the voltage limits are reset to 0.3 to 0.5 mV as the upper limit and to 0.1 mV as the lower, representing dense scar) can help maximize the color contrast between adjacent myocardium with different electrogram voltage levels within the 0.5-mV scar and thus unmask channels of viable myocardium within a dense scar (Fig. 25.6).^{51,53}

Recent evidence, however, has questioned the value of this method (voltage scanning) for the identification of conducting channels. This technique likely has limited sensitivity and specificity. The technique utilizing late potentials identifies a higher proportion of conducting channels and, more importantly, most conducting channels that serve as the substrate for VTs. This may not be surprising since voltage mapping incorporates the larger far-field signals commonly present at sites recording smaller near-field late potentials.

Late potentials. The majority of VT isthmus sites are associated with the presence of multipotential and fractionated electrograms (i.e.,

Fig. 25.4 Voltage Mapping in Nonischemic Dilated Cardiomyopathy. Left ventricular (LV) endocardial (bipolar and unipolar) and epicardial bipolar voltage maps are shown in two different patients. (A) Maps are shown in the posterior-anterior projection. The LV endocardial bipolar voltage map (*left*) is normal, whereas the endocardial unipolar voltage map (*middle*) shows extensive low voltage involving the lateral and inferior LV walls. There is a large region of corresponding LV epicardial bipolar low voltage (*right*) seen corresponding spatially with the endocardial unipolar abnormality. (B) Maps are shown in the lateral projection. The LV endocardial bipolar voltage map (*left*) is normal, whereas the endocardial unipolar voltage map (*middle*) shows two confluent low voltage regions at the basal-mid lateral and apical LV segments, which correspond to the low voltage zone identified on the corresponding LV epicardial bipolar voltage map (*right*). (From Hutchinson MD, Gerstenfeld EP, Desjardins B, et al. Endocardial unipolar voltage mapping to detect epicardial ventricular tachycardia substrate in patients with nonischemic left ventricular cardiomyopathy. *Circ Arrhythmia Electro-physiol.* 2011;4:49–55.)

electrograms with three or more sharp spikes, either separated by an isoelectric interval or continuous) and/or late potentials (i.e., low-voltage electrograms with a single-component or multiple continuous delayed electrical components separated from the higher-amplitude component of the local ventricular electrogram by at least 20 milliseconds and recorded after the end of the surface QRS). Electrogram fractionation reflects slow and nonuniform anisotropic conduction, while late potentials can reflect local depolarization of surviving muscle bundles that are well insulated by dense scar, where local activation is recorded late, well after the higher amplitude far-field electrogram and often well after the end of the surface QRS complex or T wave.^{38,54,55} In DCM, late

potentials are recorded more frequently in association with the infero-lateral than antero-septal scar subtypes. When recorded endocardially, abnormal local ventricular activity usually suggests the presence of a transmural scar.⁴⁹

However, local abnormal electrical activity is limited by imperfect specificity due to bystander cul-de-sacs or nonspecific slowed conduction, as well as imperfect sensitivity due to low-amplitude local signals or the direction of wavefront propagation obscuring isolated potentials. Nevertheless, late potentials can help refine the area of interest. The areas demonstrating such electrograms are relatively small compared with scar areas; therefore this method permits a focus on the diagnostic

Fig. 25.5 Scar Distribution in Nonischemic Dilated Cardiomyopathy. Bipolar voltage map of the left ventricle in a patient with ventricular tachycardia and nonischemic dilated. Scar cutoff value is set at <0.5 mV (red area), and border zone is set at 0.5 to 1.5 mV. (A) Apical view. (B) Posterior view. (C) Right lateral view. Note predilection of scar distribution to the left ventricular basal and perivalvular regions, and the patchy nature of the scar. AO, Aorta; MA, mitral annulus.

Fig. 25.6 Voltage Channels. Bipolar voltage map of the left ventricle (*inferior view*) in a patient with ventricular tachycardia and nonischemic dilated. (A) Large basal inferior wall scar is obtained when the cutoff value is set at <0.5 mV (red area), and border zone is set at 0.5 to 1.5 mV. (B) By modifying the color scale, different areas within the scar can be identified: very low voltage areas (<0.3 mV) corresponding to true scar (border zone is set at 0.3 to 0.4 mV) and corridors between them with slightly greater voltage (in green and yellow) constituting voltage channels and potential circuit isthmuses. (C) Catheter ablation (red dots) is performed to transect the voltage channels. MA, Mitral annulus.

techniques and ablation in defined areas. Furthermore, recording these electrograms before and during VT induction serves to relate them and VT within seconds, provided that the isolated diastolic component of the electrogram precedes the first VT beat and then becomes mid-diastolic. In addition, pacing is systematically attempted at these sites looking for morphology match with any induced VT and for latency between the stimulus and the QRS. The paced wavefront at those sites usually propagates slowly out of the scar, resulting in a long S-QRS

interval (greater than 40 milliseconds) and, if sharing an exit of a targeted VT, a good or excellent pace map.

Late potentials typically are low-amplitude and often are obscured by larger far-field electrograms produced by activation of the surrounding myocardium outside the scar region. Changing the direction of depolarization approaching the mapping site (e.g., sinus rhythm vs. RV pacing) and premature ventricular stimulation (causing decremental conduction) can help separate local (near-field) from far-field potentials.

Furthermore, pacing at the local site can help distinguish far-field from near-field signals. When the recorded electrogram is near-field, capture of the pacing stimulus results in capturing the tissue generating all components of the electrogram, so that no clear electrogram component is identifiable during pacing. Conversely, when the recorded electrogram is far-field, pacing may not capture (due to dense scar) or, when it captures local tissue, the far-field electrograms remain discernible during pacing (since they reflect activation of myocardium adjacent to the pacing site).⁵⁴

Sites recording abnormal electrograms are tagged and superimposed on voltage maps to further delineate their relationship to scar distribution. Late potential conducting channels are defined as a path of more than two adjacent late potentials connecting with healthy tissue. Further, late potentials are classified as being an entrance or an inner part of a given conducting channel, depending on the local activation time of the near-field component. The entrance of a conducting channel is tagged as sites within the border zone (i.e., voltage zone of 0.5 to 1.5 mV) recording late potentials with the shortest delay between the far-field component (low frequency, usually high voltage) and the near-field, local component (delayed, high frequency, usually fractionated and low voltage). Sites with longer delays likely reside farther along the conducting channel within the dense scar.^{49,56}

Activation Mapping

After construction of an endocardial voltage map during the baseline rhythm, VT is induced by programmed ventricular stimulation. VT activation mapping has several prerequisites, including inducibility of VT by programmed stimulation, hemodynamic stability of the VT, and stability of the VT reentry circuit (i.e., stable VT morphology and TCL). If the tachycardia is not stable (morphologically or hemodynamically), mapping can still be performed by starting and stopping the VT after data acquisition at each site. In addition, poorly tolerated rapid VTs sometimes can be slowed by antiarrhythmic drugs to allow for mapping. Furthermore, the use of intravenous vasopressors and external hemodynamic support devices can potentially provide hemodynamic support and allow mapping of otherwise unstable VT.^{42–44} The use of 20-pole catheter (PentaRay; 2–6–2 mm interelectrode spacing, 1 mm electrodes), the mini-basket catheter (Orion), and noncontact mapping can also provide large amounts of activation mapping data during nonsustained or unstable VT.

Activation mapping aims to identify with continuous activity spanning diastole or with an isolated mid-diastolic potential, presumably representing the diastolic pathway (critical isthmus) of the reentrant circuit. Unlike focal tachycardias, a presystolic electrogram preceding the tachycardia complex by 10 to 40 milliseconds is not adequate in defining the site of origin of a macroreentrant tachycardia (eFig. 25.3). The earliest presystolic electrogram closest to mid-diastole is the most commonly observed indicator of an isthmus site in a VT circuit; however, continuous diastolic activity and/or bridging of diastole at adjacent sites or mapping a discrete diastolic pathway would be most consistent with a reentrant circuit.

Initially one should seek the general region of the origin of the tachycardia guided by VT morphology on the surface ECG, as well the findings on substrate mapping and preprocedural substrate imaging studies localizing the arrhythmogenic substrate. In particular, activation mapping during VT should first be directed to conducting channels and sites with late potentials identified during NSR. Most reentrant circuits in DCM cluster around the basal anteroseptal and inferolateral LV.

Once identified, the relationship of sites with mid-diastolic activity to the VT should be verified. One must always confirm that the diastolic electrical activity (early, mid, or late) cannot be dissociated from the VT and is required for VT maintenance. Thus during spontaneous

changes in the TCL or those produced by programmed electrical stimulation, the electrogram, regardless of its position in diastole, should show a fixed relationship to the subsequent QRS and not the preceding QRS. The ability to dissociate diastolic electrical activity from the VT indicates that those sites are parts of areas of abnormal slow conduction unrelated to the VT circuit (i.e., a dead-end pathway) or bystander sites attached to the VT isthmus. Entrainment mapping (see later) can help establish the relationship of those sites to the tachycardia circuit.

If, after very detailed mapping, the earliest recorded site is not at least 50 milliseconds presystolic, this suggests that either the map is inadequate (most common) or the VT arises deeper in the midmyocardium or subepicardium.

Entrainment Mapping

Entrainment mapping during reentrant VT is used to verify whether a site recording diastolic activity (regardless of where in diastole it occurs, its position, and appearance on initiation of VT) is functionally involved in the VT circuit.

Entrainment mapping is directed to sites identified by other mapping modalities, such as activation and pace mapping, as potentially related to the reentrant circuit. These include areas of slow conduction (manifest as fractionated electrograms), sites with mid-diastolic electrograms, or those displaying long delays between the pacing stimulus and the captured surface ECG complex. Pacing is performed during VT at a PCL 10 to 30 milliseconds shorter than the TCL, at sites identified during activation mapping, demonstrating continuous activity or isolated mid-diastolic potentials.

Once the presence of entrainment is verified, several criteria can be used to indicate the relation of the pacing site to the reentrant circuit. The first entrainment criterion to be sought is concealed fusion. Entrainment with concealed fusion indicates that the pacing site is in a protected isthmus located within or attached to the reentrant circuit. Whether this protected isthmus is crucial to the reentrant circuit or is just a bystander site needs to be verified by other entrainment criteria including the postpacing complex (PPI) versus the TCL and the local electrogram-QRS interval during VT versus the S-QRS interval (see Fig. 22.20).⁵⁷

For stable SMVTs, the following three criteria are used to define the critical isthmus and predict the success of radiofrequency (RF) application in termination of the VT: (1) entrainment with concealed fusion; (2) PPI equal to the TCL (± 30 milliseconds); (3) and S-QRS interval equal to the local electrogram-to-QRS interval (± 20 milliseconds; see eFig. 25.3). Other predictors of successful ablation sites include S-QRS interval-to-VT CL ratio less than 70%, long S-QRS interval, and alteration of the TCL or VT termination by subthreshold or nonpropagated stimuli.⁵⁸

As noted, when hemodynamic compromise during the VT is the main limitation for conventional activation and entrainment mapping methods, inductions of brief episodes of VT (with the mapping catheter at the optimal site, as identified by substrate and pace mapping approaches) can allow assessment of the relationship of the abnormal electrograms to the VT circuit. This can also allow entrainment maneuvers to be performed at those sites to help distinguish sites critical to the VT circuit from bystander sites. VT is then quickly terminated before significant hemodynamic compromise ensues. This approach can be facilitated by hemodynamic support with the use of IV vasopressors, LV assist devices, or both. This approach, however, requires being able to induce the same VT reproducibly.

Pace Mapping

Pace mapping has been shown to be an effective corroborative method to regionalize the VT circuit and define potential exit sites along the

eFig. 25.3 Entrainment Mapping of Ventricular Tachycardia (VT) in Dilated Nonischemic Cardiomyopathy. VT is shown at left, with the ablation catheter at a site with an early diastolic recording; entrainment at this site has a stimulus-QRS interval similar to that of the electrogram-QRS during VT, with a perfect pace match. Ablation at this site eliminated VT. *Abl_{dist}*, Distal ablation; *Abl_{prox}*, proximal ablation; *EGM*, electrogram; *His_{prox}*, proximal His bundle; *HRA*, high right atrium; *RVA*, right ventricular apex.

border zone of any low-voltage region. Pace mapping in NSR is attempted after VT termination at potential isthmus sites (as identified by activation and entrainment mapping during VT as well as substrate mapping during NSR). Pace mapping is preferably performed with unipolar stimuli (10 mA, 2 milliseconds) from the distal electrode of the mapping catheter (cathode) and an electrode in the inferior vena cava (anode), at a PCL around 600 milliseconds.

The resulting 12-lead ECG morphology is compared with that of the VT. The greater the degree of concordance between the morphology during pacing and tachycardia, the closer the catheter is to the exit zone of the VT isthmus (see Fig. 5.23). In addition, pace mapping can identify regions of slow conduction with a stimulus-QRS interval (S-QRS) greater than 40 milliseconds and a pace map match consistent with the exit region from an isthmus. Pace mapping at sites more proximally located in the isthmus can also produce a similar QRS complex, but with a longer S-QRS interval (due to the delay of conduction of the paced wavefront to the exit site). The S-QRS interval lengthens progressively as the pacing site is moved more proximally along the isthmus, consistent with pacing progressively farther from the exit (see Fig. 5.23). Sites from which pace mapping produces the same QRS as that of the initial isthmus site with different S-QRS delays are identified in an attempt to trace the course of the VT isthmus (see Figs. 5.16 and 5.23).

Importantly, pace mapping has significant limitations in its ability to identify the critical isthmus of the VT circuit. A poor pace map does not reliably indicate that the pacing site is distant from the reentry circuit, since the VT wavefront is forced by fixed and functional conduction barriers to follow an orthodromic direction through the diastolic pathway of the tachycardia circuit, whereas the paced wavefront can follow different directions that are not constrained by functional barriers present during tachycardia but absent during NSR. In fact, it is rather uncommon to have an identical morphology result from pacing from a known isthmus determined by mapping. On the other hand, pacing during NSR from sites attached to the reentrant circuit but not part of the circuit can occasionally produce QRS morphology identical to that of the VT, because the stimulated wavefront can be physiologically forced by fixed conduction barriers to follow the same route of activation as the VT, as long as pacing is carried out between the entrance and exit of the protected isthmus.⁵⁹

Therefore, in the setting of scar-related macroreentrant VT, pace mapping serves only as a corroborative method of localizing the VT circuit. It can be used to identify the presumptive exit or isthmus region of the VT circuit, but is not sufficiently specific or sensitive to be the sole guide for ablation. Pace mapping can also be used in conjunction with substrate mapping when other mapping techniques are not feasible, so that it can provide information on where ablation can be directed.⁵⁹

Epicardial Mapping

Because of the propensity for epicardial scar in DCM, an endocardial mapping strategy often is limited. Therefore an epicardial approach should be considered early in the mapping process, especially in patients with limited endocardial substrate and those with failed or late VT termination with endocardial RF delivery. In addition, unipolar voltage mapping from the endocardium may be used for evaluation of epicardial scar. Endocardial unipolar (rather than bipolar) voltage mapping can predict the presence of and more closely approximate the extent of epicardial involvement and hence the need for the epicardial approach.⁶⁰

Some studies have shown that a combined endocardial-epicardial mapping and ablation as a first-line strategy in patients with DCM, and especially in those with failed prior endocardial ablation, could improve the procedure results and midterm outcomes. Furthermore, if there are clues on the ECG that suggest an epicardial VT or if there is documentation by CMR imaging of largely epicardial scar, a simultaneous

endocardial and epicardial mapping approach should be considered in the initial ablation procedure, whereby percutaneous epicardial access is obtained as the first step (before the administration of heparin).

The approach to epicardial mapping is essentially the same as for endocardial ablation, including activation mapping, entrainment mapping, substrate mapping, and pace mapping, and is discussed in detail in Chapter 27.

ABLATION

Target of Ablation

There are two strategies for ablation of scar-related VT: (1) selective targeting the critical isthmus that supports the development and maintenance of VT (as identified by activation, entrainment, and pace mapping techniques); and (2) extensive substrate modification to reduce the arrhythmogenicity of a scar without any specific arrhythmia targeting (see Fig. 22.31).^{36,45,61–63}

Selective Ablation of the Critical Isthmus of the Reentrant Circuit

Identification and ablation of the critical isthmus of the VT circuit is the gold standard for macroreentrant VT. This approach provides focused, high-yield ablation, and avoids unnecessary ablation at bystander sites. However, this strategy may not be feasible when the VT is not reproducibly inducible or is poorly tolerated. Even in the setting of stable SMVT, this approach can be time-consuming and expose the patient to the detrimental hemodynamic consequences of prolonged periods of sustained tachycardia, especially when multiple VTs are targeted.⁶³

For each induced stable SMVT, reentry circuit isthmuses are the target of ablation and are defined by activation and entrainment mapping as sites with: (1) continuous activity or isolated mid-diastolic potentials that cannot be dissociated from the tachycardia; (2) entrainment with concealed fusion; (3) PPI equal to the TCL (± 30 milliseconds); (4) S-QRS interval equal to electrogram-to-QRS interval (± 20 milliseconds); and (5) ratio of S-QRS interval of the TCL between 30% and 70%. Alteration of the TCL or termination of VT by subthreshold or non-propagated stimuli, and repeated VT termination occurring with catheter manipulation or pacing at the site, also suggest an isthmus location. These findings are consistent with a central/proximal isthmus site.³⁶

When the critical isthmuses of the reentrant circuit(s) can be identified, linear ablation lesions are delivered to sever those isthmuses. Terminating VT by targeting this area during ablation provides confirmatory evidence that it is a critical site for the arrhythmia. Isthmuses can be relatively broad and require transection with linear ablation lesions, usually connecting two regions of scar, or scar and an anatomical barrier, such as the mitral annulus.

Substrate-Guided Ablation

Substrate-based ablation approaches aim to ablate surrogate markers of the VT circuit during NSR without the need for detailed mapping of the critical isthmus of the VT circuit. Although substrate-based ablation was initially proposed for the treatment of unstable or noninducible VT, it has been increasingly adopted in clinical practice as a primary ablation strategy for any type of scar-related VT. The added value of VT induction and activation mapping has recently been challenged.^{36,62} However, given the less precise localization of the reentry circuit, these strategies involve more extensive, nonselective ablation, frequently involving nonarrhythmogenic regions of the scar. Furthermore, a purely substrate-based mapping and ablation strategy may not address a focal mechanism of VT that can be observed in patients with structural heart disease.^{27,63}

Strategies for substrate ablation are modeled after the technique used for post-MI VT, and range from a thorough ablation of the entire

abnormal substrate harboring abnormal electrograms (scar homogenization) to more selective ablation approaches such as “scar dechanneling” and “core isolation.” The comparative efficacy and safety between those different ablation strategies and their impact on ablation outcome have not been systematically studied. Variations in anatomy often influence the effectiveness of the different methods, and in many patients, a combination of these techniques is employed.^{36,45,49,62}

Scar homogenization. This approach involves extensive RF ablation throughout the entire scar (as defined by substrate mapping) to completely eliminate all the abnormal electrograms (fragmented electrograms and late potentials) within the scar region, without verifying their relationship to the targeted VT (see Fig. 22.32). Ablation is continued until abnormal and late potentials are eliminated, as confirmed by reduction of electrogram amplitude to the noise level and electrical unexcitability in response to high-output pacing (20 mA at 10 milliseconds).^{45,49,61}

Importantly, this approach frequently requires extensive ablation, and complete elimination of abnormal ventricular activity often requires epicardial ablation, especially given the high propensity of epicardial locations of those abnormal electrograms and in areas without ventricular wall thinning (unlike the substrate in post-MI patients), rendering endocardial ablation along ineffective in eliminating epicardial targets.^{60,64}

Scar dechanneling. Scar dechanneling involves RF ablation of all conducting channels within the scar as identified by substrate mapping (see earlier). If feasible, ablation is preferentially performed at the entrance of the conducting channels to eliminate conduction downstream along the channel and its ramifications while obviating the need for extensive ablation through the scar region (see Fig. 22.33). Those targets are identified by substrate mapping as sites within the border zone (i.e., zone with 0.5 to 1.5 mV voltage) recording late potentials with the shortest delay between the far-field and near-field signals. This is in contrast to the inner points of conducting channels within the dense scar, which are characterized by longer delays between the far-field electrogram and local components of the recorded electrogram. The endpoint of this ablation strategy is conducting channel entrance block, manifest as the disappearance of the inner point of the conducting channels or delayed activation of conducting channel inner points, usually with the activation sequence in reverse order.^{45,49,56,65}

Core isolation. This approach involves ablation with contiguous RF lesions placed circumferentially all around the “core” area of the scar containing the putative VT circuit elements (defined by conventional mapping techniques, including voltage channels, sites with late potentials, sites with good pace maps and long S-QRS intervals, as well as isthmus sites defined by entrainment mapping; see Fig. 22.34). The goal of core isolation is electrically isolating the segment of low voltage scar confirmed by the demonstration of exit block from the core of the scar (i.e., failure of global ventricular capture during high-output pacing from multiple, discrete sites inside the core that had previously demonstrated capture). In addition, entrance block can be demonstrated by dissociated fragmented electrical activity inside the core. Core isolation obviates the need for extensive ablation within the scar, as proposed by scar homogenization.^{45,49,66,67}

Linear ablation. This approach entails applying linear RF lesions using one of several guiding principles: (1) ablation lines extending perpendicular to all defined isthmuses (channels of surviving myocardium) within the scar areas or between islands of unexcitable segments within the infarct (identified as a region of relatively larger voltage bordered by low voltage within the scar and abnormal electrograms during NSR); (2) ablation lines extending parallel to the scar edge at the scar border zone (voltage 0.5 to 1.0 mV) encompassing all approximate exit sites identified by pace mapping; or (3) ablation lines extending perpendicular to the scar border, from the area of dense scar (i.e.,

voltage less than 0.5 mV) across the border zone and connecting out to normal myocardium (i.e., voltage greater than 1.5 mV) or to anatomical barriers (e.g., mitral annulus; see Fig. 22.31).^{45,49}

Ablation Technique

Ablation may be performed with an 8-mm-tip (maximal temperature of 65°C and maximal power of 75 W), or an irrigated-tip catheter (maximal temperature of 40°C to 45°C and maximal power of 40 to 50 W). Irrigated RF ablation is generally preferred for scar-related VT, as it allows increased power delivery, deeper lesions in myocardial scar, and potentially improved outcomes. However, external irrigation involves administration of potentially large amounts of IV saline, which can exacerbate HF. Therefore close monitoring volume status is important, and administration of IV diuretics may be required. Internal irrigation catheters or large-tip nonirrigated catheters may be considered if IV fluid administration will be difficult to manage, as in patients with renal failure or severe HF.

When selective ablation is performed during stable VT, RF application is usually maintained for 60 to 120 seconds at the site where the tachycardia is terminated. Application of RF energy at narrow critical isthmuses can terminate VT within 1 to 15 seconds. Wider isthmuses require multiple contiguous ablation lesions transecting the isthmus. Failure of RF ablation to terminate the tachycardia at a site that appears to be in the circuit suggests that the ablated site is a bystander and should prompt reexamination of mapping findings. Persistence of inducibility of VT after successful termination with RF application is probably secondary to inadequate lesion size because of a wide isthmus, poor tissue contact, intramural or epicardial location, or the presence of significant fibrosis, thrombus, or calcification. In some cases, abrupt termination of VT during ablation results in displacement of the ablation electrode from the target tissue. In such instances, entraining VT with RV pacing at the same rate will allow continued energy delivery without catheter movement, since the ventricular rate remains constant even after VT termination.

Patients with an inferolateral scar distribution pattern frequently require epicardial ablation. RF ablation, however, can be hindered by the close proximity of coronary arteries or the left phrenic nerve. Intramural circuits can require sequential ablation on both the endocardial and epicardial aspects of the ventricular free wall. On the other hand, in patients with an anteroseptal scar subtype, the arrhythmia substrate is often intramural and can be difficult to eliminate. High-energy RF ablation at the endocardial breakthrough sites from the right and left sides of the interventricular septum can be necessary, which increases the risk of atrioventricular (AV) block. RF delivery within a perforator vein of the great cardiac vein may be considered in some cases. RF ablation of midseptal targets frequently result in acute tachycardia termination, but persistent inducibility later during the procedure as well as high recurrence of clinical tachycardias during follow-up. Transcatheter alcohol ablation can be useful in targeting basal septal or intramural substrates. For refractory intramural circuits, alternative ablation modalities have been described, including bipolar RF, high-intensity focused ultrasound, or retractable needle ablation.⁶⁸

Endpoints of Ablation

The procedural endpoints for VT ablation in patients with DCM is not well defined, and have largely been based on data derived from studies of post-MI VT ablation.²⁹

Noninducibility of All Monomorphic Ventricular Tachycardias

Noninducibility of any VT (excluding very fast [TCL <240 milliseconds] nonclinical VT, polymorphic VT, and VF), using the entire programmed

electrical stimulation protocol, is the preferred endpoint of the ablation procedure. In small, observational studies, complete VT noninducibility was found to be associated with reduced risk of VT recurrence and improved all-cause mortality in patients with DCM.^{45,69}

However, elimination of all inducible monomorphic VTs can be challenging and may not be achievable in a significant proportion of patients. In addition, achieving this endpoint typically requires extensive mapping and ablation and repetition of aggressive ventricular stimulation, which can potentially lead to hemodynamic compromise. Furthermore, the predictive value of noninducibility for VT recurrence remains limited; the rate of VT recurrence remains relatively high even in patients whose VT is rendered noninducible after ablation. Therefore, while it is reasonable to attempt modification of the arrhythmogenic substrate to achieve a complete VT noninducibility, the benefits of such approach should be weighted carefully against the risks of extensive and prolonged ablation procedure.^{45,69}

Noninducibility of All Clinical Ventricular Tachycardias

Elimination of inducibility of all clinical VTs (i.e., all inducible VTs that are known to have the same 12-lead ECG QRS morphology and approximate CL as spontaneous VTs), using the entire programmed stimulation protocol, can be an acceptable procedural endpoint, even when other “nonclinical” SMVTs remain inducible. Elimination of clinical VTs is usually associated with a favorable outcome and a decrease of the arrhythmia burden and ICD shocks in most patients (especially in patients presenting with frequent ICD shocks or incessant VT) while obviating excessive mapping and ablation and prolonged procedure duration that may not be well tolerated.⁶⁹

However, this endpoint does not apply in the majority of patients in whom recordings of all VTs before ablation often are not reliably obtainable to define clinical or presumed clinical VTs or when the clinically relevant VTs are not reproducibly inducible at the outset of the procedure.

Modification of the Arrhythmogenic Substrate

Complete elimination of all fragmented and late potentials, scar homogenization, scar dechanneling, or core isolation (as described previously) may also be utilized as alternative procedural endpoints, especially in patients in whom VT is not reproducibly inducible at baseline. Furthermore, even in patients with inducible VTs, some reports suggested an improvement in outcome (reduction in VT recurrence cardiac mortality) when these substrate-based endpoints are combined with VT noninducibility, likely by eliminating the arrhythmogenic substrate and reducing the risk of developing new VTs or preexisting VTs that were not inducible during the ablation procedure.^{66,70,71}

Outcome

The acute success rates of catheter ablation of VT in DCM (i.e., achieving VT noninducibility as an endpoint) remain modest (50% to 75%) and lower than those for post-MI VT. This might be related to differences in scar distribution between the two pathologies. Unlike post-MI patients, combined endocardial-epicardial ablation is required in a large proportion of DCM patients.

VTs recur following ablation in DCM patients at a higher rate (23% to 77%) than in patients with post-MI VT. Nonetheless, the burden of VT and the frequency of ICD shocks are reduced in the majority of patients.^{27,45,72} The higher VT recurrence rates among DCM patients is likely related, at least in part, to disease progression; the majority of recurrent VTs appear to result from new circuits, representing a changing substrate. Incomplete procedural success, lower LVEF, VT storm, higher number of clinical VTs, and a higher number of failed antiarrhythmic drugs appear to predict increased risk of VT recurrence.²⁹

CARDIAC SARCOIDOSIS

Pathophysiology

Sarcoidosis is multisystem infiltrative, granulomatous disease of unknown etiology. The pathological hallmark of sarcoidosis is the formation of noncaseating granulomas composed of epithelioid and multinucleated giant cells. Sarcoidosis is thought to represent a T cell–mediated immune process in response to an unidentified antigenic trigger. Infectious, organic, and inorganic agents have been proposed as putative antigens. Regardless of the trigger, the disease progresses through three successive histopathological stages: (1) inflammation and edema with the infiltration of leukocytes, (2) noncaseating (necrotizing) epithelioid cell granuloma formation, and (3) fibrosis leading to post-inflammatory scarring.⁷³

The clinical course and prognosis of sarcoidosis are largely dependent on the location of granulomatous infiltration. The main organ systems involved by sarcoidosis are the lungs and thoracic lymph nodes, although virtually no organ systems are spared, including the central nervous system and the skin. Intrathoracic involvement occurs in more than 90% of patients.

Among patients with extracardiac sarcoidosis, clinical cardiac involvement occurs in approximately 5%, whereas subclinical cardiac involvement was reported in more than 25% on autopsy and in up to 55% on cardiac imaging studies. Only 40% to 50% of patients with cardiac sarcoidosis at necropsy had clinical evidence of myocardial involvement during their lifetime. Importantly, extracardiac involvement can be minimal or even clinically absent, whereby extensive cardiac sarcoid can be present as the only disease manifestation.

Cardiac sarcoidosis can affect the interventricular septum, RV and LV free walls, and atria. Involvement of the basal septum by scar tissue, granulomas, or the involvement of the nodal artery can lead to various degrees of AV block and intraventricular conduction abnormalities. A recent study primarily implicated inflammation-induced edema in the interventricular septum, rather than fibrosis, in the pathophysiology of AV block. Focal inflammation in the septum (as detected on CMR and positron emission tomography [PET]) was significantly associated with complete AV block, while septal fibrosis and scarring were not.⁷⁴

Atrial involvement is common but tends to be less extensive as compared with ventricular involvement. Atrial disease can precipitate atrial arrhythmias (AF and AT are the most common) as well as sinus node dysfunction (SND).⁷⁵

Involvement of the ventricular myocardium can lead to LV and RV dysfunction and DCM. Two patterns of regional wall motion abnormalities are frequently observed, involving the basal free wall and the anteroapical septum. Mitral valve abnormalities, papillary muscle dysfunction, LV aneurysm formation, and pericardial effusions are also seen. The inflammatory process in cardiac sarcoidosis often is initiated in the myocardium, creating lesions (granulomas) that then extend to the epicardium, endocardium, or both.^{75,76}

Early inflammation and late fibrosis participate in ventricular arrhythmogenesis, one of the hallmarks of cardiac sarcoidosis. Sustained monomorphic VTs are predominantly due to scar-related macroreentry. RV involvement seems to be particularly arrhythmogenic, as the VT substrate preferentially involves confluent regions of endocardial and, more predominantly, epicardial RV scarring. Although some studies suggested predilection of the peritricuspid region or RV apex, a recent report found no predilection for any particular RV region. In contrast to the confluent RV scarring, LV scarring in patients with clinical VTs tends to be patchy, with less epicardial predominance, and with a predilection for the basal septum, anterior wall, and perivalvular regions. The diffuse and heterogeneous ventricular infiltration in cardiac sarcoidosis provides

a substrate potentially capable of sustaining a large number of reentrant VT circuits, explaining the common occurrence of multiple monomorphic VTs and pleomorphic VT in cardiac sarcoidosis. In a small proportion of patients, monomorphic sustained VT seemed to be secondary to a reentrant or nonreentrant mechanism closely associated with a diseased Purkinje system in either ventricle, including bundle branch reentry.⁷⁵⁻⁷⁷

Myocardial inflammation also plays a role in arrhythmogenesis in cardiac sarcoidosis. Triggered activity and abnormal automaticity secondary to inflammation are the likely mechanisms of frequent PVCs in these patients. Further, active inflammation can potentially promote macroreentrant VT either by increasing the frequency of triggers (i.e., PVCs) or by slowing conduction in diseased tissue within granulomatous scar.^{75,79}

Epidemiology and Natural History

The estimated annual incidence of sarcoidosis is about 5 to 64 per 100,000. The incidence varies greatly by ethnicity and region, with the highest rates occurring in northern Europeans and African Americans, particularly in women. Sarcoidosis occurs at all ages, with peak incidence in young adults (25 to 45 years).^{75,80}

Patients with cardiac sarcoidosis have a much worse prognosis than patients without cardiac involvement. In fact, progressive HF and malignant ventricular arrhythmias account for up to 77% of deaths due to sarcoidosis. However, the prognosis in cardiac sarcoidosis is highly variable, with 5-year survival rates ranging from 60% to 90%. Prior to the use of ICDs, SCD accounted for approximately 25% to 65% of deaths caused by cardiac sarcoidosis. LV dysfunction and deterioration in HF symptoms were found to be independent predictors of mortality.⁷⁵ The prognosis of clinically silent cardiac sarcoidosis has not been well defined. Progression to end-stage HF or intractable ventricular arrhythmias is observed in some patients despite optimal therapy. Ventricular assist devices or cardiac transplantation may be required.

Clinical Presentation

Clinical manifestations of cardiac sarcoidosis are highly variable and dependent on the location, extent, and activity of the disease. Patients with cardiac sarcoidosis can present with (1) AV and intraventricular conduction abnormalities, (2) ventricular arrhythmias, (3) supraventricular arrhythmias, (4) congestive HF, and (5) sudden death.⁷³

Biventricular HF is the most common clinical feature of cardiac sarcoidosis. Papillary muscle involvement can result in severe mitral regurgitation. Complete AV block can be observed in up to 30% of patients, whereas various types of intraventricular conduction disturbances (IVCDs) occur in up to 61%. Approximately 50% of patients with cardiac sarcoidosis require treatment for ventricular arrhythmias. These patients usually have multiple monomorphic VTs, with either RBBB or LBBB morphology.⁷⁵ Atrial arrhythmias can be observed in up to one-third of patients with clinical cardiac sarcoidosis, with AF and AT being the most common. Both reentrant and nonreentrant ATs can be observed.

In some patients, cardiac symptoms can be the first presentation of sarcoidosis from any organ. Studies have found that up to 19% of young adults (less than 55 years old) presenting with AV block of unknown etiology, and up to 28% of patients presenting with unexplained monomorphic VT (without idiopathic VT, ischemic VT, or known sarcoidosis) had cardiac sarcoidosis. AV block was observed in the majority of that latter cohort of patients.⁸¹ Furthermore, cardiac sarcoidosis has been reported to represent 5% to 17% of unexplained nonischemic cardiomyopathy patients referred for management of ventricular arrhythmias.⁸²

Initial Evaluation

The diagnosis of cardiac sarcoidosis should be considered in patients with biopsy-proven extracardiac sarcoidosis, with or without cardiac symptoms. Initial evaluation includes ECG and echocardiography. The presence of suggestive cardiac symptoms or abnormal findings on ECG or echocardiography should prompt additional cardiac studies (CMR and PET).⁷⁵

In the absence of previous diagnosis of extracardiac sarcoidosis, screening for cardiac sarcoidosis should be considered in young patients (less than 60 years) with unexplained Mobitz II or third-degree AV block, in those with unexplained monomorphic VT, and in those with unexplained nonischemic cardiomyopathy presenting with ventricular arrhythmias (Box 25.2).^{75,82} Initial testing typically includes a computed tomographic scan of the chest for pulmonary sarcoid and advanced cardiac imaging (CMR or PET). Abnormal findings on those tests should prompt definitive histological diagnosis.⁷³

Electrocardiography

The sinus rhythm surface ECG commonly exhibits BBB (RBBB in particular), QRS complex fragmentation, atrial or ventricular ectopy, or some degree of AV block. Unexplained pathological Q waves (pseudo-infarct patterns) can be observed in localized myocardial infiltration.⁷⁵

The QRS morphology during monomorphic VT varies according to the origin of the tachycardia. The majority of VTs in cardiac sarcoidosis originate from the RV and hence manifest a LBBB pattern on

BOX 25.2 Heart Rhythm Society Expert Consensus Recommendations on Criteria for Diagnosis of Cardiac Sarcoidosis

There are two pathways to a diagnosis of CS:

1. Histological diagnosis from myocardial tissue

CS is diagnosed in the presence of noncaseating granuloma on histological examination of myocardial tissue with no alternative cause identified (including negative organismal stains, if applicable).

2. Clinical diagnosis from invasive and noninvasive studies

It is probable that there is CS if:

a. There is a histological diagnosis of extracardiac sarcoidosis

and

b. One or more of the following is present:

1. Steroid ± immunosuppressant-responsive cardiomyopathy or heart block
2. Unexplained LVEF <40%
3. Unexplained sustained (spontaneous or induced) ventricular tachycardia
4. Mobitz type II second- or third-degree heart block
5. Patchy uptake on dedicated cardiac FDG-PET (in a pattern consistent with CS)
6. LGE on CMR (in a pattern consistent with CS)
7. Positive gallium uptake (in a pattern consistent with CS)

and

c. Other causes for the cardiac manifestation(s) have been reasonably excluded

CMR, Cardiovascular magnetic resonance; CS, cardiac sarcoidosis; FDG-PET, fluorodeoxyglucose-positron emission tomography; LGE, late gadolinium enhancement; LVEF, left ventricular ejection fraction.

From Birnie DH, Nery PB, Ha AC, Beanlands RSB. Cardiac sarcoidosis. *J Am Coll Cardiol*. 2016;68:411-421.

the surface ECG. When VT is the first manifestation of sarcoidosis, VT morphology on the surface ECG can mimic VTs observed in patients with ARVC. One report suggested that a reduced LVEF should raise suspicion of cardiac sarcoidosis, even if ARVC diagnostic criteria are fulfilled. As compared with patients with ARVC, patients with cardiac sarcoidosis tend to have a significantly lower mean LVEF, significantly wider QRS complexes, and more different morphologies of inducible monomorphic VT, which originated more commonly in the apical region of the RV.^{83,84}

In addition, VT in cardiac sarcoidosis can occur in the absence of structural heart disease on echocardiography, in which case it can be misdiagnosed as idiopathic VT. Unlike idiopathic VT, significant variations in the TCL and pleomorphism (i.e., VT with more than one morphologically distinct QRS complex occurring during the same episode of VT, but the QRS not continuously changing) is commonly (in about 50% of cases) observed in cardiac sarcoidosis. Although pleomorphic VT is not pathognomonic of cardiac sarcoidosis and can be observed in other structural heart diseases (e.g., MI, HCM, DCM, ARVC), it is rare in idiopathic VT. Therefore the presence of this feature in a structurally normal heart on echocardiogram and in the absence of coronary artery disease should raise the suspicion for cardiac sarcoidosis.⁸⁵

Echocardiography

About 14% to 56% of the patients with cardiac sarcoidosis have detectable abnormalities on echocardiogram, such as LV or RV systolic dysfunction, wall-motion abnormalities (often in a noncoronary distribution), ventricular aneurysm, or basal septum thinning. Early stages of the disease may not be detected.⁷⁵

Cardiac Magnetic Resonance

CMR is very valuable in the diagnosis of cardiac sarcoidosis. CMR has a high sensitivity (100%) and specificity (78%) for myocardial scar detection in patients with sarcoidosis, with positive and negative predictive values of 55% and 100%, respectively, and an overall accuracy of 83%.⁷³

CMR findings are not pathognomonic for cardiac sarcoidosis, and can vary depending on the stage of the pathological process. Early gadolinium enhancement of sarcoid granulomas in CMR T2-weighted images suggests the presence of acute inflammation-induced edema, whereas delayed enhancement can assess the presence, extent, and distribution of myocardial fibrosis or scar (Fig. 25.7). CMR imaging with delayed enhancement can sometimes detect the granular cells, which resemble clumps of sand or salt grains, and help regionalize the disease process. Patchy regions of myocardial fibrosis are the most common findings on CMR, but confluent areas of scar (mimicking MI) can occasionally be observed.⁷⁵

Positron Emission Tomography

The uptake of fluorine-18 fluoro-2-deoxyglucose (18-FDG) PET appears to detect the inflammatory activity in cardiac sarcoidosis with a slightly higher sensitivity than CMR, but with a slightly lower specificity. In addition, PET can be particularly useful in patients with a pacemaker or ICD who are unable to undergo CMR. PET and CMR imaging allow visualization of different aspects of cardiac sarcoidosis and can have a complementary role (see Fig. 25.7). Cardiac sarcoidosis typically manifests with focal (patchy) uptake either in isolation or on a background of mild diffuse uptake with or without resting perfusion defects and

Fig. 25.7 Cardiac Magnetic Resonance (CMR) and Positron Emission Tomography (PET) Imaging in Cardiac Sarcoidosis. Top row, CMR images in 4-chamber (A), short-axis (B), and 2-chamber (C) orientations showing three-dimensional (3-D) late gadolinium enhancement (LGE) scar imaging. Arrows indicate regions of abnormal LGE, consistent with mature scar. Bottom row (D–F), shows 3-D LGE images with fusion of fluorodeoxyglucose-PET signal, suggestive of active inflammation surrounding regions of established scar. (From Birnie DH, Nery PB, Ha AC, Beanlands RS. Cardiac sarcoidosis. *J Am Coll Cardiol*. 2016;68:411–421.)

wall motion abnormalities. Importantly, PET findings are not pathognomonic for cardiac sarcoidosis, and should be interpreted in the appropriate clinical context.⁷⁵

Histological Examination

Cardiac sarcoidosis can only be confirmed by histological examination of cardiac tissue. However, endomyocardial biopsy is generally not required, and myocardial involvement can be diagnosed by noninvasive cardiac imaging, if sarcoidosis has already been demonstrated histologically in another organ and other causes for the cardiac manifestations have been reasonably excluded. Nevertheless, tissue examination showing noncaseating granulomas (in the absence of any other identifiable cause such as tuberculosis) is required in those patients with features suggestive of cardiac sarcoidosis but no prior diagnosis of pulmonary/systemic sarcoidosis.⁷⁵

Biopsies should first be obtained from the most accessible lesion that appears to be affected (e.g., cutaneous lesions or palpable lymph nodes), and then lung or intrathoracic lymph nodes are typically targeted if radiographic and CT abnormalities are detected. In cases of isolated cardiac sarcoidosis or negative extracardiac biopsy, endomyocardial biopsy may be considered to confirm the diagnosis. However, endomyocardial biopsy has very limited sensitivity (less than 25%) due to the focal and patchy nature of cardiac sarcoidosis. To increase the yield, low voltage areas on electroanatomic voltage mapping or affected myocardial segments identified on PET or CMR are targeted by the biopsy.^{73,75}

Electrophysiological Testing

EP testing may be considered in patients with documented or suspected cardiac arrhythmias, when catheter ablation is contemplated. EP study may also be considered in patients with syncope and those with first-degree AV block or fascicular block to define levels of conduction system disease and guide pacing therapy. EP testing may also be of value for SCD risk stratification.⁷⁵

Risk Stratification

Left Ventricular Ejection Fraction

Reduced LVEF is an independent predictors of mortality and appropriate ICD therapy in ICD recipients for primary or secondary prevention. Even mild degrees of LV systolic dysfunction (LVEF of 35% to 49%) predict a substantial risk of arrhythmia. In one study, a large proportion of primary and secondary prevention ICD recipients who received appropriate ICD therapies had an LVEF of greater than 35%. In contrast, none of the primary prevention ICD recipients with normal RV and LV function received an appropriate therapy.⁷⁵

Electrophysiological Testing

Invasive EP testing with programmed ventricular stimulation to assess inducibility of sustained ventricular arrhythmias can potentially provide prognostic information in asymptomatic patients with cardiac sarcoidosis. In small series, VT inducibility was associated with increased risk for clinical arrhythmic events (ICD shocks or death), as well as with progressive deterioration of LVEF, especially in patients with reduced LVEF at baseline. A negative EP study appears to predict a benign course within the first several years after diagnosis. Until more data become available, EP testing may be considered for risk stratification in patients with LVEF greater than 35%, despite optimal medical therapy and a period of immunosuppression (if there is active inflammation).⁷⁵

Cardiac Magnetic Resonance

Late gadolinium enhancement on contrast CMR reflects myocardial fibrosis, which represents a potential substrate for ventricular arrhyth-

mias. Fibrosis detected by CMR is evident in 20% to 30% of patients with extracardiac sarcoidosis. Several studies showed a direct correlation between the presence of myocardial scar and arrhythmic events, with a high negative predictive value in patients with cardiac sarcoidosis; however, these findings have not been consistent in all studies. Despite the limitations of the current data, CMR may be considered for the purpose of SCD risk stratification, particularly in patients chronic LVEF above 35%.⁷⁵

Positron Emission Tomography

Small studies correlated the presence and extent of active myocardial inflammation identified on PET with increased risk of SCD and sustained VT, likely related to disease activity and increased risk of progression. However, the utility of PET for SCD risk stratification is still uncertain.

Syncope

Syncope in patients with cardiac sarcoidosis can be a clinical marker for either ventricular arrhythmias or bradyarrhythmias, and was found to predict higher risk of arrhythmic events (ICD shocks) in ICD recipients.⁸⁶

Complete Heart Block

Advanced AV block was found to be a significant predictor of appropriate ICD therapy. Advanced conduction disease is likely to be a surrogate marker for more extensive myocardial involvement and hence higher risk of ventricular arrhythmias.⁸⁶

Management

Immunosuppression

Although data are limited, immunosuppressive therapy is commonly utilized in patients with active cardiac sarcoidosis. Early initiation of therapy to control inflammation, before the development of advanced clinical manifestations, can potentially help prevent extensive fibrosis, retard disease progression, and improve survival. However, the true benefit of immunosuppressive therapy on the disease course and outcome remains to be evaluated. Also, the timing, dose, and duration of treatment remain uncertain.⁸⁰

Corticosteroids are the primary immunosuppressive therapy, with gradual tapering over a period of months until establishing a minimum effective maintenance dose. Other immunosuppressants (e.g., infliximab, methotrexate, azathioprine) are frequently utilized to help reduce the dose or duration of steroid therapy.⁷³

Management of Conduction Abnormalities

In addition to the conventional recommendations for management of AV block (discussed in **Chapter 9**), pacemaker implantation can be useful in patients with cardiac sarcoidosis with an indication for pacing even if the AV block reverses transiently. In these patients, since AV block likely signifies extensive cardiac disease and portends a higher risk of future ventricular arrhythmias, implantation of an ICD implantation (for the primary prevention of SCD) instead of a pacemaker needs to be considered, regardless of LVEF or prior occurrence of ventricular arrhythmias.^{74,75,86}

Immunosuppression results in improvement in AV conduction in almost half of patients with cardiac sarcoidosis presenting with advanced AV block. Focal inflammation (detected on CMR and PET) with preserved wall thickness in the interventricular septum (suggesting the lack of significant scarring) might predict recovery of AV conduction after corticosteroid therapy. However, even in the setting of positive response to medical therapy, ICD or pacemaker implantation is recommended because reversibility is unpredictable. Since immunosuppression

can potentially increase the risk of device infection and impair wound healing, it may be prudent to postpone immunosuppression until after device implantation and complete wound healing.⁷⁵

Management of Atrial Arrhythmias

For patients with symptomatic AF, beta-blockers, calcium-channel blockers, sotalol, dofetilide, and amiodarone can be considered. Also, a trial of immunosuppression can be useful in some. Given the frequent presence of myocardial scarring, class I agents are not recommended. Anticoagulation is recommended in patients with cardiac and AF if there is sufficiently high risk, as determined by CHA₂DS₂-VASc score. The role of catheter ablation has not been well defined. On the other hand, catheter ablation may be considered in patients with focal or reentrant ATs. These arrhythmias are typically related to atrial scarring identified on electroanatomic mapping.⁷⁵

Management of Ventricular Arrhythmias

Pharmacological therapy. Active inflammation can precipitate frequent PVCs and promote VT and exacerbation of electrical storm. Thus a trial of immunosuppression therapy with corticosteroids, alone or in combination with antiarrhythmic drug therapy, is often utilized to suppress symptomatic ventricular arrhythmias or electrical storm. Immunosuppression is likely to be beneficial for ventricular arrhythmias in the early (inflammatory) phase of cardiac sarcoidosis or when active inflammation is observed on cardiac imaging studies. When antiarrhythmic drug therapy is required, amiodarone and sotalol are the most widely utilized. Ventricular arrhythmias can be refractory to a combination of steroids and antiarrhythmic drugs in about 35% to 50% of patients.^{77,86}

Catheter ablation. Catheter ablation is typically considered in patients with incessant VT, electrical storm, or frequent ICD discharges refractory to immunosuppressive and antiarrhythmic therapy. Ablation can be effective in eliminating or markedly reducing VT burden, with success rates ranging from 25% to 70%, depending on the location of the reentrant circuit. Efficacy is more limited in patients with advanced LV dysfunction. Importantly, because of the future risk of life-threatening arrhythmias, catheter ablation is not a substitute for an ICD, even when excellent short-term results are achieved.^{76,77,87}

Sustained monomorphic VTs in patients with cardiac sarcoidosis are predominantly secondary to scar-related macroreentry involving confluent regions of RV endocardial and epicardial scarring (with no predilection for any particular RV region) and patchy endocardial LV scarring (with a predilection for the septum, anterior wall, and perivalvular regions; Fig. 25.8). The techniques for mapping and ablation of VT in these patients are similar to those described for patients with nonischemic DCM. QRS morphology during VT can be used to regionalize the site of origin of the VT. Most VTs are commonly localized to the scar areas in the RV. Since the scar formation in cardiac sarcoidosis is patchy and can be intramural or epicardial, both endocardial as well as epicardial approaches to ablation may be required. Multiple, monomorphic VTs are commonly observed in cardiac sarcoidosis.⁷⁶ Preprocedural evaluation of the extent and distribution of myocardial scarring by CMR can be of particular value.⁷⁵⁻⁷⁷

In a small proportion of patients, monomorphic sustained VT can be secondary to a reentrant or nonreentrant mechanism closely associated with a diseased Purkinje system in either ventricle (including bundle branch reentry), as evidenced by the finding that Purkinje potentials were observed during sinus rhythm and always preceded VT-QRS onset by at least 20 milliseconds at the successful ablation site. Those VTs tend to have shorter QRS duration (less than 170 milliseconds) as compared with scar-related VT originating elsewhere in the ventricle.⁷⁷

ICD implantation. ICD implantation is recommended for secondary prevention in patients with cardiac sarcoidosis and spontaneous sustained ventricular arrhythmias, including prior cardiac arrest (Fig. 25.9). In addition, prophylactic ICD implantation is recommended in those with LVEF less than 36%, despite optimal medical therapy and a period (3 to 9 months) of immunosuppression (if there is active inflammation). Furthermore, ICD implantation can be useful for primary prevention in patients with LVEF greater than 35% and (1) unexplained syncope or near-syncope, felt to be arrhythmic in etiology; (2) inducible sustained monomorphic or polymorphic VT or clinically relevant VF; or (3) an indication for permanent pacemaker implantation. Prophylactic ICD implantation may also be considered in patients with late gadolinium enhancement on CMR (even if LVEF is normal). In the latter group, invasive EP testing may be of value for further risk stratification.⁷⁵

When clinically feasible, it is prudent to perform ICD implantation when immunosuppressive therapy is at the lowest possible maintenance dose or temporarily withheld.⁷⁵

Cardiac sarcoidosis patient cohorts appear to have more frequent appropriate ICD therapies (approximately 15% per year) than other populations, not only in patients with secondary prevention devices but also in those with an ICD implanted for primary prevention. The annual rate of inappropriate ICD shocks (most commonly secondary to atrial arrhythmias) is about 4.1% to 5.7%.^{75,88,89}

CHAGAS CARDIOMYOPATHY

Pathophysiology

Chagas disease is caused by a unicellular parasite, *Trypanosoma cruzi*. Chronic Chagas heart disease, the most serious manifestation of Chagas disease, is an inflammatory form of DCM. Although the mechanism of the chronic myocarditis remains uncertain, parasite persistence in cardiac tissue, immune-mediated myocardial injury, and microvascular disturbances likely play a role.⁹⁰

The panmyocarditis of Chagas heart disease progressively involves the various cardiac tissues and results in extensive myocardial fibrosis. When the extent of myocardial damage is severe, the disease manifests as myocardial dysfunction that may be segmental, typically a ventricular aneurysm, or global, resembling a DCM. The LV is generally affected more frequently and earlier than the RV.⁹¹

Myocardial damage can occur in various areas of both ventricles, but the inferolateral segment of the LV is the most commonly involved site, with frequently observed wall motion abnormalities. Apical, septal, and inferoapical aneurysms can be observed in 8.5% of asymptomatic patients with mild cardiac damage and in 45% of patients with LV systolic dysfunction and HF. The classic lesion of Chagas disease is a localized aneurysm of the LV apex, with relatively normal surrounding wall motion. This results in a narrow neck when visualized by echocardiography or ventriculography; when present, this can usually distinguish an aneurysm of Chagas heart disease from one due to coronary artery disease.⁹¹

On histological examination, chronic chagasic cardiomyopathy is characterized by a focal, diffuse inflammatory process that results in cell death and severe reparative fibrosis. Myocardial fibrosis is focal and diffuse, predominantly subepicardial, interspersed with viable but often damaged myocardial fibers. VT can arise from various regions in both ventricles, but LV inferolateral scar is the main source of sustained VT reentrant circuits. In these areas, endocardial mapping frequently shows fragmented and late potentials during sinus rhythm, as well as continuous or diastolic activity during VT. Epicardial VT reentrant circuits occur frequently in Chagas cardiomyopathy; approximately 70% of VTs have epicardial sources.⁹¹

Fig. 25.8 Catheter Ablation of Scar-Related Ventricular Tachycardia in Cardiac Sarcoidosis. (A) Positron emission tomographic (PET) scan showing active inflammation of the whole inferior septum (red arrowheads) and anterolateral wall (red arrows). (B) Contrast-enhanced magnetic resonance imaging of the same patient showing diffuse myocardial scar involving the basal inferior septum (green arrowhead), the septal apex (asterisk), and the anterolateral wall (green arrows). (C–F) Left ventricular (LV) endocardial (Endo) electroanatomic map (EAM) showing a low bipolar voltage area (≤ 1.5 mV) on the basal septum (C, right anterior oblique [RAO] view; E, modified posteroanterior view) and a more diffuse area of low unipolar voltage (≤ 8.3) on the midbasal septum and anterolateral wall (D, RAO view; F, modified posteroanterior [PA] view). EAM shows areas of abnormal voltage largely superimposable with both scar and inflammation particularly at midbasal wall level. Red dots represent ablation lesions. LGE, Late gadolinium enhancement. (From Muser D, Santangeli P, Pathak RK, et al. Long-term outcomes of catheter ablation of ventricular tachycardia in patients with cardiac sarcoidosis. *Circ Arrhythm Electrophysiol.* 2016;9:e004333.)

Diffuse fibrosis of the conduction system often results in bundle branch and fascicular block, different grades of AV block, and SND.⁹² Chagas disease is also associated with cardiac autonomic denervation secondary to inflammation and autoantibodies against cholinergic and adrenergic receptors, which can potentially promote arrhythmogenesis.⁹¹

Epidemiology and Natural History

Chagas disease (American trypanosomiasis) is a vector-borne infection that is endemic in 21 continental Latin American countries (from

southern United States to the north of Argentina and Chile), where 10 to 20 million people are infected and nearly 100 to 120 million are at risk of contracting the disease. The prevalence of Chagas disease in endemic areas is in the range of 1% to 6%, with 300,000 new cases being reported each year.⁹⁰

Chagas disease had attracted little attention outside endemic areas, and many cases of Chagas cardiomyopathy likely remain undiagnosed or are misdiagnosed as idiopathic DCM. However, recent patterns of emigration from endemic countries have drastically altered the

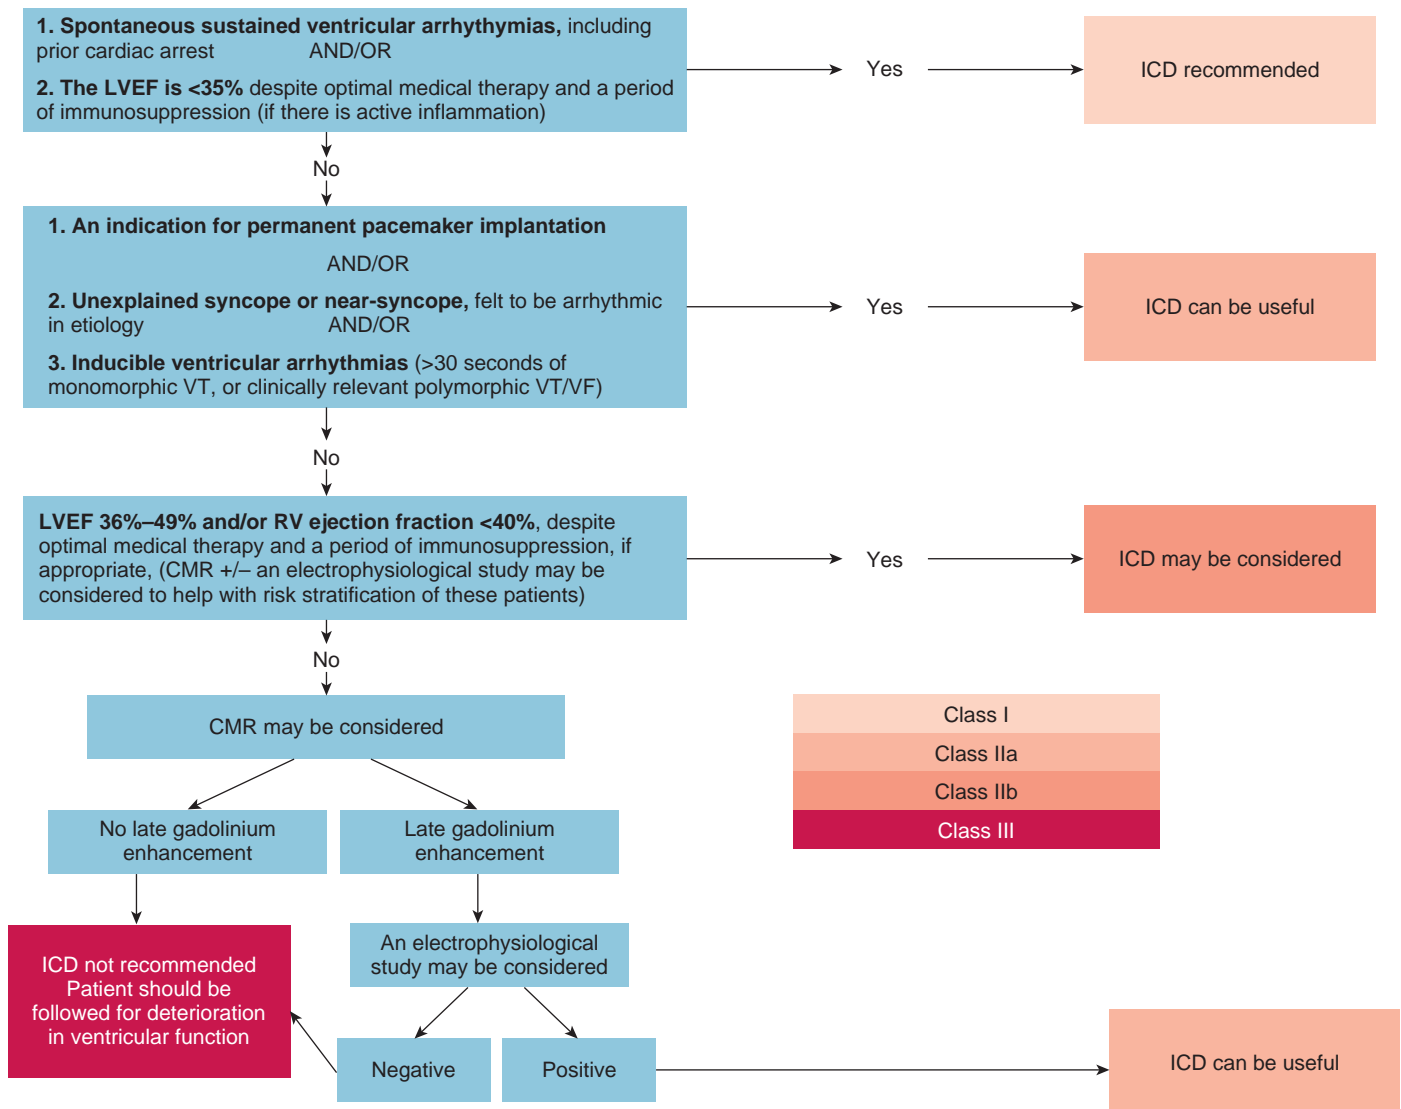

Fig. 25.9 Heart Rhythm Society Expert Consensus Recommendations for Implantable Cardioverter-Defibrillator (ICD) Implantations in Patients Diagnosed With Cardiac Sarcoidosis. *CMR*, Cardiovascular magnetic resonance; *LVEF*, left ventricular ejection fraction; *RV*, right ventricle; *VF*, ventricular fibrillation; *VT*, ventricular tachycardia. (From Birnie DH, Sauer WH, Bogun F, et al. HRS expert consensus statement on the diagnosis and management of arrhythmias associated with cardiac sarcoidosis. *Heart Rhythm*. 2014;11:1305–1323.)

epidemiology of this disease in the United States and other nonendemic regions. It is estimated that there are more than 300,000 immigrants living in the United States infected with *T. cruzi*. Of these, 30,000 to 45,000 have clinical manifestations of Chagas cardiomyopathy, and the estimated index of underdiagnosis is around 95%.^{90,91,93}

In endemic areas, *T. cruzi* infection is acquired most commonly during childhood and young adulthood, primarily through parasite-laden secretions from bloodsucking insects (triatomine). The triatomine vectors are only found in the Americas. Oral transmission through food or drink contaminated with triatomine feces also has been described. Other modes of transmission that do not involve insect vectors include transfusion of contaminated blood products, organ transplantation, and vertical transmission (from mother to child at birth). The non-vectorial modes of transmission are most prominent in nonendemic countries.

The natural history of Chagas disease is characterized by successive stages of disease progression. The acute phase of Chagas disease is most often asymptomatic but can manifest nonspecific symptoms and signs (e.g., fever, inflammation at the inoculation site, lymphadenopathy, and hepatosplenomegaly). Less than 1% to 5% of patients develop acute myocarditis, pericardial effusion, or meningoencephalitis, which can be fatal in some cases.

The acute phase usually resolves spontaneously within a few weeks, and most patients, if left untreated, enter into a lengthy “indeterminate” form of Chagas disease that is defined by the presence of positive serologic tests but no clinical evidence of heart or visceral involvement. The indeterminate phase persists indefinitely in about half of infected patients and does not adversely impact prognosis or life expectancy. However, 30% to 40% of infected patients ultimately develop chronic symptomatic disease (cardiac or digestive), which typically develops 10

BOX 25.3 Clinical Stages of Chronic Chagasic Cardiomyopathy

Stage A

- Patients with “indeterminate form,” without present or previous symptoms of heart failure, without structural heart disease (normal ECG and chest x-ray). As long as the patient remains in this form of the disease, prognosis is not compromised.

Stage B

- Patients with structural heart disease, who have never had signs or symptoms of heart failure. This stage is divided into:
 - B1: Patients with ECG changes (arrhythmias or conduction disorders) may have mild echocardiographic abnormalities (such as abnormalities of regional contractility), but global ventricular function is normal
 - B2: Patients with global ventricular dysfunction (decreased LV ejection fraction)

Stage C

- Patients with LV dysfunction and prior or current symptoms of heart failure (NYHA I, II, III, and IV)

Stage D

- Patients with symptoms of heart failure at rest, refractory to maximized medical therapy (NYHA IV), requiring specialized and intensive interventions

ECG, Electrocardiogram; LV, left ventricle; NYHA, New York Heart Association.

From Andrade JP, Marin Neto JA, Paola AA, et al. I Latin American Guidelines for the diagnosis and treatment of Chagas' heart disease: executive summary. *Arq Bras Cardiol.* 2011;96:434–442.

to 30 years after acute infection. New ECG abnormalities or evidence of definite cardiomyopathy develop in 1.8% to 5% of patients each year. Cardiac and gastrointestinal involvement seldom (in 5% to 20% of patients) present together. A direct progression from acute infection to any clinical form of Chagas disease occurs in just 5% of cases.⁹¹

The natural history and the type of cardiac involvement can vary widely in patients with Chagas disease. Patients with Chagas cardiomyopathy have worse long-term outcomes than patients with non-Chagas cardiomyopathy. Chagas cardiomyopathy results in approximately 50,000 deaths per year. Of these, 60%, 25%, and 15% are related to SCD, HF, and stroke, respectively.

Chagasic damage to the myocardium is generally a progressive process and has been classified into clinical stages (Box 25.3). Importantly, SCD can occur at any time during the evolution of the disease and can be related to ventricular arrhythmia, AV block, stroke, or refractory HF.⁹³

Clinical Presentation

Patients with Chagas cardiomyopathy can present with a wide variety of clinical manifestations; the most important of these are ventricular arrhythmias, sudden death, congestive HF, thromboembolism, and AV block.

The most common initial manifestations include ECG abnormalities (RBBB, LAF block, PVCs) and echocardiographic abnormalities (segmental ventricular wall motion abnormalities, diastolic dysfunction). Disease progression is associated with worsening conduction system abnormalities (AV block, SND), LV systolic dysfunction (DCM, congestive HF, ventricular aneurysms), complex ventricular arrhythmias, and thromboembolism.⁹²

Thromboembolic events, including cardioembolic stroke, are relatively common in Chagas cardiomyopathy, with an annual incidence of 1% to 2%. The incidence is higher in patients with advanced HF,

apical aneurysm, and LV mural thrombosis. Also, pulmonary thromboembolism can occur, predominantly in patients with HF and those with mural thrombosis in the right heart chambers.

VT in Chagas disease can have heterogeneous presentations. SCD, usually due to VF and VT, is the most common cause of death, occurring more often than in other types of DCM, with an incidence ranging from 51% to 65%. Frequently the arrhythmic episodes are clustered in short periods, causing electrical storms (“chagasic storm”). Ventricular ectopy is remarkably frequent in all stages of the disease, even when there is no other evidence of cardiac involvement.

Initial Evaluation

Electrocardiography

ECG abnormalities are often the first indicator of Chagas heart disease. RBBB and LAF block are the most common ECG findings. In fact, the pattern of RBBB and LAFB in patients with cardiomyopathy of unknown etiology and epidemiologic risk factors should raise the possibility of Chagas disease and prompt specific diagnostic testing. Unlike other types of DCM, LBBB and left posterior fascicular block are rare in Chagas cardiomyopathy. PVCs, repolarization abnormalities, abnormal Q waves, various degrees of AV block, SND, and low QRS voltage can be observed on the surface ECG.

Ambulatory Cardiac Monitoring

On Holter monitoring, the burden of PVCs is usually high and temporally unvarying, with patients often having tens of thousands of ectopic beats per day. Nonsustained VT is observed on ambulatory monitoring in 10% of patients with mild wall motion abnormalities, in 56% of those with severe wall motion abnormalities or aneurysms without HF, and in 87% of those with advanced congestive HF. Ambulatory cardiac monitoring may also reveal varying degree AV block, sinus bradycardia, and sinus pauses.^{93,94}

Echocardiography

Echocardiography allows evaluating ventricular systolic and diastolic function, chamber size, and wall motion, as well as the presence of aneurysms or cavity thrombus. Echocardiographic findings can vary depending on the stage of the pathological process. Early evidence of cardiac involvement can manifest as isolated segmental inferior or apical LV wall motion abnormalities (with preserved global systolic function). Ventricular dilatation with diffuse hypokinesia and mitral and tricuspid insufficiency are observed in advanced stages. Ventricular aneurysms (predominantly LV apical) are observed in approximately half of patients with moderate to severe cardiac impairment, but also may be present in up to 9% of asymptomatic patients.^{91,93}

Cardiac Magnetic Resonance

CMR is valuable for evaluating chamber size and function. Furthermore, CMR with delayed enhancement can assess the presence and extent of myocardial fibrosis, which correlates well with disease stage and prognosis. Myocardial fibrosis on CMR is observed in 20% of patients without clinical cardiac involvement, 85% of those with clinical cardiac involvement, and 100% of those with VT. Furthermore, the extent of fibrosis increases across the three groups (0.9%, 16%, and 25% of LV mass, respectively). CMR allows early detection of myocardial involvement unrecognized by ECG and echocardiography.⁹¹

Serologic Testing

Diagnosis of chronic infection relies on serological testing based on detection of antibodies against the *T. cruzi*. Given the low parasitemia in the chronic phase of the disease, parasitological examinations are not routinely used.⁹³

Fig. 25.10 Algorithm for Risk Stratification in the Chronic Phase of the Chagas Disease. FC, Functional class; LVEF, left ventricular ejection fraction; NSVT, nonsustained ventricular tachycardia; NYHA, New York Heart Association. (From Andrade JP, Marin Neto JA, Paola AA, et al. I Latin American Guidelines for the diagnosis and treatment of Chagas' heart disease: executive summary. *Arq Bras Cardiol.* 2011;96:434–442.)

Electrophysiological Testing

Invasive EP testing can be considered in patients with documented or suspected cardiac arrhythmias, when catheter ablation is contemplated. Sustained VT is inducible with programmed ventricular stimulation in most patients who present with sustained ventricular arrhythmias and in half of those who have symptomatic nonsustained VT. EP testing in asymptomatic patients with cardiac involvement has shown that SND is present in 18%, pacing-induced AV block in 41%, and multiple sites of conducting system dysfunction often coexist.⁹³

Risk Stratification

Predictors of poor prognosis include LV systolic dysfunction, NYHA class III/IV, and cardiomegaly on chest x-ray. In patients with LV dysfunction or HF, the presence of NSVT on Holter monitoring also predicts a higher risk for sudden death (Fig. 25.10). Aneurysms are predictors of mural thrombus and stroke; however, their association with the risk of death is uncertain.⁹³

Management

The treatment of Chagas disease involves (1) parasite-specific therapy; (2) HF management; and (3) management of cardiac arrhythmias.

Antiparasitic therapy is indicated for patients with acute infection. The value of antitrypanosomal treatment in the management of chronic disease remains uncertain; however, current evidence indicates no apparent benefit from treating patients with established Chagas cardiomyopathy.⁹⁵

Management of Chagas cardiomyopathy and HF follows the standard recommendations for treatment of HF due to other conditions. Cardiac transplantation is considered in patients with advanced HF.

Ventricular tachyarrhythmias in the setting of Chagas disease are very difficult to treat. Antiarrhythmic drug therapy is frequently ineffective. Limited data exist on the catheter ablation of VTs associated with Chagas cardiomyopathy. Success rates are limited when only endocardial mapping and ablation techniques are used. Epicardial ablation has been shown to improve outcome and should be considered in these cases, perhaps as the initial ablation strategy. Despite the lack of strong evidence, the recommendations for ICD implantation for primary and secondary prevention follow criteria extrapolated from those used for patients with idiopathic DCM. Of note, the incidence of appropriate ICD therapies and sustained ventricular tachyarrhythmias in Chagas patients with ICDs (for primary or secondary prevention indications) is higher than in those with non-Chagas cardiomyopathy.^{96,97}

Similarly, the indications of pacing therapy for symptomatic bradyarrhythmias follow the same guidelines as for non-Chagas patients with AV block or SND.

Because of the high incidence of thromboembolic phenomena, oral anticoagulants are recommended for patients with AF, previous embolism, and apical aneurysm with thrombus.

PATHOPHYSIOLOGY

Bundle branch reentrant (BBR) ventricular tachycardia (VT) is a reentrant VT with a well-defined reentry circuit, incorporating the right bundle branch (RB) and left bundle branch (LB) as obligatory limbs of the circuit, connected proximally by the His bundle (HB) and distally by the ventricular septal myocardium (Fig. 26.1). Fascicular reentry is very uncommon (see below). The QRS during BBR VT can display either left bundle branch block (LBBB) or right bundle branch block (RBBB) when anterograde ventricular activation occurs over the RB or LB, respectively. The vast majority of BBR VTs exhibit LBBB configuration (“counterclockwise” BBR), whereby the reentrant wavefront propagates anterogradely down the RB, crosses the septum, and then travels retrogradely up the LB. In clockwise BBR, the reentrant wavefront propagates in the opposite direction, and ventricular activation occurs via anterograde conduction over the LB, resulting in a RBBB pattern.^{1,2}

Single BBR beats can be induced in up to 50% of patients with normal intraventricular conduction undergoing electrophysiological (EP) study. The QRS during BBR typically exhibits LBBB pattern, although an RBBB pattern (clockwise BBR) can rarely be induced by right ventricular (RV) pacing; the latter condition requires that the effective refractory period of the LB be longer than that of the RB, or that retrograde conduction over the RB be resumed after an initial bilateral block in the His-Purkinje system (HPS; i.e., gap phenomenon). Left ventricular (LV) pacing does not seem to increase the yield of induction of BBR with RBBB morphology.^{1,2}

In patients with normal intraventricular conduction, BBR is a self-limited phenomenon. The rapid conduction and long refractory period of the HPS prevent sustained BBR in normal hearts. Spontaneous termination of BBR most commonly occurs in the retrograde limb between the ventricular muscle and the HB. Sometimes, anterograde block can also occur, making refractoriness in the RB-Purkinje system the limiting factor. Continuation of BBR as a tachycardia is critically dependent on the interplay between conduction velocity and recovery of the tissue ahead of the reentrant wavefront. Two changes from normal physiology

must occur for BBR to become sustained: (1) an anatomically longer reentrant pathway caused by a dilated heart, providing sufficiently longer conduction time around the HPS; and (2) slow conduction in the HPS caused by HPS disease. These two factors are responsible for sufficient prolongation of conduction time to permit expiration of the refractory period of the HPS ahead of the propagating reentrant wavefront.¹⁻³

Rarely, self-terminating BBR can occur with a narrow QRS during ventricular extrastimulation (VES) in the setting of normal intraventricular conduction. After retrograde conduction via the left anterior fascicle (LAF) or left posterior fascicle (LPF), anterograde propagation occurs over the RB and the remaining LB fascicle, resulting in a narrow QRS with either LAF or LPF block.

EPIDEMIOLOGY

Sustained BBR VT usually occurs in patients with structural heart disease, especially dilated cardiomyopathy. Idiopathic dilated cardiomyopathy is the anatomical substrate for BBR VT in 45% of cases, and BBR VT accounts for up to 13% to 41% of all inducible sustained VTs in this population. BBR VT can also be associated with cardiomyopathy secondary to valvular or ischemic heart disease, and has been reported with Ebstein anomaly, hypertrophic cardiomyopathy, and even in patients without structural heart disease other than intraventricular conduction abnormalities (and even normal baseline QRS configuration in rare cases).⁴

In patients with spontaneous sustained monomorphic VT, the incidence of inducible BBR VT ranges from 4.5% to 6% in patients with ischemic heart disease to 16.7% to 41% in patients with nonischemic cardiomyopathy. BBR VT accounts for up to 6% of all forms of induced sustained monomorphic VT. Importantly, additional myocardial VTs occur in about 25% of patients presenting with BBR VT.⁵ Of note, BBR VT is more frequently found in patients with VT clusters (up to 12.5%) than in patients with less frequent episodes of VT.⁶ Because the incidence of BBR VT is not trivial, and is imminently curable, it is important for the electrophysiologist to consider it as a possible cause of VT.

Fig. 26.1 Schematic Illustration of the Two Types of Bundle Branch Reentry (BBR) Circuits. At left is the most commonly seen type of BBR ventricular tachycardia (VT). Retrograde conduction occurs via the left bundle branch (LB) and anterograde conduction occurs via the right bundle branch (RB). This yields a VT in which the QRS has a left bundle branch block pattern. At right is the uncommon type of BBR VT. Retrograde conduction occurs via the RB and anterograde conduction occurs via the LB, which yields a VT in which the QRS has an RBBB pattern. AVN, Atrioventricular node; HB, His bundle.

CLINICAL PRESENTATION

Sustained BBR VT is typically unstable secondary to very rapid ventricular rates (often 200 to 300 beats/min) and poor underlying ventricular function; 75% of patients present with syncope or cardiac arrest.

INITIAL EVALUATION

BBR VT should be suspected in the presence of typical QRS morphology on the surface electrocardiogram (ECG) during normal sinus rhythm (NSR) and VT (see later), especially in a patient with dilated cardiomyopathy. Echocardiographic examination and coronary arteriography are required in most patients to evaluate for structural heart disease.

PRINCIPLES OF MANAGEMENT

Pharmacological antiarrhythmic therapy is usually ineffective for BBR VT. On the other hand, RF catheter ablation of a bundle branch (typically the RB) is very successful in eliminating BBR VT and hence is currently regarded as first-line therapy.

As noted, associated myocardial VT occurs in approximately 25% of patients post ablation of BBR VT, and these patients continue to be at a high risk of sudden cardiac death. Therefore implantable cardioverter-defibrillator (ICD) therapy is indicated for secondary prevention, and additional antiarrhythmic therapy is required for some patients. ICD implantation will also provide backup pacing, which is frequently required post ablation secondary to the development of AV block or an excessively prolonged His bundle–ventricular (HV) interval. Implantation of a dual-chamber or biventricular ICD should be considered in these patients.

Because BBR VT has a limited response to antiarrhythmic drugs and can be an important cause of repetitive ICD therapies, catheter ablation of the arrhythmia should always be considered as an important adjunct to the device therapy.

EP testing should be considered in patients with repetitive episodes of VT and dilated cardiomyopathy, history of cardiac valve repair or replacement, or QRS morphology during VT similar to sinus rhythm

QRS. If sustained BBR VT is inducible during programmed stimulation, catheter ablation is recommended.⁶

ELECTROCARDIOGRAPHIC FEATURES

Baseline Electrocardiogram

The baseline rhythm is usually NSR or AF. Almost all patients with BBR VT demonstrate intraventricular conduction abnormalities. The most common ECG abnormality is nonspecific intraventricular conduction defect (IVCD) with an LBBB pattern and PR interval prolongation (Fig. 26.2). Complete RBBB is rare but does not preclude BBR as the mechanism of VT. Although total interruption of conduction in one of the bundle branches would theoretically prevent occurrence of BBR, an ECG pattern of complete BBB may not be an accurate marker of *complete* conduction block; a similar QRS configuration can be caused by conduction delay, rather than block, in the bundle branch. In addition, anterograde block can be present with retrograde conduction. Occasionally, complete AV block may be observed.

Electrocardiogram During Ventricular Tachycardia

Twelve-lead ECG documentation of BBR VT is usually unavailable because the VT is rapid and hemodynamically unstable. The VT rate is usually 200 to 300 beats/min. QRS morphology during VT is a typical BBB pattern and can be identical to that in NSR. BBR VT with an LBBB pattern is the most common VT morphology, and it usually has normal or left axis deviation (see Fig. 26.2). In contrast to VT of myocardial origin, BBR with an LBBB pattern characteristically shows a rapid intrinsicoid deflection in the right precordial leads, suggesting that initial ventricular activation occurs through the HPS and not ventricular muscle. BBR VT with an RBBB pattern usually has a leftward axis, but it can have a normal or rightward axis, depending on which fascicle is used for anterograde propagation.⁴

ELECTROPHYSIOLOGICAL TESTING

Baseline Observations During Normal Sinus Rhythm

Conduction abnormalities in the HPS are almost invariably present and are a critical prerequisite for the development of sustained BBR, regardless of the underlying anatomical substrate (Fig. 26.3). The average HV interval is about 80 milliseconds (range, 60 to 110 milliseconds). Although some patients can have the HV interval in NSR within normal limits, functional HPS impairment in these patients manifests as HV interval prolongation or split HB potentials, commonly becoming evident during atrial programmed stimulation or burst pacing. Nonspecific IVCD with an LBBB pattern and PR interval prolongation are the most common abnormalities.

Induction of Tachycardia

VES from the RV apex is the usual method used to induce BBR with an LBBB pattern. Induction is consistently dependent on the achievement of a critical conduction delay in the HPS (i.e., critical ventricular–His bundle [VH] interval) following the VES.

During RV pacing at a constant PCL and during introduction of VES at relatively long coupling intervals, retrograde conduction to the HB occurs via the RB. At shorter VES coupling intervals, retrograde delay and block occur in the RB when its relative and effective refractory periods are encountered, respectively. When retrograde block occurs in the RB, the impulse propagates across the septum and retrogradely up the LB to the HB, producing a long V₂–H₂ interval. The LB would still be capable of retrograde conduction because of its shorter refractoriness and because of the delay associated with transeptal propagation. Further shortening of the coupling intervals is associated with increasing

Sinus rhythm

Bundle branch reentrant VT

Fig. 26.2 Electrocardiogram of Bundle Branch Reentrant (BBR) Ventricular Tachycardia (VT). (A) Normal sinus rhythm baseline with intraventricular conduction delay resembling left bundle branch block. (B) BBR VT. Note typical-appearing complete left bundle branch block in this rapid VT.

delay in LB conduction (i.e., increasing V_2 - H_2 interval). Within a certain range of coupling intervals, increasing retrograde LB delay allows for the recovery of anterograde conduction via the RB, and another ventricular activation ensues, displaying a wide QRS with an LBBB pattern. This beat is called the “BBR beat” or “ V_3 phenomenon.”

An inverse relationship exists between retrograde conduction delay in the LB (V_2 - H_2 interval) and the time of anterograde conduction in the RB (H_2 - V_3 interval). This is because the faster the impulse propagates

transseptally and up the LB, the more likely it will reach the RB while it is still refractory from the previous retrograde activation (concealment) by the VES, resulting in slower anterograde conduction down the RB.

BBR is more likely to occur when the VES is delivered following pacing drives incorporating long to short CL changes as compared with constant CL drives, because of CL dependency of the HPS refractoriness. An abrupt change in CL (i.e., long to short) can result in a

Fig. 26.3 Bundle Branch Reentrant (BBR) Ventricular Tachycardia (VT) Versus Normal Sinus Rhythm (NSR). Sinus and BBR VT with His, left bundle branch (LB), and right bundle branch (RB) recordings in a patient with a prior septal myocardial infarction. Dashed lines mark the onset of His deflection. During NSR, the His potential is followed first by the LB potential; RB activation is further delayed. The fact that left bundle branch block (LBBB) is present on the electrocardiogram (ECG) suggests that, although the LB is activated prior to the RB, delay is encountered more distally in the left ventricular His-Purkinje system such that LBBB is evident on the ECG. During BBR VT, activation propagates in an LB-His-RB sequence. Retrograde LB activation is very delayed, most likely because of the same factors responsible for the ECG in NSR. *His_{dist}*, Distal His bundle; *LB_{dist}*, distal left bundle branch; *LB_{prox}*, proximal left bundle branch; *RB_{dist}*, distal right bundle branch; *RVA*, right ventricle apical.

more distal site of retrograde block, and less concealment, along the myocardium-Purkinje-RB axis, which can allow sufficient recovery of excitability in the anterograde limb of the circuit (i.e., the RB-Purkinje-myocardium axis) for reentry to develop. In addition, earlier recovery of excitability along this axis, because of the more distal site of block and less concealment, is associated with a shorter H_2 - V_3 interval in this reentrant beat.

Procainamide (which increases conduction time within the HPS, especially in the diseased HPS), and potentially isoproterenol can facilitate induction of sustained BBR. In some patients, the arrhythmia can be inducible only with atrial pacing.

Tachycardia Features

BBR VT can only be definitively diagnosed using intracardiac recordings (Box 26.1); most particularly, HB recordings are essential. Many electrophysiologists do not use a HB recording catheter during VT diagnostic studies and will thus likely miss diagnosing some cases of BBR. AV dissociation is typically present, during the tachycardia, but 1:1 VA conduction can occur. BBR VT is characterized by inscription of the His potential before the QRS complex, with the HV interval during BBR with LBBB pattern generally being similar to or longer than that during baseline rhythm (the HV interval is usually 55 to 160 milliseconds; see Fig. 26.3).¹

The relative duration of the HV interval recorded during VT as compared with NSR would depend on two factors: the balance between anterograde and retrograde conduction times from the upper turnaround point of the reentry circuit, and the site of HB recording relative to the

BOX 26.1 Diagnostic Criteria of Bundle Branch Reentrant Ventricular Tachycardia

- The QRS morphology of the tachycardia shows a typical RBBB or LBBB pattern.
- The onset of ventricular depolarization is preceded by HB and either RB or LB potentials with an appropriate sequence of H-RB-LB activation and relatively stable HV, RB-V, or LB-V intervals.
- Spontaneous variations in V-V intervals are preceded by similar changes in H-H/RB-RB/LB-LB intervals, but the HV interval remains constant.
- The induction of tachycardia during programmed stimulation is consistently dependent on achieving a critical conduction delay in the HPS.
- Tachycardia termination is preceded by a spontaneous or pacing-induced block in the HPS.
- The HV interval during tachycardia is equal to or longer than HV interval during sinus rhythm.
- BBR is noninducible after successful ablation of the RB.
- Entrainment from the RV apex results in manifest fusion and a (PPI – TCL) difference <30 msec.

upper turnaround point (i.e., the HB catheter electrode positioned at the proximal versus distal HB). Conduction delay in the bundle branch used as the anterograde limb of the circuit tends to prolong the HV interval during VT, whereas retrograde conduction delay to the HB recording site, as well as the use of a relatively proximal HB recording site (far from the turnaround point), tend to shorten the HV interval.^{1,2} During NSR, activation of the HB and activation of the bundle branch occur in sequence; hence the HV interval represents a true conduction time from HB depolarization, through the bundle branches, to ventricular myocardium. In contrast, during BBR VT, the HB is activated in the retrograde direction concurrently (in parallel) with the proximal part of the bundle branch serving as the anterograde limb of the reentry circuit. Therefore the HV interval during BBR represents the difference in local activation timing of two points (the HB and the ventricle) being activated in parallel by the reentry wavefront, rather than an actual conduction time from sequential activation of the HB, bundle branch, and ventricle.^{1,2}

Although the HV interval during BBR VT is intuitively expected to be falsely abbreviated and shorter than the “true” HV interval during NSR, this occurs only in rare cases of BBR VT. Two possible mechanisms can potentially explain the longer HV interval during BBR VT: (1) rate-related decremental conduction in the bundle branch used as the anterograde limb of the BBR circuit, and (2) anisotropic conduction in the upper turnaround between the LB and the RB. Both mechanism can result in prolongation of the anterograde conduction times from the upper turnaround point of the reentry circuit to the ventricle, resulting in a longer HV interval during tachycardia than NSR. Furthermore, the recorded His potential might in fact be a RB potential, and hence the measured HV interval actually represents the right bundle-ventricular (RB-V) interval. The RB and ventricle are activated sequentially during both NSR and counterclockwise BBR VT; thus the RB-V interval during BBR VT must always be longer (due to the decremental conduction in the RB during tachycardia) than that during NSR.^{1,7}

Of note, the HV interval during clockwise BBR (RBBB pattern) can be significantly longer than that during NSR (the HV interval is usually

65 to 250 milliseconds). During NSR, the HV interval is usually determined by conduction over whichever bundle branch conducts most rapidly, whereas during BBR with RBBB pattern, it is determined by anterograde conduction over the typically diseased LB.

In the common type of BBR VT (LBBB pattern), the activation wavefront propagates retrogradely up the LB to the HB and then anterogradely down the RB, with subsequent ventricular activation. This sequence is reversed in BBR with an RBBB pattern (Fig. 26.4). The HV and RB-V (during VT with LBBB morphology) or left bundle–ventricular (LB-V) intervals (during VT with RBBB morphology) are relatively stable.¹

During BBR VT, spontaneous variations in the V-V intervals are preceded and dictated by similar changes in the H-H (and RB-RB or LB-LB) intervals. In other words, the tachycardia cycle length (TCL) is affected by variation in the V-H (V-RB or V-LB) intervals. These changes can occur spontaneously, most commonly immediately after induction of the VT, or be demonstrated by ventricular stimulation during VT. However, oscillations in the V-V intervals can occasionally precede those of the H-H intervals during BBR VT because of conduction variations in the anterograde, rather than the retrograde, conducting bundle branch.⁵

Because the breakout of the RBB is near the RV apex, an electrode catheter at this site should record an electrogram very close to the onset of the QRS in BBR VT and serve as a good site for entrainment. Thus an effort should be made to place the RV catheter close to the apex. In patients who have an ICD with an RV apical lead position, a clue to the diagnosis of BBR VT is that (1) the timing of the bipolar ventricular electrogram during VT is similar to the onset of the far-field shock electrogram (an analog of the QRS complex); and (2) both bipolar and shock electrograms in VT should have a very similar appearance to those during sinus rhythm (Fig. 26.5).

Recording from both sides of the septum can help identify the BBR mechanism. Documentation of a typical H-RB-V-LB activation sequence (during VT with LBBB morphology), or of an H-LB-V-RB activation sequence (during VT with RBBB morphology), supports the diagnosis of BBR (see Fig. 26.3). Unfortunately, the RB and LB potentials are not always recorded, so that the typical activation sequences (LB-H-RB-V or RB-H-LB-V) are not available for analysis. Even if either activation sequence is present, the HPS (usually the LB) could be activated passively in a retrograde fashion to produce an H-RB-V sequence during a VT with LBBB pattern without reentry requiring the LB. In these

Fig. 26.4 Electroanatomic Three-dimensional (CARTO) Activation Map of the Bundle Branch Reentrant Ventricular Tachycardia. The left posterior fascicle (LPF) serves as the descending limb and the right bundle branch (RB) serves as the ascending limb of the reentry circuit. The earliest activation displayed in red (LPF proximal) and the latest in violet (RB proximal). The yellow dots and the numbered sites with arrows indicate the fascicular potentials and local activations of the His-Purkinje system (left boxes), respectively. The sequential activations of the local His-Purkinje system accounted for the entire tachycardia cycle length. (From Machino T, Tada H, Sekiguchi Y, Aonuma K. Three-dimensional visualization of the entire reentrant circuit of bundle branch reentrant tachycardia. *Heart Rhythm*. 2013;10:459–460.)

Fig. 26.5 Implantable Cardioverter-Defibrillator Recordings During Bundle Branch Reentrant Ventricular Tachycardia (VT). Panels show stored electrograms as labeled. (A) VT is shown. The timing of the near-field bipolar electrogram is similar to the onset of the far-field shock electrogram (a rough correlate of the QRS complex; dashed blue line in C). (B) The last few complexes of antitachycardia pacing are shown after which sinus rhythm (SR) ensues. The SR ventricular electrogram is very similar to that during VT as shown in C (SR electrogram in red superimposed on VT electrogram). AS, Atrial sensed event; EGM, electrogram; STIM, antitachycardia ventricular stimulation; VS, ventricular sensed event.

cases, other diagnostic criteria for BBR should be used. In addition, during VT with LBBB morphology, RV activation must precede the LV activation. The opposite is true for the VT with RBBB morphology.

BBR can be terminated by block in the HPS—spontaneous, pacing-induced, secondary to catheter trauma, or caused by ablation.

Diagnostic Maneuvers During Tachycardia

Pacing maneuvers can be extremely helpful to establish the diagnosis of BBR; however, application of these maneuvers during BBR is often not feasible because of the hemodynamic compromise commonly associated with these VTs.

Entrainment

BBR VT can be entrained by ventricular pacing. Entrainment from the protected isthmuses within the BBR circuit (i.e., the LB and RB) results in concealed fusion (i.e., QRS morphology during entrainment resembles the tachycardia) and a short postpacing interval (PPI), with a (PPI – TCL) difference of less than 30 milliseconds. Entrainment from the RV apex (within the BBR circuit, but not within a protected isthmus) results in a (PPI – TCL) difference of less than 30 milliseconds but with manifest fusion. Importantly, a (PPI – TCL) difference of more than 30 milliseconds during entrainment of VT performed from the RV apex excludes a BBR mechanism, provided that the RV apex catheter is correctly positioned. The greater this value is, the more reliable is the certainty of exclusion.¹

Entrainment of BBR VT with concealed QRS fusion can also occur during atrial pacing. This approach, however, demands that the patient not be in AF and usually requires the infusion of atropine or isoproterenol to avoid AV block during rapid atrial pacing. The combination of entrainment with concealed QRS fusion during atrial pacing and entrainment with manifest QRS fusion during ventricular pacing (outside the HPS) has been recently proposed as a useful diagnostic criterion for BBR VT with LBBB QRS morphology.

Resetting

VES can reset the VT by advancing the HB or bundle branch potential. Even a late-coupled VES can reset the VT when pacing is performed

from sites within or close to the BBR circuit (RB, LB, RV apex). In addition, VES can reverse the direction of impulse propagation during BBR. Theoretically this requires double VESs, with the first VES producing block and the second initiating the reentry in the opposite direction.¹

Other Pacing Maneuvers

The ability to dissociate the HB or, particularly, a bundle branch (RB or LB) potential strongly argues against a BBR mechanism. An AES that blocks below the HB deflection should terminate BBR. In addition, simultaneous LV and RV pacing should prevent BBR.

Exclusion of Other Arrhythmia Mechanisms

Myocardial Ventricular Tachycardias

Myocardial VTs can have 1:1 VH relation during tachycardia with passive retrograde activation of the HB. However, myocardial VTs are rarely associated with classic LBBB (or RBBB) QRS morphology, as is expected with BBR VT. In addition, in myocardial VTs, the His potential is often obscured within the local ventricular electrogram. Occasionally, the His potential can precede the onset of the QRS, thus resembling BBR VT; however, the HV interval in myocardial VTs is usually shorter than that during NSR. In contrast to BBR VT, spontaneous or induced TCL variations during myocardial VTs usually precede and dictate H-H interval changes.⁵

Entrainment with concealed QRS fusion during atrial pacing excludes myocardial VT and should be expected in BBR VT. When entrainment with concealed fusion can be demonstrated by pacing at the LB or RB, BBR VT is very likely. In addition, a (PPI – TCL) difference of less than 30 milliseconds after entrainment of the VT from the RV apex is suggestive of BBR VT; in contrast, in myocardial VTs, the (PPI – TCL) difference is greater than 30 milliseconds, unless the VT originates in (exits from) the apex.¹

Idiopathic (Fascicular) Left Ventricular Tachycardia

The QRS and HV interval are normal during NSR in patients with fascicular VT. In contrast, BBR VT is rare in the absence of baseline HPS conduction abnormalities. In addition, the His potential falls within

or before the QRS in fascicular VT, producing a negative or short HV interval, and HB activation follows activation of the left fascicles, which is inconsistent with RBBB-type BBR VT.

Supraventricular Tachycardia With Aberrancy

BBR VT typically exhibits AV dissociation, which excludes atrial tachycardia (AT) and atrioventricular reentrant tachycardia (AVRT). Occasionally, BBR VT can be associated with 1:1 VA conduction, and it can then mimic supraventricular tachycardia (SVT) with aberrancy.

Multiple HB recordings, using a hexapolar or octapolar catheter, can help demonstrate the direction of HB depolarization—anterograde during SVT and retrograde during BBR VT. Also, recording LB and RB potentials in addition to the HB potential can be helpful; activation of the HB occurs anterogradely via the atrioventricular node (AVN) during SVT and precedes the RB potential by an interval equal to or longer than that during NSR.

The atrium is not part of the circuit in the BBR VT and can be dissociated by atrial pacing, which excludes AT and AVRT as the mechanism of wide complex tachycardia. Moreover, during entrainment from the RV apex, a (PPI – TCL) difference greater than 30 milliseconds excludes a BBR mechanism. Conversely, a (PPI – TCL) difference less than 30 milliseconds excludes atrioventricular nodal reentrant tachycardia (AVNRT). In addition, entrainment with manifest fusion during ventricular pacing excludes AVNRT and AT, and should be expected in BBR VT. Furthermore, the ability to terminate or reset the tachycardia with a VES introduced when HB is refractory excludes AT and AVNRT.

Antidromic Atrioventricular Reentrant Tachycardia Using an Atriofascicular Bypass Tract

Several findings can help distinguish antidromic AVRT from BBR VT. During antidromic AVRT, the impulse propagates retrogradely over the RB to the HB, a sequence inconsistent with the common type of BBR VT (LBBB pattern). The timing of a HB recording during the arrhythmia also differs: with antidromic atriofascicular reentry, the HB is typically recorded just after the onset of the QRS (or near the end of the QRS, in the presence of RBBB), whereas in BBR, the HB is recorded well before (in LBBB BBR) or after (in RBBB BBR) the QRS complex. In addition, the AV relationship is always 1:1 during AVRT and rarely so during BBR VT. Because the atrium is not part of the circuit in BBR VT, it can be dissociated by atrial pacing, which excludes AVRT. Moreover, resetting the tachycardia with an AES from the right atrial (RA) free wall, timed when the AV junctional atrium is refractory, excludes VT. Similarly, the ability of an AES to terminate the tachycardia without conduction to the ventricle or to retard (delay) the following ventricular activation excludes VT (see Figs. 18.41 and 19.5).¹

ABLATION

Target of Ablation

The ablation target is either the RB or the LB; RB ablation is easier and usually is the method of choice. However, in most patients with BBR VT, although diffuse conduction system disease is present, the conduction abnormality in the LB is more severe than that in the RB. Nonetheless, preserved slow conduction over the LB can be demonstrated in the majority of patients, and the LB can still maintain 1:1 AV conduction during NSR following ablation of the RB. For the occasional patients in whom anterograde conduction down the LB is known to be inadequate for maintaining 1:1 AV conduction, ablation of the RB will commit the patient to a permanent pacemaker. Therefore ablation of the LB in these patients is preferable because it can prevent BBR and still preserve anterograde conduction.^{5,8}

The mere presence of LBBB on the surface ECG does not mean complete block in the LB. Signs that can indicate that conduction down the LB may be inadequate in maintaining 1:1 AV conduction and favor ablation of the LB over the RB include: (1) development of high-grade AV block below the HB on transient RBBB that can occur secondary to RV catheter manipulation, and (2) observation of an LB potential following the ventricular electrogram either intermittently or during every sinus beat.

Importantly, the HB is not an essential component of the BBR circuit; hence ablating the HB rather than the RB would not adequately eliminate the arrhythmia.

Ablation Technique

Ablation of the Right Bundle Branch

The HB divides at the junction of the fibrous and muscular boundaries of the intraventricular septum into the RB and LB. The RB is a long, thin, discrete structure that travels as the extension of the HB after the origin of the LB. The RB courses down the right side of interventricular septum near the endocardium in its upper third, deeper in the muscular portion of the septum in the middle third, and then again near the endocardium in its lower third. The RB does not divide throughout most of its course, and begins to ramify as it approaches the base of the right anterior papillary muscle, with fascicles going to the septal and free walls of the RV.

A quadripolar catheter is positioned at the HB region and maintained as a reference. The ablation catheter is initially positioned in the HB region and the area of the septum at which the largest His potential is recorded. The catheter is then advanced gradually (in the right anterior oblique [RAO] view) superiorly and to the patient's left side, with clockwise torque to ensure adequate catheter tip contact with the septum and RB and continuous adjustment of the catheter's curvature until the RB potential is recorded. Attempts should be made to obtain the distal RB recording to ensure that the catheter tip is away from the HB and LB.

The RB potential can be distinguished from the HB potential by the absence of or minimal atrial electrogram on the recording and presence of a sharp deflection inscribed at least 10 to 15 milliseconds later than the His potential (Fig. 26.6). Notably, the RB-V interval can be abnormally prolonged (more than 30 milliseconds) due to the frequently prevalent RB conduction disease in these patients.

When there is RB conduction delay at baseline, the RB potential can become hidden within the ventricular electrogram, and it may be impossible to map during NSR, especially when the surface ECG shows complete or incomplete RBBB. However, the RB potential should be readily observed during BBR beats induced by RV stimulation or during BBR VT. In this setting, anatomically guided lesions or a linear ablation perpendicular to the axis of the RB distal to the HB recording can be effective.

A 4-mm-tip ablation catheter is typically used for RB ablation. RF application is usually started at low levels (5 W) and gradually increased every 10 seconds, targeting a temperature of 60°C. In general, RBBB develops at 15 to 20 W. Successful ablation will result in clear development of RBBB in lead V₁ (see Figs. 26.6 and 26.7). Occasionally, an accelerated rhythm from the RB is observed during ablation (analogous to accelerated junctional rhythm with HB ablation; see Fig. 26.7).

Ablation of the Left Bundle Branch

Whereas the RB is anatomically a continuation of the HB, the LB arises as a broad band of fibers from the HB in a perpendicular direction toward the inferior septum. The main LB penetrates the membranous portion of the interventricular septum under the aortic ring and then divides into several fairly discrete branches. The LPF, which arises more

Fig. 26.6 Ablation of Bundle Branch Reentry (BBR). Sinus and right ventricular apical paced complexes from before (left) and after (right) catheter ablation of the right bundle branch (RB) in a patient with BBR ventricular tachycardia (VT). Four bipolar recordings from a catheter at the His position and RB are shown. Prior to RB ablation, propagation along the His-RB axis is linear, antegrade during sinus rhythm (green arrow), and retrograde during RV pacing (purple arrow). After RB ablation, antegrade propagation is interrupted (green arrow, red line) and retrograde activation of the His electrograms occurs after the local ventricular electrogram (purple arrow), indicating block in the RB with transseptal propagation, then up the left bundle. *His_{dist}*, distal His bundle; *His_{prox}*, proximal His bundle; *RB_{dist}*, distal right bundle branch; *RB_{prox}*, proximal right bundle branch; *RVA*, right ventricle apical.

Fig. 26.7 Right Bundle Branch (RB) Ablation. During RB ablation, delivery of radiofrequency current causes accelerated rhythm from the RB until complete block occurs (note lead V1). The His bundle–ventricular interval after ablation is 145 milliseconds (baseline, 80 milliseconds). *His_{dist}*, Distal His bundle; *His_{mid}*, middle His bundle; *His_{prox}*, proximal His bundle; *NSR*, normal sinus rhythm; *RBBB*, right bundle branch block; *RVA*, right ventricle apical.

proximally than the LAF, appears as an extension of the main LB, and is large in its initial course. The LPF then fans out extensively posteriorly toward the papillary muscle and inferoposteriorly to the free wall of the LV. The LAF crosses the LV outflow region and terminates in the Purkinje system of the anterolateral wall of the LV. In the RAO view, the LPF extends from the HB region toward the inferior diaphragmatic

wall and the LAF extends toward the apex of the heart. However, considerable variability exists.

The mapping catheter is placed via a retrograde aortic approach into the LV. The inferoapical septum is a starting point. The catheter is then gradually withdrawn toward the HB until a discrete LB potential is recorded. The LB-V interval should be less than 20 milliseconds, and

the AV electrogram amplitude ratio should be less than 1:10. At this position, the tip of the catheter typically is 1 to 1.5 cm inferior to the optimal HB recording site near the distal portion of the common LB.

Because the LB is a broad band of fibers (typically 1 to 3 cm long and 1 cm wide), it can be difficult to ablate with a single RF application. Furthermore, the fascicles can diverge proximally; thus ablation of the LB can be difficult without harming the HB. In these situations, it may be necessary to deliver several lesions along the left side of the septum in an arc distal to the HB, extending from the anterior superior septum (a point near the RB in the RAO view) to the inferior basal septum to transect both fascicles. Nevertheless, the disease process that results in LBBB in patients with BBR probably leaves only a remnant of conducting tissue that may be more readily ablated than a normal LB would be.

It is more difficult to monitor the progress of LB ablation during RF delivery. Most patients will already have some IVCD localized to the LB system. As opposed to the usually clear development of RBBB in lead V₁ during RB ablation, LB ablation can produce relatively subtle ECG changes, primarily manifesting as widening of the QRS and changes in the QRS axis. One can also monitor the presence of retrograde conduction during VES after each RF application. Elimination of the retrograde V₂-H₂ conduction that was present before ablation is a good indication that sufficient ablation of the LB has been achieved to eliminate BBR.

Endpoints of Ablation

Endpoints of RB ablation include the development of an RBBB pattern (see Fig. 26.7), noninducibility of BBR, and reversal of the direction of HB and RB activation during RV pacing. Prior to ablation, HB electrodes are depolarized during RV pacing from distal to proximal (RB-HB); after RB ablation, HB activation is delayed and reversed (HB-RB; see Fig. 26.6).

Endpoints of LB ablation include elimination of retrograde conduction of VESs over the LB and noninducibility of BBR.

After ablation, aggressive ventricular stimulation should be performed to evaluate the inducibility of VT. Also, decremental atrial pacing should be performed to evaluate the conduction properties of the HPS and the propensity for infra-Hisian AV block. It is advisable to stress the HPS with intravenous procainamide and ensure that anterograde conduction is preserved.

Outcome

The acute success rate of BBR VT approaches 100%, and tachycardia recurrence after successful ablation is extremely rare. However, myocardial VTs can be induced in up to 60% of these patients, and the risk of SCD remains high. Therefore ICD implantation is indicated for secondary prevention in such cases.

The reported incidence of clinically significant conduction system impairment requiring implantation of a permanent pacemaker varies from 10% to 30%. Pacemaker implantation is indicated when infra-Hisian AV block is demonstrated with atrial pacing, or when the postablation HV interval is 100 milliseconds or greater.

INTERFASCICULAR REENTRANT VENTRICULAR TACHYCARDIA

Of the two types of macroreentry in the HPS (i.e., BBR and interfascicular reentry), BBR is by far the most common mechanism of VT. VT secondary to interfascicular reentry is extremely rare; when it does occur, it is most commonly seen in patients with coronary artery disease, specifically those with anterior MI with LAF or LPF block. In these patients, RBBB is usually complete and bidirectional; hence true BBR cannot occur. In addition, there is slow conduction in the apparently

Fig. 26.8 Schematic Illustration of the Two Types of Interfascicular Ventricular Tachycardia (VT) Circuits. *Left*, The interfascicular reentrant VT uses the left posterior fascicle (LPF) as the retrograde limb of the reentrant circuit and the left anterior fascicle (LAF) as the anterograde limb. *Right*, The interfascicular reentrant VT uses the LAF as the retrograde limb of the reentrant circuit and the LPF as the anterograde limb. In both types, because the ventricle is activated via the left bundle branch (LB), the QRS has right bundle branch block morphology. The QRS axis will depend on which fascicle serves as the anterograde route of ventricular activation. The right bundle branch (RB) is activated in a bystander fashion and is not necessary for sustaining the tachycardia. AVN, Atrioventricular node; HB, His bundle.

blocked fascicle. Of note, interfascicular reentrant VT can develop in patients following ablation of the RB for the treatment of BBR VT.⁹

Interfascicular reentry incorporates the LAF and LPF as obligatory limbs of the circuit, connected proximally by the main trunk of the LB and distally by the ventricular myocardium (Fig. 26.8). The tachycardia usually has RBBB morphology. The orientation of the frontal plane axis is variable and depends on the direction of propagation in the reentrant circuit. Anterograde activation over the LAF and retrograde through the LPF would be associated with right axis deviation, whereas the reversed activation sequence shows left axis deviation.¹⁰

In contrast to BBR VT, the HV interval during interfascicular VT is usually shorter (by more than 40 milliseconds) than that recorded in NSR. This is because the upper turnaround point of the circuit, the distal end of the LB bifurcation point, is relatively far from the retrogradely activated HB. In addition, the LB potential is inscribed before the His potential during interfascicular VT. Contrariwise, during BBR VT with RBBB morphology, the His potential usually precedes the LB potential, although the reverse is theoretically possible if the retrograde conduction time to the HB recording point is significantly prolonged. Interfascicular reentry also demonstrates variations in the V-V interval preceded by similar changes in the H-H interval.¹

Atrial pacing, AES, VES, and ventricular pacing can initiate interfascicular reentry by producing transient anterograde block in the slowly conducting fascicle (LAF or LPF), with subsequent impulse anterograde conduction over the healthy fascicle, giving rise to a QRS morphology identical to that during NSR, and then retrogradely in the initially blocked fascicle to initiate reentry. Compared with BBR VT, interfascicular VT can be more difficult to induce by ventricular pacing, because of the inability to create the necessary EP conditions for this type of reentry during ventricular stimulation (i.e., retrograde block in the distal LAF and slow conduction via the LPF, or vice versa), although this may occur during anterograde penetration of the HPS by supra-ventricular impulses (i.e., anterograde block in the LPF and slow conduction in the LAF, or vice versa).⁹

Successful ablation of the arrhythmia can be performed by targeting the diseased fascicle (LAF or LPF), guided by fascicular potentials. When interfascicular reentry occurs in the setting of an anterior MI, complete cure by ablation is usually not possible because other myocardial VTs are almost always present, and the LV ejection fraction is usually poor, thereby mandating ICD implantation for improved survival. When interfascicular reentry occurs without coronary artery disease, in association with degenerative disease of the conduction system, LV systolic function is usually normal and cure of the VT is possible by ablation of the diseased fascicle, although implantation of a permanent pacemaker will likely be required.¹⁰

Ventricular tachycardia (VT) originating from the subepicardium is an important cause of failure of endocardial VT ablation approaches. Mapping arrhythmia foci or circuits that are deep within the myocardium or in the epicardium can be attempted via the coronary sinus (CS) or pericardial space. However, the CS approach has important limitations. Catheter manipulation is limited by the anatomical distribution of the cardiac veins, and epicardial circuits may be identified only when the vessel cannulated happens to be in the region of the circuit. An alternative epicardial approach involves inserting an introducer sheath percutaneously into the pericardial space in the manner used for pericardiocentesis. The subxiphoid approach to the epicardial space allows extensive and unrestricted mapping of the epicardial surface of both ventricles (assuming no areas of pericardial adhesions), and has been used most commonly for VT mapping and ablation (far less so for supraventricular arrhythmias). Nevertheless, mapping within the CS and accessible coronary venous branches can be performed prior to the percutaneous epicardial approach to look for clues of an epicardial origin of the VT circuit, and has been particularly useful in idiopathic focal VTs.

ELECTROPHYSIOLOGICAL SUBSTRATE

Mapping and ablation of arrhythmogenic substrates have traditionally been performed via the endocardial approach. Often, however, the site of origin of a focal tachycardia or a portion of the critical isthmus or even the entire circuit of a macroreentrant VT is located intramurally or in the subepicardium and cannot be identified or ablated from the

endocardium. In these settings, the epicardial approach to mapping and ablation can be a valuable strategy for elimination of the arrhythmia.

The importance of epicardial VT circuits was first highlighted in Chagas disease, which classically results in an epicardial involvement in approximately 70% of patients. Epicardial substrates also have been increasingly recognized in the setting of scar-related VT in patients with nonischemic dilated cardiomyopathy (DCM), arrhythmogenic right ventricular cardiomyopathy (ARVC), post-myocardial infarction (MI) VT, as well as in patients with idiopathic VT. Among patients with VT, an arrhythmogenic substrate requiring epicardial ablation is seen more commonly in patients with nonischemic DCM (25% to 50%), ARVC (30% to 40%), and less frequently in ischemic cardiomyopathy (10% to 16%).^{1,2}

Ischemic Cardiomyopathy

MI produces a predictable wavefront of necrosis progressing from subendocardium to epicardium, resulting in a wedge-shaped, primarily subendocardial scar with variable epicardial extension (depending on the transmural extent of the infarction), usually confined to a specific coronary vascular territory. Therefore, unlike VT substrates in patients with nonischemic cardiomyopathy, the arrhythmogenic tissue can be accessed from the endocardium in the majority of post-MI patients. Even when the arrhythmogenic substrate is located epicardially, elimination of the overlying epicardial substrate is often successful by endocardial ablation through the thinned transmural scar, minimizing the need for epicardial ablation in this population. Nonetheless, VT originating from the subepicardium remains an important cause of failure of endocardial ablation

approaches. In tertiary centers, epicardial ablation has been required in approximately 10% to 25% of post-MI VTs, and seems to be more common with inferior than anterior wall MI.³ However, epicardial access frequently is not feasible for patients who have undergone prior cardiac surgery (which is the case in more than half of post-MI patients undergoing VT ablation).^{1,2,4}

Arrhythmogenic Right Ventricular Cardiomyopathy

In ARVC, fibrofatty replacement usually begins in the subepicardium or midmural layers and progresses to the subendocardium. Thus the arrhythmogenic substrate in patients with ARVC is more extensive epicardially, predominantly located in the subtricuspid and right ventricular outflow tract (RVOT) regions. Although epicardial ablation is required in a significant proportion of these patients, the often-thinned right ventricular (RV) wall often allows for successful elimination of the epicardial substrate by endocardial ablation.

Nonischemic Dilated Cardiomyopathy

Myocardial scarring in nonischemic DCM has been shown to have a predilection for the midmyocardium and epicardium. The epicardial left ventricular (LV) scar areas in nonischemic DCM are typically larger than the endocardial scar and have a typical distribution similar to that for endocardial LV scars, usually located in basal lateral areas of the LV adjacent to the mitral valve annulus. Often, the epicardial substrate can exist with no significant endocardial scarring or ventricular wall thinning (unlike the substrate in post-MI and ARVC patients), rendering endocardial ablation alone ineffective in eliminating epicardial targets. As a result, epicardial ablation is needed more often in patients with VT associated with nonischemic DCM than in patients with prior MI.^{1,2}

Idiopathic Ventricular Tachycardia

Idiopathic focal VTs requiring epicardial ablation are observed in up to 14% of patients, and they typically arise in close proximity to the coronary venous system in the LV summit and cardiac crux. On the other hand, the anterior and lateral portions of the RVOT are fairly thin; thus ablation from the endocardium is usually effective, even when VT foci occur on the epicardial surface. The posterior RVOT (infundibulum) is much thicker, but the epicardial surface of the posterior infundibulum is the left ventricular outflow tract (LVOT), and thus ablation may be effective from either the LVOT or the RVOT for arrhythmias arising deep in the myocardium of the posterior RVOT. For the supraaortic region there is no true epicardial location because the RVOT lies anterior to the right and left coronary cusps and the atria lie posterior to the noncoronary cusp.

For epicardial idiopathic VT, a combined approach from the coronary venous system and adjacent anatomical sites has been most effective, with a success rate around 70%. The outcome of the subxiphoid epicardial ablation is poor in the majority of cases due to the close proximity of the coronary arteries and the thick layer of epicardial fat that overlies the ablation targets.

ELECTROCARDIOGRAPHIC FEATURES

Various electrocardiogram (ECG) characteristics have been used to predict whether an epicardial approach may be required based on the VT morphology (Box 27.1). Those ECG methods are mainly based on the concept that when ventricular activation starts at the epicardial level, the initial part of the wavefront progresses slowly through the myocardial wall until reaching the Purkinje system, which is located only at the subendocardium. This slow transmural activation is reflected as slurred onset of the QRS on the surface ECG. Furthermore, propagation of ventricular activation from the epicardial surface results in

BOX 27.1 Electrocardiographic Characteristics Suggesting an Epicardial Origin of Ventricular Tachycardia

LV VT in Nonischemic Dilated Cardiomyopathy

- Pseudo-delta wave >34 msec
- Long R-wave peak time (≥ 85 msec) in lead V_2
- Shortest precordial RS complex duration >120 msec
- QRS duration >200 msec
- The presence of a Q wave in lead I (for basal superior and apical superior VTs)
- The absence of a Q wave in any of the inferior leads (for basal superior VTs)
- The presence of a Q wave in the inferior leads (for basal inferior and apical inferior VTs)
- Maximum deflection index ≥ 0.59 (for basal-superior/lateral VTs)

RV VT in Arrhythmogenic Cardiomyopathy

- The presence of an initial Q wave in lead I and QS in lead V_2 (for anterior sites in the RV).
- The presence of an initial Q wave in leads II, III, and aVF (for inferior sites in the RV)

LV Summit Idiopathic VT

- Pseudo-delta wave >34 msec
- Long R-wave peak time (≥ 85 msec) in lead V_2
- Shortest precordial RS complex duration >120 msec
- Delayed shortest precordial maximal deflection index (≥ 0.55)
- Peak deflection index >0.6
- R wave amplitude ratio in leads III/II ratio of >1.25
- R wave amplitude ratio in leads aVL/aVR >1.75

LV, Left ventricle; RV, right ventricle; VT, ventricular tachycardia.

a QS pattern in the ECG leads over that region. This is in contrast to endocardial VT exit sites, which produce an initial “r” wave in the corresponding ECG leads, reflecting transmural ventricular activation in an endocardial-to-epicardial direction (towards the overlying ECG lead).

It is important to understand that in the setting of scar-related VT, the QRS morphology is related solely to the VT exit site and this does not imply that some other component of the circuit (such as the critical isthmus or entrance site) cannot be ablated from the endocardium, even when an epicardial exit is indicated by the ECG characteristics. Therefore it is unlikely that the surface ECG by itself will ever be entirely predictive of the need for epicardial access for mapping and ablation for any given VT. In addition, large areas of conduction delay often present in patients with myocardial scar can produce misleading activation sequences and confound ECG prediction.

Furthermore, ECG criteria for identifying an epicardial origin of VT appear to be region and substrate specific. The published ECG criteria have very limited accuracy (40% to 60%) for differentiating epicardial from endocardial VT sites of origin when applied indiscriminately to all ventricular locations. The development of region-specific criteria has significantly improved the sensitivity and specificity (up to the 90% range). However, these criteria were validated only for a single region in the heart and only for patients with nonischemic cardiomyopathy.⁵

A computerized algorithm was recently reported to improve ECG utility for identifying epicardial sites of origin of VT, with an accuracy of 80%. The algorithm has been validated for all regions of the

endocardium and epicardium in patients with and without structural heart disease, and it performed better in most regions than previously described criteria. However, this will require further validation in large clinical studies.⁵

Ventricular Tachycardia in Nonischemic Dilated Cardiomyopathy

Several ECG findings can suggest an epicardial origin of the LV VT with right bundle branch block (RBBB)-like configuration, and all generally rely on the late engagement of the rapidly conducting His-Purkinje fibers by exits on the epicardium, resulting in intramyocardial delay of conduction and a slurred initial part of the QRS complex. These ECG criteria include: (1) pseudo-delta wave (so called because of its similarity to the slurred upstroke delta wave observed during ventricular preexcitation) greater than 34 milliseconds (measured from the earliest ventricular activation to the earliest fast deflection in any precordial lead), which has a sensitivity of 83% and a specificity of 95%; (2) long R-wave peak time in lead V₂ (i.e., interval from the beginning of the QRS complex to the time of initial downstroke of the R wave after it has peaked [previously known as the *intrinsicoid deflection*]) greater than 85 milliseconds, which has a sensitivity of 87% and a specificity of 90%; (3) shortest RS complex duration (measured from the earliest ventricular activation to the nadir of the first S wave in any precordial lead) greater than 120 milliseconds, which has a sensitivity of 76% and a specificity of 85%; and (4) QRS duration greater than 200 milliseconds (see Fig. 22.11).⁶ However, all of these interval criteria suffer from being absolute numbers, which can be modified by effects of antiarrhythmic drugs; that is, an unmedicated patient's pseudo-delta interval of 28 milliseconds (i.e., not epicardial) may be nonspecifically prolonged to 38 milliseconds (i.e., epicardial) by the effect of a sodium channel blocking antiarrhythmic drug. Morphological criteria and the maximum and peak deflection indices (see below) are not subject to this limitation.

However, these criteria do not seem to apply uniformly to all LV regions or to VTs originating from the RV. Other site-specific criteria have been suggested for identifying an epicardial origin for LV VTs: (1) the presence of a Q wave in lead I for basal superior and apical superior VTs; (2) the absence of a Q wave in any of the inferior leads for basal superior VTs; and (3) the presence of a Q wave in the inferior leads for basal inferior and apical inferior VTs. Also, measurement of the *maximal deflection index* (defined as the time from QRS onset to maximal deflection in precordial leads divided by the QRS duration) can help identify epicardial VT originating in the LVOT region.

Given the limited predictive value of ECG criteria when applied individually, a multistep algorithm that incorporates several criteria (two morphology criteria and two adjusted interval criteria) was proposed to predict the site of origin of VTs from the basal-superior/lateral epicardium in patients with nonischemic DCM. The criteria included, in a stepwise fashion: (1) the absence of Q waves in inferior leads; (2) a pseudo-delta wave greater than or equal to 75 milliseconds; (3) maximum deflection index (defined as the interval measured from the earliest ventricular activation [or from the stimulation artifact] to the peak of the largest amplitude deflection in each precordial lead [taking the lead with shortest time] divided by the QRS duration) greater than or equal to 0.59; and (4) the presence of a Q wave in lead I. This four-step algorithm had a 95% specificity and at least 20% sensitivity for identifying basal-superior/lateral epicardial origin of VTs in nonischemic cardiomyopathy. The morphological criteria (presence of a q wave in lead I and absence of q waves in the inferior leads) appear to be the most specific criteria. In particular, the presence of a q wave in lead I is a very specific (88%) and a very sensitive criterion (88%) for identifying an epicardial site of origin.⁷

Ventricular Tachycardia in Arrhythmogenic Cardiomyopathy

Ventricular ectopy in ARVC usually arises from the "triangle of dysplasia" in the RV and therefore has a left bundle branch block (LBBB) pattern with superior, inferior, or indeterminate axis. Most sustained VTs arise from the RV free wall, and most VTs display LBBB configuration with poor R-wave progression in the precordial leads. Nonetheless, VT with RBBB morphology can be observed in patients with LV disease or when advanced structural RV disease distorts normal ventricular geometry within the thorax (see Fig. 29.7).⁸ For VTs originating from the RV, the presence of an initial Q wave in lead I and QS in lead V₂ for anterior sites in the RV strongly predicts an epicardial origin. Similarly, an initial Q wave in leads II, III, and a VF is observed with pace mapping from the inferior epicardial locations in the RV.⁹

Idiopathic Ventricular Tachycardia

The LV summit is the most superior aspect of the "epicardial" LVOT. Hence, VTs originating from this region exhibit the classic slower spread of activation from a focus on the epicardial surface relative to the endocardium and delayed global ventricular activation resulting from later engagement of the His-Purkinje network. Several ECG characteristics can help distinguish epicardial idiopathic VTs from endocardial arrhythmias, including: (1) pseudo-delta wave ≥ 34 milliseconds, (2) long R-wave peak time (≥ 85 milliseconds) in lead V₂, and (3) shortest precordial RS complex of greater than 120 milliseconds.

Furthermore, the degree of initial QRS slurring, as measured by the *maximal deflection index* (defined as the product of the time from QRS onset to maximal deflection [i.e., the largest positive or negative amplitude deflection] in precordial leads divided by the total QRS duration), can help identify epicardial LV summit VTs. A delayed shortest precordial maximal deflection index (≥ 0.55) discriminates LV summit VTs from those originating within the aortic sinuses of Valsalva.¹⁰ Similarly, a peak deflection index (determined in the inferior lead presenting the tallest R wave by dividing the time from the QRS onset to the peak QRS deflection by a total QRS duration) of greater than 0.6 predicts an epicardial LV summit origin.¹¹ This observation is consistent with slower spread of activation from a focus on the epicardial surface relative to the endocardium and delayed global ventricular activation resulting from later engagement of the His-Purkinje network.

Because of its superior location in the LV, VTs originating from the LV summit uniformly exhibit large R wave amplitudes in the inferior leads. However, R wave amplitude ratio in leads III/II can vary according to the location of VT focus within the LV summit. As the site of origin shifts progressively more laterally (from the superior region of the summit towards the inferior region, then towards the lateral mitral annulus), R wave amplitude becomes progressively larger in lead III compared to lead II (concurrent with progressively more steeply negative complexes in lead I). R wave amplitude ratio in leads III/II ratio of greater than 1.25 can predict the requirement of a pericardial approach for VT ablation (i.e., origins from the inferior aspect of the LV summit).^{10,12}

Similarly, the aVL/aVR Q-wave ratio was strongly correlated with the anatomical distance between the successful site and the apex of the LV summit; the longer distances away from the apex of the LV summit the larger the aVL/aVR Q-wave ratio. This indicates that the ECG vectors would shift laterally and inferiorly if the distance between the VT and the apex of the LV summit increased. Also, the aVL/aVR Q-wave ratio was found to predict the approach to successful ablation; the aVL/aVR Q-wave ratio was significantly higher for VTs requiring an epicardial approach, followed by VTs arising from the coronary venous system, subvalvular area, and aortic sinuses of Valsalva. An aVL/aVR Q-wave

ratio of less than 1.45 predicted successful ablation from aortic sinuses of Valsalva or subvalvular approaches, whereas an aVL/aVR Q-wave ratio of greater than 1.75 indicated the need for a pericardial approach.^{13,14}

VTs originating from the superior region of the LV summit (the “inaccessible region” close to the apex of the summit) typically exhibit LBBB pattern, larger R wave amplitudes in the inferior leads, and absence of an S wave in leads V₅ to V₆.¹⁰ When LV summit VTs exhibit an RBBB pattern, transition zone earlier than lead V₁, aVL/aVR amplitude ratio of greater than 1.1, and S waves in V₅ to V₆, those VTs are likely to be cured by catheter ablation within the great cardiac or anterior interventricular veins. As noted, when LV summit VTs exhibit lead III/II amplitude ratio of greater than 1.25 and lead aVL/aVR amplitude ratio of greater than 1.75, those VTs are likely to require a pericardial approach for ablation.^{12,15}

Postinfarction Ventricular Tachycardia

The proposed 12-lead ECG features for differentiation of epicardial versus endocardial VT exit sites were assessed in patients without MI, and their utility for localization of post-MI VTs has not been validated. In fact, in a recent report, those QRS characteristics failed to reliably identify post-MI VTs requiring epicardial ablation. Slow initial forces can be present during tachycardia at the MI scar region and, hence, are not specific for epicardial origins. Furthermore, the presence of typical Q waves in the VT ECGs of patients with previous MI precludes the use of morphological ECG criteria, and when present in the precordial leads, Q waves can interfere with the measurement of all interval criteria.^{6,16–18}

As noted earlier, epicardial VT exits are uncommon in post-MI VT because of the subendocardial nature of the underlying substrate. Furthermore, the VT 12-lead ECG provides information about the VT exit site from the scar border, which generally is not the target of ablation. The critical isthmus of the VT circuit, which constitutes the ablation target, often is complex, and can have an endocardial and epicardial trajectory permitting successful ablation from the endocardium (especially in the presence of wall thinning caused by the infarct scar) even in the setting of VT with an epicardial exit. Therefore endocardial mapping should be the first approach to catheter ablation for VTs in patients with ischemic heart disease, even when the surface ECG suggests an epicardial origin of the tachycardia.^{17,18}

CLINICAL CONSIDERATIONS

Catheter ablation from the epicardium is often required for elimination of VTs due to nonischemic cardiomyopathy and is occasionally useful for VTs in a variety of other diseases, as well as some idiopathic VTs. In addition, epicardial mapping and ablation is necessary in patients in whom endocardial ablation cannot be performed (e.g., LV thrombus, mechanical aortic and mitral valve prosthesis). However, there are several conditions that can significantly limit the feasibility of percutaneous epicardial mapping and ablation. Previous cardiac surgery or pericarditis usually results in significant pericardial fibrosis, and the pericardial space is often, but not always, virtually replaced by fibrotic adhesions. In this setting, percutaneous cannulation of the pericardial sac is very difficult; even when percutaneous cannulation is successful, manipulation of the instruments can be extremely limited.^{19,20}

The need for epicardial ablation, however, is often difficult to determine at the beginning of a procedure. Although percutaneous epicardial VT ablation frequently is pursued after extensive endocardial mapping or ablation fails in achieving the desired procedural endpoint, the epicardial approach should be considered early in the procedure in patients known to have high propensity of epicardial substrates (including those with DCM and ARVC).

Combined endocardial and epicardial mapping during the initial procedure is increasingly being utilized in selected VT patients. Such an approach allows for performing pericardial puncture before initiating systemic anticoagulation and offers a better chance to map and ablate all inducible VTs during the index procedure (eFig. 27.1).²¹ However, this strategy inevitably leads to unnecessary pericardial punctures in some patients. In fact, in a recent study employing simultaneous endocardial and epicardial mapping, the endocardium was ultimately thought to be a better target than the epicardium in up to 21% of patients. Therefore epicardial access should be obtained at the beginning of a procedure only when an epicardial origin of the VT circuit is strongly suspected based on a thorough preprocedural assessment.

Several preprocedural clues can potentially help select VT patients in whom a combined endocardial-epicardial approach is appropriate as a first-line approach (Box 27.2), including: (1) the presence of a predominantly epicardial underlying disease substrate (e.g., nonischemic DCM, ARVC, Chagas disease); (2) previously failed endocardial ablation; (3) predominantly epicardial location of myocardial scar on preprocedural cardiac imaging studies (cardiac magnetic resonance [CMR] or computed tomography [CT]); or (4) ECG criteria suggesting an epicardial VT exit site. As noted previously, while ECG characteristics can help predict an epicardial exit site, they alone are not reliably predictive of the need for epicardial access and mapping for any given VT. QRS morphology is related solely to the VT exit site and this does not imply that the critical isthmus of the VT circuit cannot be ablated from the endocardium, even when an epicardial exit is implied by the ECG characteristics.^{22–25}

During endocardial VT mapping and ablation, several findings should prompt early consideration of the epicardial approach: (1) the inability to identify the reentry circuit isthmus on the endocardium; (2) endocardial activation mapping demonstrating a focal point of earliest

BOX 27.2 Factors Predicting the Need for an Epicardial Approach for Ventricular Tachycardia Ablation

Preprocedural Factors

- Intracavitary thrombus
- Mechanical aortic and mitral valves
- Prior failed endocardial ablation
- Predominantly epicardial underlying disease substrate (nonischemic cardiomyopathy or arrhythmogenic right ventricular cardiomyopathy)
- Predominantly epicardial scar on preprocedural cardiac magnetic resonance
- Electrocardiographic criteria suggesting an epicardial VT exit site

Intraprocedural Factors

- Inability to identify the reentry circuit isthmus on the endocardium
- Failed or late VT termination with endocardial radiofrequency ablation
- Endocardial activation mapping demonstrating a focal point of earliest endocardial activation with unfavorable results of entrainment or pace mapping
- Endocardial activation mapping demonstrating diffusely endocardial area of equally earliest activation, with unfavorable unipolar electrogram characteristics or paced mapping results
- Endocardial bipolar voltage mapping demonstrating small areas of abnormalities
- Abnormal endocardial unipolar voltage mapping suggestive of greater extent of epicardial scar

VT, Ventricular tachycardia.

eFig. 27.1 Combined Endocardial and Epicardial Mapping of Ventricular Tachycardia (VT) in Dilated Nonischemic Cardiomyopathy. Shown are fluoroscopic views of endocardial and epicardial ablation catheter positions. VT was eventually eliminated with endocardial ablation at the site shown (basal left ventricle). ICD, Implantable cardioverter-defibrillator.

endocardial activation with unfavorable results of entrainment or pace mapping techniques; or (3) large endocardial area ($>2 \text{ cm}^2$ region) of equally earliest activation, with no single site showing favorable unipolar electrogram characteristics or paced mapping results; (4) failed or late VT termination with endocardial radiofrequency (RF) energy application; (5) limited endocardial substrate, as indicated by endocardial bipolar voltage mapping demonstrating small areas of abnormalities; and (6) endocardial unipolar voltage mapping is suggestive of greater extent of epicardial bipolar signal abnormalities compared to the bipolar voltage abnormalities.^{23,26–28}

On the other hand, it is probably more appropriate to defer epicardial intervention in patients with ischemic cardiomyopathy and those anticipated difficult epicardial access (due to prior cardiac surgery) until an endocardial approach has failed ablation.^{1,2}

Anticoagulation

Epicardial access is generally avoided in patients on therapeutic doses of oral or IV anticoagulation. In patients requiring both endocardial and epicardial LV mapping, the pericardial access is typically obtained before endocardial mapping and before administering anticoagulation. When the decision to proceed to the epicardial approach is made after the patient has already received IV heparin during endocardial LV mapping, reversal of anticoagulation effects of heparin with protamine is generally recommended prior to pericardial puncture to reduce the risk of intrapericardial or access-related bleeding. Heparin may be started (if additional endocardial LV mapping is required) after safe epicardial access has been obtained without significant bleeding complications.

Of note, a recent report found that percutaneous pericardial access could be performed safely in anticoagulated patients. This approach obviates the need for temporary reversal of systemic anticoagulation (and potential difficulties in reestablishing therapeutic anticoagulation following protamine administration) in patients who already had endocardial LV ablation, which can potentially increase the risk of systemic thromboembolism. Furthermore, this approach obviates obtaining epicardial access until its value is confirmed based on findings of endocardial mapping.²⁹

Contrast-Enhanced Cardiac Magnetic Resonance

Delayed contrast-enhanced CMR delineates regions of scar tissue potentially forming part of the arrhythmia substrate in patients with ischemic and nonischemic cardiomyopathy, and enables the depiction of transmural and nontransmural scars with high spatial resolution, allowing determination of whether the scar is endocardial, intramyocardial, or epicardial (Fig. 27.1).^{30,31}

The suspicion of an epicardial VT substrate can facilitate planning of VT ablations, such as for a combined endocardial and epicardial approach, especially given the fact that visualization of epicardial or intramyocardial scar on preprocedure-delayed enhancement CMR was found to be predictive of failure of the endocardial approach and of the need for the epicardial approach for VT ablation.^{32,33}

CMR can also help determine the underlying etiology of nonischemic cardiomyopathy in some patients, such as myocarditis, sarcoidosis, and ARVC, which can be associated with a higher susceptibility for epicardial VTs. Furthermore, in patients undergoing epicardial mapping and ablation procedures, the registration of preacquired CMR images with real-time electroanatomic mapping allows visualization of the ventricular anatomy and obstacles to procedural success, such as epicardial fat, which can be helpful during the mapping procedure in differentiating the cause of low epicardial voltages (fat vs. scar).

One potential disadvantage concerns the safety and quality of CMR imaging in patients with implanted cardiac devices. However, recent studies have consistently demonstrated the feasibility and safety of CMR in patients with pacemakers and defibrillators, and evolving technologies have further improved the CMR imaging compatibility of some devices. Also, the device hardware introduces significant artifacts, especially in the basal anterior free LV wall, which degrades the image quality and often limit interpretation of CMR in VT patients. Nonetheless, the interventricular septum, and the LV lateral and inferior walls are mostly free of artifact in most patients. Recently, a wideband late gadolinium enhanced CMR technique has been reported to reduce hyper-intense artifacts from the cardiac device generator.^{30,34} When CMR cannot be obtained, cardiac CT may be used for scar and fat imaging.

Fig. 27.1 Epicardial Fat and Scar. (A) Extracted epicardial fat (yellow) together with the epicardium (dark red) in a patient with nonischemic cardiomyopathy. (B) Short-axis magnetic resonance imaging indicates an epicardial scar in the inferolateral left ventricular area (arrows). (C) Voltage map in the same patient, indicating an area of low voltage extending from the basolateral free wall of the left ventricle to the left ventricular apex. The epicardial fat (yellow) is merged with the electroanatomic voltage map. The low-voltage area projects on the left ventricular epicardium that is devoid of fat. (From Desjardins B, Morady F, Bogun F. Effect of epicardial fat on electroanatomical mapping and epicardial catheter ablation. *J Am Coll Cardiol*. 2010;56:1320–1327.)

Contrast-Enhanced Computed Tomography

Contrast-enhanced CT scanning enables detailed and comprehensive evaluation of LV myocardium using triple multimodality imaging based on anatomical, dynamic, and perfusion parameters to identify abnormal substrate (myocardial scar and border zone) with high spatial (≤ 1 mm) and temporal resolution. Areas of CT hypoperfusion correlate best with areas of abnormal voltage (<1.5 mV) rather than scar alone (<0.5 mV). Perfusion imaging from CT enables characterization of the transmural extent and intramyocardial location of scar tissue and visualization of surviving mid- and epicardial myocardium in the regions of the scar, which can help identify areas potentially involved in the VT substrate. Such preprocedural information can help the operator to plan an appropriate mapping and ablation strategy, and better inform the patient about the risks, benefits, and chances of procedural success.

The three-dimensional (3-D) CT-defined abnormal myocardium can be accurately extracted and embedded in clinical mapping systems displaying areas of abnormal anatomical, dynamic, and perfusion parameters for substrate-guided VT ablations. In addition, CT epicardial fat imaging can be used to characterize the extent of fat tissue by extracting and integrating epicardial fat information into the 3-D electroanatomic voltage map, thereby helping to distinguish epicardial fat from scar tissue.

NAVIGATING THE PERICARDIAL SPACE

Anatomical Considerations

The pericardium is a double-walled sac that contains the heart and the roots of the great arteries, the superior vena cava (SVC), and pulmonary veins (PVs). By separating the heart from its surroundings—the descending aorta, lungs, diaphragm, esophagus, trachea, and tracheobronchial lymph nodes—the pericardial space allows complete freedom of cardiac motion within this sac.^{35,36}

The pericardium consists of two sacs intimately connected with one another: an outer fibrous envelope (the fibrous pericardium) and an inner serous sac (the serous pericardium). The fibrous pericardium (0.8 to 2.5 mm in thickness) consists of fibrous tissue and forms a flask-shaped bag, the neck of which is closed by its fusion with the adventitia of the great vessels, while its base is attached by loose fibroareolar tissue to the central tendon and to the muscular fibers of the left side of the diaphragm. The fibrous pericardium is also attached to the posterior sternal surface by the superior and inferior sterno-pericardial ligaments. These attachments are essential to maintain the normal cardiac position in relation to the surrounding structures, to restrict the volume of the thin-walled cardiac chambers (right atrium [RA] and ventricle), and to serve as direct protection against injuries.

The fibrous pericardium extends up to 5 to 6 cm along the great vessels, including the aorta, the SVC, the right and left pulmonary arteries, and the four PVs. The inferior vena cava (IVC) enters the pericardium through the central tendon of the diaphragm and receives no covering from the fibrous pericardium.³⁷ Nerve fibers from the parietal layer of the pericardium transmitted by the phrenic nerve are sensitive to pain (e.g., during pericarditis). In contrast, the visceral pericardial layer on the cardiac surface is insensitive to pain.³⁸

The serous pericardium is a delicate membrane that lies within the fibrous pericardium and lines its walls; it is composed of two layers: the parietal pericardium and the visceral pericardium. The parietal pericardium is fused to and inseparable from the fibrous pericardium. On the other hand, the visceral pericardium, which is composed of a single layer of mesothelial cells, is part of the epicardium (i.e., the layer immediately outside the myocardium) and covers the heart and the great vessels except for a small area on the posterior wall of the atria.

The visceral layer extends to the beginning of the great vessels, and is reflected from the heart onto the parietal layer of the serous pericardium along the great vessels in tube-like extensions. This happens at two areas: where the aorta and pulmonary trunk leave the heart and where the SVC, IVC, and PVs enter the heart.

At the pericardial reflections and at the posterior wall between the great vessels, the pericardial space is divided up into a contiguous network of recesses and sinuses (eFig. 27.2). There are three sinuses in the pericardial space: superior, transverse, and oblique. The two pericardial space sinuses that can be accessed in electrophysiological (EP) procedures are the transverse and oblique sinuses. The superior sinus (superior aortic recess), which lies anterior to the upper ascending aorta and main pulmonary artery, is irrelevant to the EP procedure.¹⁹

The oblique sinus is a cul-de-sac located posterior to the atria (particularly the left atrium [LA] in the region between the four PVs) and anterior to the esophagus and descending aorta. The oblique sinus is an inverted U-shaped pericardial reflection bordered by the right PVs and IVC on the right side, the left PVs on the left side, and the right and left PVs superiorly (Fig. 27.2). The right and left PV recesses extend from the oblique sinus between the upper and lower PVs on each side.^{19,35–37}

The tunnel-shaped transverse sinus lies posterior to the ascending aorta and pulmonary trunk, anterior to the SVC and superior PVs (eFig. 27.3). The roof of the transverse sinus is formed in parts by the aortic arch, the floor of the right pulmonary artery, and a part of the main pulmonary artery. Inferiorly, the transverse sinus is bound by the LA roof and by the pericardial reflection between the right and left superior PVs (which separates the transverse sinus from the oblique sinus below). The transverse sinus contains the right pulmonary artery and the inferior aortic recess (between the ascending aorta and the LA).³⁷ Catheter exploration of the sinus allows access to the anterior portion of the LA, the area of Bachman's bundle, and via the inferior aortic recess, the noncoronary and right coronary aortic sinuses of Valsalva.^{19,39} The transverse sinus can be accessed by a catheter passed posteriorly around the lateral wall of the LV and LA, and then under the pulmonary arteries.^{35,36}

The pericardial cavity or sac is a continuous virtual space that lies between the parietal and visceral layers of serous pericardium. The heart invaginates the wall of the serous sac from above and behind, and practically obliterates its cavity, the space being merely a potential one. The sac normally contains 20 to 40 mL of clear fluid that occupies the virtual space between the two layers. Although pericardial reflections can become anatomical obstacles for catheter navigation, all those reflections are located basally in relation to the great vessels; thus most of the epicardial surface is freely accessible from the pericardial space, except for the atrial and ventricular septa (which are not in direct contact with the pericardium) and the atrioventricular (AV) grooves and interventricular sulci (which are separated from the visceral pericardium by epicardial fat). Unlike the endovascular approach, the pericardial space is notable for the absence of obstacles and the relative ease with which catheter manipulation can be performed. By the same token, achieving firm, stable contact with the catheter tip at the target site can be difficult.¹⁹

Technical Considerations

A thorough understanding of the clinical anatomy of the epicardial space and the reflections and recesses of the pericardium is necessary for the mapping procedure. In addition, contrast pericardiography, once the epicardial access is obtained, can help delineate the anatomy and assess for the presence of adhesions, which can limit catheter navigation.³⁸ Techniques of obtaining pericardial access are discussed in Chapter 4.

eFig. 27.2 Anatomy of Pericardial Sinuses and Recesses. Anterior view of the sinuses and recesses of the pericardium. Ventral aspect of the pericardium with the anterior portion of the pericardial sac and the heart removed to show the great vessels at the base of the heart. The aorta (Ao) and pulmonary artery (PA) have been transected to show the path of the transverse sinus (*dotted line*) that separates the arteries from the venae cavae and pulmonary veins (PVs). The pericardial reflection extends to the proximal aortic arch and the recess between the aorta and the superior vena cava (SVC) is called the superior aortic recess (*dotted line*). The left lateral extension of the transverse sinus is the left pulmonic recess bordered by the left PA and left superior PV. The oblique sinus is the cul-de-sac behind the left atrium and bound by the pericardial reflection over the inferior PVs and the inferior vena cava (IVC). Note the abundance of adipose tissue between the pericardium and diaphragm. LPA, Left pulmonary artery; LPV, left pulmonary veins; RPA, right pulmonary artery; RPV, right pulmonary veins. (From Rodriguez ER, Tan CD. Structure and anatomy of the human pericardium. *Prog Cardiovasc Dis.* 2017;59:327–340.)

eFig. 27.3 The Transverse Sinus of the Pericardium. (A) and (B) The transverse sinus is shown in this anterior view (probe). The transverse sinus is the pericardial space delimited by the superior vena cava (SVC) and anterior surfaces of the right atrium (RA) and left atrium (LA) dorsally. The ventral surface of the transverse sinus is formed by the posterior aspect of the ascending aorta and the inferior-posterior surface of the right and left pulmonary arteries before they emerge from the pericardial sac. (C) and (D) In this anterior view, most of the heart and the anterior portion of the pericardial sac have been removed. Only the dorsal segments of the RA, interatrial septum and LA remain. The red dots delineate the cut border of the pericardial sac. The asterisks below the atria mark the pericardial space. The white dots delineate the transverse sinus as it spans from right to left. The pericardial space bounded by the cephalad surface of the left superior pulmonary vein and inferior-posterior surface of the left pulmonary artery (PA) is designated the left pulmonary recess (double arrows). Ao, Aorta; IAS, interatrial septum; LSPV, left superior pulmonary vein; LV, left ventricle; RAA, right atrium appendage; RV, right ventricle. (From Rodriguez ER, Tan CD. Structure and anatomy of the human pericardium. *Prog Cardiovasc Dis*. 2017;59:327–340.)

Fig. 27.2 The Oblique Sinus of the Pericardium. (A) and (B) The oblique sinus of the pericardium is the space flanked by the reflections of the pericardium below the inferior pulmonary veins (PVs). A and B show a slightly right cephalad-dorsal view of the left and right atria. The four PVs are shown as they drain into the left atrium (LA). The pericardial sac has been almost entirely removed. The cut border of the remaining pericardial sac is shown delineated by red dots. The white dots mark the contour of the oblique sinus. (C) and (D) A slightly left cephalad-dorsal view of the LA, PVs, and pulmonary arteries. The pericardial recesses above the inferior PVs on the right and the left sides of the LA, as well as the oblique sinus are delineated by the white dots. Ao, Aorta; IVC, inferior vena cava; LIPV, left inferior pulmonary vein; LPA, left pulmonary artery; LPVR, left pulmonary venous recess; LSPV, left superior pulmonary vein; LV, left ventricle; OS, oblique sinus; RA, right atrium; RIPV, right inferior pulmonary vein; RPA, right pulmonary artery; RSPV, right pulmonary venous recess; SVC, superior vena cava. (From Rodriguez ER, Tan CD. Structure and anatomy of the human pericardium. *Prog Cardiovasc Dis.* 2017;59:327–340.)

Once the introducer sheath and catheter are in place, the mapping catheter can be moved freely in the pericardial sac, constrained only by the reflections of the pericardial membrane located around the PVs and great vessels. Mapping of the atrial surface can be limited by the normal pericardial reflections and by the atrial irregular atrial anatomy (right and left atrial appendages). In the absence of pericardial adhesions, the epicardial surfaces of the RV and LV free walls are devoid of reflections, allowing unrestricted navigation of the mapping catheter.³⁹ The inferior and anterior approach taken during percutaneous epicardial access allows for easier access to the respective surfaces of the heart. Importantly, whereas the anterior aspects of the RVOT are easily accessible epicardially, the LVOT is bounded anteriorly by the RVOT and posteriorly by mitral valve and LA, prohibiting access via the percutaneous epicardial approach.^{35,40}

The use of a deflectable sheath can facilitate catheter navigation and improve contact with the epicardium. Careful catheter manipulation and sheath management are imperative to help avoid aspiration of air into the epicardial space and to avoid laceration of the epicardial vessels. When using stiff sheaths in the epicardial space, it is recommended to lead with a wire or ablation catheter before advancing or moving the curl of the sheath. Also, it is recommended not to leave a large sheath in the pericardial space without a catheter in place because the edges of the sheath can potentially lacerate epicardial vessels or the myocardium itself.^{41,42}

During manipulation of the sheath, small amounts of air can reach the pericardial space, which can be easily detected by fluoroscopy. The presence of air can induce instability to the catheter secondary to the lack of contact between the parietal and visceral membranes of the

pericardial sac. Aspiration of air will restore contact characteristic of the pericardial space.

Pericardial Adhesions

Percutaneous pericardial access can be obtained in more than 90% of patients who have not had prior cardiac surgery or clinical pericarditis, even in those who required repeated epicardial procedures. However, the presence of pericardial adhesions between the parietal and visceral serosal surfaces (e.g., following pericarditis, prior cardiac surgery, or previous epicardial instrumentation-induced pericarditis) can severely limit percutaneous access to the pericardium, and have been the primary reason of failure of epicardial instrumentation (Fig. 27.3). Whereas the pericardial adhesions in postpericarditis patients are often diffusely distributed, adhesions in postsurgical patients are mostly concentrated in the anterior portion of the heart (the area where the pericardial sac was opened during sternotomy). This allows subxiphoid epicardial access to the inferolateral LV (via posterior approach) in a large proportion of postsurgical patients.

Importantly, even when epicardial access is possible, the presence of pericardial adhesions can significantly limit catheter maneuverability within the pericardial space.⁴¹ Some reports described the feasibility of disruption of some adhesions with meticulous and gentle blunt dissection of the adhesions by advancing the curve of a deflected ablation and a steerable epicardial sheath. This technique can help increase the epicardial areas accessible for mapping and ablation. Flow of intrapericardial contrast dye on repeat injection helps assess effective disruption of the adhesions. Care must be taken to avoid cardiac perforation with the catheter tip in these cases. Furthermore, in patients with prior coronary bypass surgery, dense adhesions typically occupy the area of the coronary graft, hindering epicardial access to that region. In these patients, it is important to perform coronary native vessel and graft angiography to define anatomy and avoid graft disruption by catheter manipulation. It is also important to note that, in patients with coronary artery occlu-

sion, disruption of pericardial adhesions with blunt catheter dissection can potentially disrupt natural bypasses (collaterals) that form between the parietal pericardial vessels and the visceral myocardium.^{42–44}

However, in some patients, the presence of dense adhesions can produce compartmentalization of the pericardial space, which is resistant to blunt catheter dissection. In these cases, a hybrid procedure involving surgical access with a subxiphoid pericardial window or a limited anterior or lateral thoracotomy, and manual dissection and lysis of the adhesions can facilitate access to the epicardial region of interest. However, access to other areas may still be limited.⁴² However, this technique should be reserved for specific patients with recurrent VT refractory to endocardial ablation and antiarrhythmic medications, in whom a high degree of confidence exists as to the origin of the arrhythmia.^{43,44}

Epicardial Fat

Epicardial fat is the adipose tissue located between the visceral pericardium and the myocardium. Epicardial fat covers 80% of the heart surface, with a mean thickness of the fat layer of 5.3 ± 1.6 mm and variable distribution, being more abundant in the AV and interventricular grooves, and the RV lateral wall. There is a broad individual variation in the amount and distribution of epicardial fat. Epicardial fat seems to increase with age, obesity, diabetes, and female gender.^{19,45}

Epicardial fat is an important consideration as it presents two unique challenges for mapping and ablation of VT. First, interposed between the mapping catheter and myocardium, epicardial fat dampens recorded electrogram amplitude as well as the ventricular stimulation threshold, hindering activation and pace mapping techniques and making it difficult to differentiate fat from true scar. Second, interposed fat impairs the efficacy of RF ablation.¹⁹

Preprocedural CMR and CT imaging can accurately define epicardial fat thickness and distribution. Those images can be registered on the electroanatomic map and help the interpretation of mapping findings and anticipate the success of RF ablation.^{19,45}

Fig. 27.3 Pericardial Adhesions. Pericardial access is performed (anterior approach) in a patient with biventricular pacemaker and prior episode of pericarditis. Right anterior oblique (RAO) and left lateral (LL) fluoroscopy views are shown during advancing the pericardial guidewire via the pericardial access needle. Note that the contrast dye injected initially via the pericardial access needle remained stagnant at the anterior aspect of the heart, and the guidewire coiled in the same region, due to compartmentalization of the pericardial space secondary to pericardial adhesions. Right atrial (RA), right ventricular (RV), and left ventricular (LV) pacemaker leads are visualized.

TRANSTHORACIC EPICARDIAL MAPPING

The approaches to epicardial mapping are essentially the same as for endocardial ablation, including activation mapping, entrainment mapping, substrate mapping, and pace mapping. Those techniques are discussed in detail in **Chapter 22**. The following discussion highlights certain peculiarities pertaining to the percutaneous epicardial approach to mapping.

Activation Mapping

In scar-related VTs, inability to identify the reentry circuit isthmus on the endocardium can suggest that the isthmus is epicardial or intramural. In these cases, endocardial activation mapping can demonstrate a focal point of earliest endocardial activation where entrainment mapping indicates a potential exit or outer loop site, but ablation fails to interrupt VT, suggesting that there is an epicardial or intramural circuit with a broad endocardial exit.

During focal VTs originating from the epicardium, a focal origin may be identifiable during endocardial mapping, typically at a point of earliest endocardial breakthrough. However, local activation timing at that location is not particularly early. Sometimes, electrical propagation from epicardial foci results in a diffuse, broad endocardial area ($>2 \text{ cm}^2$) being activated simultaneously (**eFig. 27.4**), with no single site showing favorable unipolar electrogram characteristics or paced mapping results. Other clues suggest the presence of an endocardial far-field electrogram preceding the sharp near-field electrogram in the

region of early activation (**Fig. 27.4**), and an inability to capture the far-field component of the earliest endocardial electrogram or replicate VT morphology on the surface ECG during pace mapping at the earliest endocardial activation site.²⁶

If an appropriate target site for VT ablation cannot be identified despite extensive endocardial and epicardial mapping, an epicardial or intramural VT circuit or focus should be suspected. Epicardial mapping of local activation timing and electrogram morphology employs principles similar to those of endocardial mapping. However, because of the presence of epicardial fat, low electrogram amplitude may not have the same implications as those during endocardial mapping (see below).

Entrainment and Pace Mapping

Entrainment and pace mapping maneuvers are usually difficult to perform using bipolar pacing because of a very high epicardial stimulation threshold ($>15 \text{ mA}$) in the majority (approximately 70%) of cases, and are likely related to the presence of epicardial fat and poor catheter contact due to freedom of catheter movement in the pericardial space. With unipolar pacing, the pacing threshold generally is less than 10 mA at 2 milliseconds in normal tissue. Epicardial fat of less than 5 mm in thickness interposed between the ablating catheter and the epicardium usually does not modify the epicardial ventricular stimulation threshold. Of note, ablation with irrigated RF generally increases the pacing threshold secondary, in part, to the introduction of irrigant fluid into the pericardial space, which can potentially result in decreased physical contact between the electrode and the epicardial surface.

Fig. 27.4 Endocardial Versus Epicardial Activation Mapping. The panels depict representative electrograms (EGMs) from earliest endocardial activation (*left*) and earliest epicardial activation (*right*) during VT from three patients (A, B, and C) with nonischemic cardiomyopathy. A typical bipolar activation sequence pattern was observed reproducibly at the earliest endocardial site, with a far-field EGM preceding the near-field EGM. The sequence is reversed on the epicardium. ABL_d, Distal ablation. (From Tzou WS, Nguyen DT, Aleong RG, et al. Endocardial electrogram characteristics of epicardial ventricular arrhythmias. *J Cardiovasc Electrophysiol*. 2013;24:649–654.)

eFig. 27.4 Endocardial Versus Epicardial Electroanatomic Activation Mapping. A representative example of endocardial (A) and epicardial (B) electroanatomic activation maps is shown from a patient nonischemic cardiomyopathy. A significantly wider endocardial area of early activation is observed compared to epicardial activation. (From Tzou WS, Nguyen DT, Aleong RG, et al. Endocardial electrogram characteristics of epicardial ventricular arrhythmias. *J Cardiovasc Electrophysiol.* 2013;24:649–654.)

Fig. 27.5 Distribution of Epicardial Fat and Electroanatomic Mapping. (A) Epicardial voltage map of a patient with nonischemic cardiomyopathy. The voltage map shows surface reconstruction of the anterior surface of the heart. There is a low-voltage area (red) extending from the right ventricular outflow tract to the apex and following the lateral inferior margin to the base of the right ventricle. (B) Gross pathology of the same heart after cardiac transplantation illustrating that the area of low voltage on the left largely corresponds to an area of epicardial fat. (C) The extracted epicardial fat from the computed tomography data in this patient is shown in yellow. The remaining epicardial surface (dark red) is devoid of fat. The three-dimensional epicardial fat map was integrated with the voltage map. Low-voltage points are bright red and normal voltage points are purple. (From Desjardins B, Morady F, Bogun F. Effect of epicardial fat on electroanatomical mapping and epicardial catheter ablation. *J Am Coll Cardiol.* 2010;56:1320–1327.)

Electroanatomic Substrate Mapping

Substrate VT mapping approaches are similar to those described for the endocardium. Areas of infarction or scar have low-amplitude electrograms similar to findings during endocardial mapping. However, epicardial fat, which is concentrated along the coronary sulcus and the interventricular grooves, can cause low-amplitude electrograms, falsely suggesting scar in voltage maps. Normal epicardial electrograms demonstrate bipolar signal amplitude typically above 0.94 to 1.5 mV, whereas signal amplitude associated with fat or large vessel coronary anatomy might demonstrate significantly lower amplitude.

As noted, epicardial fat of less than 5 mm in thickness interposed between the ablating catheter and the epicardium usually does not modify the amplitude or duration of the bipolar epicardial electrogram. However, in areas with a layer of epicardial fat greater than 5 mm in thickness, the amplitude of the recorded bipolar epicardial electrogram can decrease, which may confound the ability to discriminate between fat and scar. Importantly, despite the lower electrogram amplitude, epicardial fat will not produce “abnormal” (fractionated and split) electrograms. Therefore to avoid a misclassification of low-voltage areas due to epicardial fat or major coronary vasculature as abnormal, it is important to analyze the location and extent of the confluent voltage abnormality as well as the electrogram morphology characteristics. The presence of abnormal electrograms (fractionated, split, or late potentials) is usually a more reliable indicator of scarring. Thus during epicardial bipolar voltage mapping, an amplitude cutoff of 1.0 mV combined with an abnormal electrogram morphology is used to identify the low voltage zone.

The registration of preacquired CT or CMR images detailing the LV substrate with the real-time 3-D electroanatomic voltage map allows the visualization of regions of scar tissue and can potentially facilitate mapping and ablation (see Fig. 27.1). CMR and CT imaging also can

be used to characterize the extent of fat tissue by extracting and integrating epicardial fat information into the electroanatomic voltage maps, thereby helping to distinguish epicardial fat from scar tissue and to identify areas that are difficult to penetrate because of extensive epicardial fat (Fig. 27.5).

Endocardial unipolar voltage mapping can be beneficial to indicate the presence of intramural or epicardial scar (Fig. 27.6). While endocardial bipolar mapping is capable of assessing local electrograms originating from tissue adjacent to the recording electrodes (i.e., sub-endocardium), the broader field of view of unipolar mapping enables the recording of deeper tissue layers and the identification of nonendocardial scar located intramurally or epicardially. A reduction in endocardial unipolar electrogram amplitude (<8.3 mV in the LV and <5.5 mV in the RV), even in the absence of endocardial bipolar voltage abnormalities, has been shown to identify the presence of epicardial scar.¹

TRANSTHORACIC EPICARDIAL ABLATION

Radiofrequency Ablation

The ablation target is selected exactly the same way as the endocardial target. RF energy remains the primary ablative energy source for epicardial ablation. During standard RF energy application in the pericardial space, heating to the point of thrombus formation and charring is of less concern, because there is no potential for arterial embolization from the epicardial space; therefore higher temperatures ($>60^{\circ}\text{C}$) can be tolerated. However, standard RF ablation may not be as effective when delivered to the epicardium compared with lesions delivered to the endocardium. The lack of convective cooling of the ablation electrode in the epicardium (as opposed to convective cooling provided by the circulating blood during endocardial RF ablation) results in high electrode temperatures at low-power settings (≤ 10 W), limiting power delivery in the pericardial space and impairing lesion formation. In

Fig. 27.6 Endocardial (ENDO) and Epicardial (EPI) Voltage Map With Wall Thinning Segmentation in Patient With Ischemic Cardiomyopathy. (A) Endocardial bipolar voltage map shows low voltage with the presence of local abnormal ventricular activity (LAVA, light blue dots) at the basal posterolateral left ventricle. A peak-to-peak bipolar amplitude less than 1.5 mV is defined as low voltage, and less than 0.5 mV is defined as dense scar. (B) Endocardial unipolar voltage map is shown. A unipolar amplitude of less than 8.3 mV is defined as abnormal voltage. (C) Epicardial bipolar voltage map merged with the multidetector computed tomography model shows the location of low-voltage area and LAVA corresponding to the wall thinning segmentation (white area). Endocardial ablation successfully eliminated the posterolateral LAVA (in blue box), which had the following characteristics: low bipolar amplitude; location within the wall thinning segmentation; opposite endocardial low unipolar voltage; and presence of LAVA at the opposite endocardium. On the contrary, epicardial LAVA located mid-anteriorly (in red box) could not be eliminated by endocardial ablation and needed to be ablated epicardially. They were of higher bipolar voltage (>1.5 mV), located outside the wall thinning segmentation, and opposite endocardium with higher unipolar amplitude. (From Komatsu Y, Daly M, Sacher F, et al. Endocardial ablation to eliminate epicardial arrhythmia substrate in scar-related ventricular tachycardia. *J Am Coll Cardiol*. 2014;63:1416–1426.)

addition, the presence of epicardial fat (≥ 3.5 to 10 mm in thickness) between the ablation catheter and the targeted area can also represent an important obstacle to the effectiveness of ablation.⁴⁰

On the other hand, open and closed loop irrigated catheters allow the delivery of energy at power settings capable of creating larger and deeper (up to 5 mm) epicardial lesions than standard RF ablation, even in the absence of circulating blood in the pericardial space. Nonetheless, the presence of epicardial fat interposed between the catheter tip and the myocardial tissue only moderately attenuates the efficacy of cooled-tip ablation.

Optimal parameters for RF power titration and irrigation are not completely defined. With external irrigation, it is desirable to use lower flow rates than those used during endocardial mapping and ablation, to control fluid accumulation in the pericardial space. Commonly, the flow rate is set at 0 to 1 mL/min during mapping and at 10 to 17 mL/min during ablation, and is titrated as required to maintain the electrode temperature at less than 50°C. RF energy is commonly delivered at a power output of 30 to 50 W for 60 to 120 seconds. Monitoring for an impedance fall is commonly used to assess adequacy of power delivery.⁴¹

With open irrigation, an obligatory fluid volume will enter the pericardial sac and, unless intermittently or continuously evacuated, it gradually results in cardiac tamponade (as well as allowing the catheter to “float” in the fluid as opposed to maintaining contact with target epicardial tissue). Therefore intrapericardial fluid must be periodically drained after every few RF applications or every 15 to 20 minutes. This can be accomplished by intermittently removing the ablation catheter to allow aspiration from the pericardial sheath or placing a second pericardial catheter for drainage purposes. Alternatively, using a single sheath that is larger than the ablation catheter allows aspiration of fluid around the catheter from the side port, either intermittently or continuously (via attaching the side port to a suction bottle or gravity drain) without withdrawing the ablation catheter. Internally cooled RF ablation is an attractive choice for pericardial ablation as no fluid is infused and one need not worry about monitoring pericardial fluid throughout the ablation procedure.¹

At the completion of the mapping-ablation procedure, the ablation catheter is replaced by a pigtail catheter, which is gently aspirated to remove excess intrapericardial fluid, and to confirm the absence of bleeding. Evaluation of the pericardial space can be performed by intracardiac or transthoracic echocardiography, and by injecting 2 to 3 mL of contrast under fluoroscopy, to confirm complete drainage before removing the sheath. Methylprednisolone at 0.5 to 1.0 mg can be injected into the pericardial space prior to removal of the pigtail catheter to decrease the likelihood of postprocedure pericarditis. Generally, no major reaccumulation of pericardial fluid is observed following postprocedure draining of the pericardial fluid. The pigtail catheter and ablation sheath may be removed at the end of the procedure if there is no residual pericardial fluid, or kept inside the pericardial sac for as long as it is considered necessary. After controlling the bleeding, monitoring the patient with serial transthoracic echocardiography over the following 24 hours is recommended. Antibiotic therapy is administered postprocedure and as long as a drain is left in the pericardial space.

Cryoablation

Cryoablation has two potential advantages over RF ablation in the pericardial space: (1) the absence of cooling blood flow in the pericardial space enhances the formation of the cryolesion; and (2) cryoablation is less prone to cause coronary artery injury in experimental studies. However, human experience is limited, and more studies are needed to assess safety and efficacy. Cryoablation did not produce significantly larger lesions than irrigated RF in an animal model. Cryoablation is

commonly used in the operating room. Surgical cryoablation with hand-held surgical probes achieves much lower temperatures (less than -150°C) and generates larger lesions than small EP catheters.⁴⁰

Complications of Transthoracic Epicardial Ablation

Acute complications related to the epicardial approach have been reported in about 9% of cases at experienced centers, and can be related to the pericardial access procedure or to catheter manipulation or ablation within the pericardial space.^{21,46,47}

Pericardial Bleeding

Bleeding into the pericardial space is the most common complication, with pericardial bleeding of more than 80 mL observed in up to 7%, although cardiac tamponade and severe bleeding are infrequent.^{21,46,47}

Pericardial bleeding related to the epicardial access procedure is most commonly related to RV puncture. The coronary arteries are covered by epicardial fat along the AV groove and the interventricular septum, located away from the typical path of the access needle and, therefore, are less vulnerable to injury. Occasionally, disruption of epicardial fat can result in limited bleeding. Pericardial bleeding also can develop later during the mapping and ablation procedure. Laceration of the myocardium or epicardial vessels can occur during manipulation of the pericardial sheath or catheter, or as a result of RF ablation.

Several precautions are important to reduce the risk of pericardial bleeding. The epicardial access is the most important part of the procedure, and it is critical to employ extreme caution to avoid RV puncture and to promptly recognize such a complication before introducing the pericardial sheath.⁴¹ The use of the “needle-in-needle” technique can help reduce the risk of significant bleeding in the setting of inadvertent RV puncture.^{48,49} When the curved-tip Tuohy needle is used, directing the needle bevel away from the myocardium can help minimize the risk of cardiac perforation.³⁹ In addition, systemic anticoagulation is generally deferred (or reversed) at the time of epicardial access, and may be restarted only after verifying the absence of continued pericardial bleeding. Furthermore, careful catheter manipulation leading with a wire or ablation catheter before maneuvering the curl of the pericardial sheath can help reduce the risk of damage to the myocardium and epicardial vessels.^{41,49,50}

Approximately 10% to 20% of patients experience pericardial bleeding, particularly if inadvertent RV puncture has occurred. RV puncture is usually benign if only the needle or guidewire has entered the chamber in a patient who is not anticoagulated. The amount of blood drained from the pericardial space usually ranges from 20 to 300 mL. Thus, most of the time, the occurrence of hemopericardium does not preclude the continuation of the procedure, although repeated aspiration of the pericardial space may be required throughout the procedure.³⁹ However, major pericardial bleeding remains the most common complication (4.5%), occasionally requiring surgical intervention. Therefore precautions must be in place for managing severe bleeding, including the availability of appropriate surgical expertise.³⁹

When intrapericardial bleeding continues at the end of the epicardial procedure, a pericardial drain is left in place to allow for prompt management of effusion. The drain may be removed once the absence of reaccumulating effusion is verified on echocardiographic examinations over a 24-hour period.⁴¹ Importantly, late (within 1 to 2 days) pericardial effusions and cardiac tamponade requiring pericardiocentesis can develop in up to 5% of patients after removal of the pericardial sheath. Therefore leaving a pericardial drain in place for several hours also may be considered even in patients with no evidence of pericardial effusion or intrapericardial bleeding at the end of the procedure. However, such a practice should be balanced against the risk of pericarditis, infection, and patient discomfort associated with a persistent drain.⁵¹

Coronary Artery Injury

Coronary artery injury (laceration, intimal hyperplasia, intravascular thrombus formation, or vasospasm) can occur during epicardial mapping and RF ablation. The anterior and posterior septal and basal ventricular areas, where coronary arteries and veins are known to traverse, are the more dangerous zones. Coronary artery spasm has been reported during mapping in the pericardial space and can be induced by RF energy delivery close to the artery. Extrinsic compression of a coronary artery can also result from edema caused by nearby ablation.

Laceration of a coronary vessel manifests as intrapericardial bleeding. Acute occlusion of a coronary artery (by spasm or thrombosis) can manifest as chest discomfort (in nonanesthetized patients) or acute ST-T segment changes on the surface ECG.³⁷ Importantly, delayed (chronic) coronary damage may develop in the absence of detectable acute injury, and should be suspected in patients presenting with new ischemic symptoms following a prior epicardial ablation procedure.⁴¹

Prior to the delivery of RF energy, direct visualization of the relation between the ablation site and adjacent coronary arteries must be obtained, usually by coronary angiography performed with the ablation catheter at the target site. An absolute safe distance between the ablation site and epicardial artery has not been defined, and likely varies depending on the RF energy applied; the coronary artery diameter and flow; and the presence of overlying fat. Larger vessels are less susceptible to RF-induced injury due to the enhanced cooling effect of the greater blood flow. Based on available data and experience, a distance of at least 5 mm between the coronary artery and the ablating electrode (at any point of the cardiac cycle during coronary angiography and in at least two projections) is commonly accepted. Registering preprocedural CMR or CT images of the epicardial coronary arteries or contrast coronary angiographic images acquired during the procedure on the electroanatomic map can help anticipate the risk of coronary injury during the procedure. Close monitoring of the ST-T segment on the surface ECG is important for early detection of acute coronary spasm or occlusion.^{37,39}

Cryoablation appears to have less risk of coronary injury in animal models, but can still create occlusion and intimal damage when in close proximity, particularly to small vessels. Further confirmatory studies are warranted.

Phrenic Nerve Injury

The left phrenic nerve is susceptible to injury along its epicardial course adjacent to the lateral LV wall. The left phrenic nerve descends behind the left brachiocephalic vein and passes over the aortic arch, pulmonary trunk, and then with the pericardium over the LA appendage. From there it descends either anteriorly or anterolaterally along the fibrous pericardium over the LV to insert into the diaphragm behind the cardiac apex (eFig. 27.5). The left phrenic nerve frequently passes laterally over the obtuse margin of the LV (between the fibrous pericardium and the mediastinal pleural layers), close to the lateral vein and the left marginal artery and, in only a small percentage of cases, close to the left main coronary artery and great cardiac vein.^{37,39}

Often, the phrenic nerve courses through sites that might be considered appropriate ablation target sites, potentially limiting the safety and efficacy of ablation. Proximity to the phrenic nerve can be detected by high-output pacing (20 mA, pulse width of 2 milliseconds) to detect diaphragmatic stimulation on fluoroscopy, allowing its course to be marked on a 3-D map. The phrenic nerve can branch over the LV; thus simply noting sites at which phrenic capture occurred does not necessarily delineate the course of all branches. Further, the pacing output that would indicate a safe distance for epicardial ablation is not known. Also, it is important to recognize that detection by phrenic nerve capture

is prevented by the use of paralytic agents during general anesthesia. However, these drugs are typically used during the induction of anesthesia, and their effects have dissipated by the time ablation is being performed.⁴¹

Catheter ablation should be avoided at sites adjacent to the phrenic nerve. Alternatively, interposing a balloon, saline, or air in the pericardium between the ablation catheter and the phrenic nerve can allow safe RF ablation (see Chapter 32 for detailed discussion). Mechanical separation of the phrenic nerve from adjacent structures, using a large balloon, involves insertion of a wire through one of the existing pericardial sheaths to the vicinity of the ablation catheter positioned at the target epicardial site. Another method is to introduce a combination of saline and air into the pericardium to achieve a “controlled” hydro-pneumopericardium to increase the distance between the phrenic nerve and the ablation target area. The lack of phrenic nerve capture still should be confirmed to ensure sufficient separation, and monitoring of diaphragmatic movement on fluoroscopy during RF energy application remains important, even when no phrenic nerve capture is observed during pacing. Alternative energy sources, such as cryoenergy, have been used to prevent phrenic nerve injury. Cryomapping uses reversible phrenic nerve injury to determine when to avoid full cryoablation. However, data on the success of cryoablation in the pericardial space are limited.^{39,41}

Pericarditis

Pericarditis is the most common complication of epicardial ablation, occurring in the majority of the patients, and typically manifesting as precordial discomfort and friction rub. Postprocedural pericarditis often is mild and self-limiting, and resolves within a few days with oral nonsteroidal antiinflammatory agents. The degree of severity of pericardial inflammation appears to be related to procedural duration and the extent of epicardial RF ablation, as well as individual susceptibility to develop postprocedure pericarditis. Colchicine and oral steroids may be considered for the treatment of refractory cases. Of note, pericarditis can develop even when no epicardial ablation has been performed (i.e., only pericardial access and epicardial mapping).

It is important to note that inflammatory pericarditis can render the epicardial space percutaneously inaccessible for repeat procedures because of the development of adhesions. Several measures have been suggested to help reduce the severity of pericardial inflammation: (1) injection of steroids (e.g., 0.5 to 1.0 mg/kg of methylprednisolone or 2.0 mg/kg of triamcinolone) into the pericardial space at the conclusion of the procedure has been shown in animal models to be effective in reducing postprocedural pericarditis and adhesion formation; (2) postprocedural use of colchicine has been shown in small series to reduce postsurgical pericardial inflammation; (3) the administration of antibiotic therapy as long as the pericardial drain is in place; and (4) the removal of all pericardial sheaths and drains at the end of the procedure, except in cases of continued bleeding.^{39,41,52}

Intraabdominal Bleeding

Hemoperitoneum is a rare complication of epicardial ablation (<1%), and usually results from injury to the subdiaphragmatic vessels (e.g., epigastric artery) or abdominal viscera (liver and colon). The risk is higher when the angle of the needle is too steep (during the posterior approach to pericardial access), when the subxiphoid entry site is too caudal, and in the presence of hepatomegaly, gastric or colon distension, or left diaphragmatic paralysis.^{39,41,52}

Recognition of this complication can be difficult and requires a high index of suspicion. Abdominal pain (in nonanesthetized patients), rebound tenderness, progressive hypotension in the absence of a pericardial effusion, and unexplained decrease in hemoglobin should prompt

eFig. 27.5 Anatomical Course of the Right and Left Phrenic Nerves. (A) and (B) A right lateral view showing the right phrenic nerve just anterior to the superior vena cava (SVC). It follows an almost vertical path on the right border of the heart until it reaches the diaphragm. (C) and (D) A left lateral view of the heart and pericardium showing the left phrenic nerve emerging just behind the adipose tissue in front of the left pulmonary artery. It follows a roughly vertical direction and moves slightly anteriorly as it courses over the contour of the “obtuse margin” of the left lateral ventricular wall, and it moves slightly posterior as it reaches the diaphragm. The arrowheads delineate the pericardiovertebral ligaments in the posterior aspect of the pericardium. Ao, Aorta; LIPV, left inferior pulmonary vein; LJV, left jugular vein; LPA, left pulmonary artery; LSPV, left superior pulmonary vein; LV, left ventricle; RIPV, right inferior pulmonary vein; RPA, right pulmonary artery; RSPV, right superior pulmonary vein. (From Rodriguez ER, Tan CD. Structure and anatomy of the human pericardium. *Prog Cardiovasc Dis*. 2017;59:327–340.)

evaluation with abdominal ultrasound or (in hemodynamically stable patients) CT imaging.

Adequate palpation of the xiphoid process, manual pressure over the epigastrium to push away the liver from the path of the needle—using a shallow needle angle and avoiding sideways movements of the needle—can help prevent injury to subdiaphragmatic structures. Also, avoiding general anesthesia at the time of epicardial access can help early recognition of this complication as it can manifest as abdominal pain.^{39,41,52}

Pneumopericardium

Air can be introduced into the pericardial space during the exchange of sheaths and catheters. Although pericardial air can rarely cause cardiac tamponade, it can increase the transthoracic defibrillator threshold, which can be highly detrimental given the frequent need for electrical cardioversion of ventricular arrhythmias during those procedures. Air in the pericardial space tends to stay around the cardiac apex (which is located most anteriorly in the supine position) and is easily detected on fluoroscopy. Once detected, pericardial air should be evacuated, especially before the induction of ventricular arrhythmias that may require electrical cardioversion.³⁹ Careful sheath management is important to prevent air aspiration.⁴¹

Pleuritis

Symptomatic pleuritis (dyspnea, chest pain, and a pleural friction rub) is uncommon (1.5% in one case series), and usually responds well to antiinflammatory agents.^{39,41}

Outcome

Percutaneous access to the pericardial space has improved the outcome of catheter ablation in patients with scar-related VT. Percutaneous pericardial access can be obtained in more than 90% of patients who have not had prior cardiac surgery or clinical pericarditis, even in those who required repeated epicardial procedures. However, pericardial adhesions after cardiac surgery often prevent percutaneous access, although limited access is possible in some patients. A direct surgical approach to the pericardial space via a subxiphoid pericardial window or thoracotomy can achieve access in most patients.

In several reports, arrhythmia control with epicardial ablation was achieved in 63% to 78% of patients. The acute outcome is highly dependent on the target area. Epicardial ablation has a low yield (10%) in idiopathic VTs. Success rates are highest for VTs originating in the RV in patients with ARVC.^{46,47} However, it is important to note that these findings reflect practices at centers that specialize in arrhythmia management and may not be applicable to less experienced operators or centers. Careful patient selection is important, and the procedure should be performed by experienced operators with surgical backup.

The main reason for procedural failure is the inability to access or adequately map the epicardium, which is usually because of the presence of pericardial adhesions in patients with prior cardiac surgery or previous pericarditis. Even after successful epicardial access, RF ablation can be limited by close proximity to a coronary artery or the left phrenic nerve. In addition, failure to identify an epicardial target, or the presence of a thick layer of pericardial fat precluding adequate RF lesion formation, account for a significant proportion of procedural failures.

TRANSVENOUS EPICARDIAL MAPPING AND ABLATION

Coronary veins provide endovascular access to certain epicardial regions of the ventricles, and have been used for mapping and ablation of

arrhythmia foci or circuits that are deep within the myocardium or in the epicardium without having to access the epicardium percutaneously. Access through the great cardiac and anterior interventricular veins allows mapping over a wide area of the anterolateral LV wall, whereas access through the middle cardiac vein allows mapping over the inferior wall of the ventricles and posterior aspect of the interventricular septum. Up to 14% of patients with idiopathic VT or premature ventricular complexes (PVCs) have an epicardial site of origin identified within the coronary venous system, most often in the great cardiac vein.

Anatomical Considerations

Cardiac Venous System

The myocardium drains mainly by three groups of veins: (1) the CS and its tributaries, which return blood from almost the whole heart; (2) the anterior cardiac veins, which primarily drain the anterior regions of the RV and the right cardiac border, ending principally in the RA; and (3) the Thebesian venous network (*venae cordis minimae*), which is the smaller cardiac venous system and is composed of small venous branches made primarily of endothelial cells that are continuous with the lining of the cardiac chambers. The Thebesian veins drain the sub-endocardium and open directly into any of the four chambers but are more prominent on the right and, to a lesser extent, the LA and sometimes the LV.⁵³

Normally, the CS has five first-order tributaries: the great cardiac vein, the middle cardiac vein, the small cardiac vein, the posterior cardiac vein of the LV, and the oblique vein of the LA (oblique vein of Marshall) (Fig. 27.7). These tributaries then branch into second- and third-order tributaries. The CS returns the blood to the RA from the whole heart (including its septa) except the anterior region of the RV and small, variable parts of both atria and the LV.³⁵

The CS is a short trunk that begins as a continuation of the great cardiac vein, extending from the valve of Vieussens (which often marks the junction of the CS with the great cardiac vein) to the ostium of the CS as it terminates in the RA. The length of the CS varies from 15 to 55 mm and its diameter varies from 6 to 16 mm in its middle portion (depending on the loading conditions and the presence of underlying cardiac disease or prior cardiac surgery).⁵⁴

The CS invariably lies in the posterior aspect of the AV groove in the sulcus between the LA and LV and opens into the RA. The coronary sinus ostium (CS os) is 5 to 15 mm in diameter and is located on the posterior interatrial septum anterior to the eustachian ridge and valve and posterior to the tricuspid annulus. The CS os is guarded by the highly variable, crescent-shaped Thebesian valve, which can be grossly identified in approximately two-thirds of hearts. When present, the valve is located on the posterior aspect of the CS os and extends to the superior aspect in about half the cases. The orientation of the Thebesian valve favors cannulation of the CS from an anterior (ventricular) and inferior approach. Occasionally, the Thebesian valve nearly completely cover the CS os, with formation of fenestrations, and can hinder cannulation of the CS.^{54,55}

The anterior interventricular vein is the largest and most consistent of the cardiac veins. It drains a significant portion of the LV anterior wall and the interventricular septum, begins at the cardiac apex, and ascends toward the base of the heart in the anterior interventricular sulcus, parallel to the left anterior descending coronary artery. The phrenic nerve may lie close to the lateral branches of this vein. The anterior interventricular vein is the most anterior vein seen in the right anterior oblique (RAO) projection. At the base of the heart, near the bifurcation of the left coronary artery, the anterior interventricular vein turns laterally and becomes the “great cardiac vein,” which courses along the left AV groove (parallel to the left circumflex coronary artery) and wraps around the left side of the heart.⁵⁴

Fig. 27.7 Anatomy of the Coronary Venous System. (A) Posterior view of the heart showing the coronary sinus (CS) and its major venous tributaries. Note the cross-overs between veins and arteries. The obtuse marginal artery (oa) passes underneath the great cardiac vein (v) and then over the left obtuse marginal vein (ov). An inferior left ventricular vein (iv) ascends to enter the CS. Note the course of the ligament of Marshall (arrow) passing between the left atrial appendage (LAA) and the left upper and lower pulmonary veins (LU and LL). (B) Left lateral view of the heart showing the obtuse margin demonstrates the course of the v relative to the main branches of the left coronary artery. The arrow indicates the main stem of the left coronary artery. The oa passes underneath the v and is then crossed superficially by the ov. (From Ho SY, Sánchez-Quintana D, Becker AE. A review of the coronary venous system: a road less travelled. *Heart Rhythm*. 2004;1: 107–112.)

The great cardiac vein is joined by the LA oblique vein of Marshall and the posterolateral vein of the LV to form the CS (see Fig. 27.7). In addition to several smaller tributaries from the LA and ventricles, the great cardiac vein receives two main branches; namely, the large left marginal vein (along the lateral border of the heart), and the posterior cardiac vein of the LV (also known as the posterolateral vein).

The middle (or “posterior interventricular”) cardiac vein is the largest proximal tributary of the CS and is present in nearly all hearts. This vein drains the inferior walls of both ventricles and interventricular septum and courses with the posterior descending coronary artery in the posterior interventricular groove, joining the CS close to the RA orifice or, rarely, entering the RA directly.

The small cardiac vein receives blood from the back of the RA and RV, runs in the coronary sulcus between the RA and RV parallel to the right coronary artery, and empties into either the CS, the middle cardiac vein, or the RA.

Of all the branches of the coronary venous system, the anterior interventricular and middle cardiac veins are the two most consistently present branches. Unlike the middle cardiac vein, the great cardiac vein varies considerably in its course. Lateral and posterior venous branches together are seen in approximately 50% of human hearts, unlike the anterior interventricular and middle cardiac veins, which are seen in more than 90%.⁵⁶

The venous valves can hinder catheter access within the coronary venous system, especially the Thebesian valve, which may completely cover the CS os in a variety of forms or be imperforate. Other venous valves, like the valve of Vieussens, are often present at the entrances of the ventricular veins into the great cardiac vein, or at the entrance of a smaller vein into a larger vein. These tend to be flimsy endothelial

ridges but can present some resistance on probing or when trying to pass a catheter.

Left Ventricular Summit

The LV summit, the most superior portion of the LV myocardium, lies on the anterior mitral annulus epicardially, abutting on the left CS of Valsalva superiorly, laterally, and anteriorly. The LV summit represents the triangular region in the epicardial LVOT with its apex at the bifurcation of the left main coronary artery (between the left anterior descending and the circumflex coronary arteries) and its base formed by an arc connecting the first septal perforator branch of the left anterior descending coronary artery and the circumflex coronary artery (Fig. 27.8). The great cardiac vein bisects by the LV summit into superior (closer to the apex of the summit) and inferior regions.

The LV summit is the most common site of idiopathic epicardial LV arrhythmias, accounting for about 12% of idiopathic LV VTs. LV summit VTs are most commonly ablated within the great cardiac or anterior interventricular veins. However, while the inferior portion of the summit is usually accessible to epicardial catheter ablation, successful ablation in the superior region is frequently limited by the close proximity of the coronary arteries and the thick layer of epicardial fat that overlies the proximal portion of these vessels.¹⁵

Cardiac Crux

The cardiac crux is the posteroseptal region (the diaphragmatic aspect) of the heart where the AV, interventricular, and interatrial grooves form a roughly cross-shaped intersection, which represents the confluence of all four cardiac chambers with the CS in their nearest proximity. The “basal” crux area lies in proximity to the ostium of middle cardiac

vein, whereas the “apical” crux area lies near the posterior interventricular artery, which is more inferior and epicardial compared with the basal crux area. Hence, the apical crux is often not accessible from the proximal CS or the middle cardiac vein. VTs originating from the basal crux of the heart can be ablated via the middle cardiac vein, whereas ablation of apical crux VAs often requires the percutaneous subxiphoid epicardial approach.^{57,58}

Technical Considerations

Baseline CS venography is typically required to help delineate its anatomy and guide ablation. The great cardiac and the anterior interventricular

Fig. 27.8 Diagrammatic Representation of Left Ventricular Summit. The heart is viewed from a cranially angulated left anterior oblique perspective. The aorta is shown from which the left main coronary artery (LMCA) arises, branching to the left anterior descending (LAD) and circumflex arteries with their respective branches. The great cardiac vein (GCV) leaves the atrioventricular groove to become the anterior interventricular vein (AIV) that parallels the LAD. The LV summit is outlined by green dashes and is roughly bisected by the AIV. LAA, Left atrial appendage.

veins allow epicardial access to the anterior basal ventricular surface. The middle cardiac vein allows epicardial access to the inferior ventricular surface.

Mapping can be facilitated using small (2.5 Fr), flexible, multipolar electrode catheters introduced through a guiding catheter positioned at the CS os. The catheter can be positioned in different coronary venous branches to map different regions of the epicardial surface of the ventricles.

Once the ablation catheter is positioned at the target site, and before RF energy delivery, coronary arteriography is performed to outline the spatial relationship between the target vein and the adjacent coronary artery (see Fig. 23.19). Although the minimal safe distance between ablation sites and coronary arteries is not clear, ablation is not performed within 5 mm of a coronary artery (Fig. 27.9). In addition, pacing from the distal ablation electrode should be performed at an output of 20 mA. If diaphragmatic capture can be demonstrated, then ablation should not be attempted unless phrenic nerve injury can be avoided by physical displacement, as discussed earlier.

RF ablation within the coronary venous system is usually performed with a 3.5-mm open-irrigated-tip catheter at a power output of 15 to 25 W (with an irrigation flow rate of 30 mL/min) for up to 60 seconds (eFig. 27.6). If this catheter cannot be maneuvered to the ablation target site, a 5 Fr, 6 Fr, or 7 Fr ablation catheter may be used. For nonirrigated-tip catheters, the target temperature is usually set to 55°C to 60°C with a power output of 15 to 30 W. Impedance should be monitored during RF applications, and RF energy delivery should be stopped if impedance rises significantly.^{10,13,59,60}

Cryoablation can also be considered because it is not limited by high impedance. In fact, formation of the cryolesion is likely facilitated by the low blood flow in the coronary venous system. Freezing also seems less likely to damage adjacent coronary arteries. However, the cryocatheter often is difficult to maneuver in the coronary venous system.

Outcome

The outcome of the ablation procedure is a function of the proximity of the ideal target site to accessible portions of the coronary venous system as well as the ability to deliver an effective amount of ablative

Fig. 27.9 Idiopathic Ventricular Tachycardia (VT) Originating From the Left Ventricular Summit. Right anterior oblique (RAO) and left anterior oblique (LAO) fluoroscopic views during selective left coronary angiography with the ablation (Abl) positioned at the site of origin of focal VT originating from the left ventricular summit. The ablation catheter is positioned epicardially via the subxiphoid percutaneous approach. Note the proximity of the ablation catheter to the coronary sinus (CS) catheter. Ablation from the CS failed in terminating the VT. Ablation via the epicardial approach was not feasible due to the proximity of epicardial coronary arteries.

B

eFig. 27.6 Idiopathic Epicardial Ventricular Tachycardia (VT). (A) Surface electrocardiogram of a slow VT that was ablated from the coronary sinus (CS) after both endocardial and epicardial mapping failed to eliminate the VT. (B) Right anterior oblique (RAO) and left anterior oblique (LAO) fluoroscopic views of catheter location for VT ablation from the CS.

energy to the target site. When the VT substrate can be accessed via the coronary venous system and the cardiac vein is of sufficient size to allow adequate RF energy applications, elimination of VT can be achieved in most patients.

However, epicardial mapping and ablation via the coronary venous system has important limitations. Epicardial VT sites of origin can be identified only when the cannulated vessel happens to be in the region of the VT origin. In addition, catheter manipulation is limited by the anatomical distribution and size of these vessels. Currently available ablation catheters often are difficult to advance beyond the distal great cardiac vein or the proximal portions of the middle cardiac vein because of the tortuosity, sharp angulation, and small caliber of the distal veins. Furthermore, a conventional ablation catheter can potentially completely occlude a branch of the CS, preventing cooling of the ablation electrode and resulting in high impedance when RF energy is delivered. This markedly reduces the amount of power that can be delivered and may result in adherence of the ablation electrode to the wall of the vein. In fact, delivery of more than 10 to 15 W seldom is possible. An external saline-cooled ablation catheter allows more consistent delivery of RF energy, with less heating at the electrode-tissue interface.³⁵ RF energy delivery in a small venous branch can cause thrombotic occlusion or severe stenosis, such that it may be impossible, subsequently, to maneuver the catheter tip more distally in the vessel; thus ablation should not be performed unless the more distal portion of the vessel has been explored (or been shown to be too narrow to advance the catheter) and shown to have less attractive electrogram ablation site characteristics.

Coronary artery injury is an ever-present risk, especially near the proximal part of the anterior interventricular vein. Arterial injury, including thrombosis, medial necrosis, and hyperplasia, is inversely proportional to vessel diameter; there is little evidence of injury when vessel diameter exceeds 0.5 to 1.0 mm. Similar findings were reported for cryoablation. As noted, coronary angiography should be performed before delivering RF energy near or within a branch of the CS to determine whether there are any branches of the right or left coronary artery in proximity to the ablation site. Unfortunately, proximity to within 5 mm of a coronary artery (as defined by coronary angiography) can be observed in about three-quarters of patients, prohibiting RF ablation.^{10,12,13,59–61}

Despite the anatomical constraints, ablation of LV summit VTs via the coronary venous system has yielded success rates of approximately 70%. Using the coronary venous system for mapping and ablation can potentially result in a lower complication rate than the percutaneous pericardial approach because damage to the RV or extracardiac structures is less likely to occur. When endocardial ablation and ablation from within the coronary venous system is not feasible or unsuccessful, the percutaneous transthoracic epicardial approach may be considered. However, the latter approach to epicardial idiopathic VTs has very limited success rates. The close proximity of the coronary arteries and the thick layer of epicardial fat that overlies the proximal portion of coronary veins (“the inaccessible area” in the superior aspect of the LV summit) often prohibit successful ablation in a significant proportion of these patients. Also, the percutaneous epicardial approach often requires deeper levels of sedation, which can suppress idiopathic VT and hinder the mapping and ablation procedure.^{10,12,13,59,60,62}

PATHOPHYSIOLOGY

Hypertrophic cardiomyopathy (HCM) is characterized by a thickened but nondilated left ventricle (LV) in the absence of any other cardiac or systemic condition capable of producing the magnitude of hypertrophy evident (e.g., aortic valve stenosis, systemic hypertension, some expressions of athlete's heart, infiltrative or storage disorders), independent of whether obstruction to the left ventricular outflow tract (LVOT) is present.¹

Ventricular Hypertrophy

HCM is characterized by myocyte disarray. Cardiomyocytes in HCM become hypertrophied, enlarged, and distorted, which leads to disorientation of adjacent cells and arrangement in chaotic disorganized patterns (instead of the normal parallel cellular arrangement), forming circles or whorls around foci of connective tissue. Although the disorganized architecture is evident in the majority (95%) of patients dying from HCM, it is not specific to HCM, and it occurs in other syndromic causes of LV hypertrophy such as Noonan syndrome and Friedreich ataxia, congenital heart disease, hypertension, and aortic stenosis. Nevertheless, myocyte disarray in HCM is typically more extensive, occupying more than 5% of the total myocardium (including substantial portions of hypertrophied as well as nonhypertrophied LV myocardium), 33% of the ventricular septum, and 25% of the free wall.¹

Changes in myocyte architecture, myocyte hypertrophy, and expanded extracellular matrix composed of interstitial and replacement fibrosis lead to ventricular hypertrophy (Fig. 28.1). The degree and distribution

of LV hypertrophy vary markedly. LV hypertrophy can be asymmetrical or symmetrical. Asymmetrical septal hypertrophy is the most common variant and is associated with thickening of the basal anterior septum, which bulges beneath the aortic valve and causes narrowing of the LVOT region. However, isolated segmental hypertrophy can affect the LV apex (apical HCM) or any portion of the LV. The symmetrical form accounts for more than one-third of cases and is characterized by concentric thickening of the LV with small ventricular cavity dimensions. The morphological pattern of LV hypertrophy is not closely predictive of the severity of symptoms or prognosis.²

Diastolic Dysfunction

Diastolic dysfunction is a major pathophysiological abnormality in HCM. Myocardial hypertrophy, LVOT obstruction, myocardial ischemia, replacement scarring, extracellular fibrosis, and disorganized cellular architecture, as well as abnormal cellular energetics and calcium handling, all contribute to increased LV stiffness, reduced compliance, impaired relaxation, and diastolic dysfunction.³

Left Ventricular Outflow Obstruction

In the majority of patients, LVOT obstruction is precipitated by prolapse of the anterior leaflet of the mitral valve into the LVOT. This is related to systolic anterior motion (SAM) of the leaflet caused by systolic flow against the abnormally positioned mitral valve apparatus, independent of the presence of septal hypertrophy. Morphological abnormalities of the mitral valve (elongation of leaflets or accessory tissue), as well as papillary muscle abnormalities (hypertrophy, displacement, direct

Fig. 28.1 Pathological Features of Hypertrophic Cardiomyopathy (HCM). (A) Gross pathology showing markedly increased left ventricular wall thickness associated with HCM (*left*) as compared with normal cardiac morphology (*right*). (B) Histological sections stained with hematoxylin and eosin demonstrate myocyte disarray, where myocytes are oriented at bizarre and variable angles to each other, and increased myocardial fibrosis (*left*), the pathognomonic features of HCM. In contrast, normal myocardium demonstrates a very orderly arrangement of myocytes (*right*). Images are shown at $\times 10$ magnification. (From Ho CY. Hypertrophic cardiomyopathy. *Heart Fail Clin*. 2010;6:141–159.)

insertion into the anterior leaflet of the mitral valve), contribute to LVOT obstruction. In addition, septal hypertrophy can cause narrowing of the LVOT and promote obstruction caused by SAM. Almost always, SAM results in failure of normal leaflet coaptation and eccentric mitral regurgitation, with the jet directed laterally and posteriorly and predominating during mid and late systole.⁴ In addition, LVOT obstruction can result in reduced forward cardiac output, impaired LV relaxation, increased LV diastolic pressure, and myocardial ischemia.

In a minority of patients, obstruction occurs at the mid LV cavity level, caused by systolic apposition of hypertrophied (abnormally positioned) papillary muscle and LV wall. This form of obstruction may be associated with LV apical aneurysm (in up to 25% of patients).

LVOT obstruction is dynamic and is typically aggravated by maneuvers that decrease LV preload or afterload or increase contractility or heart rate. By convention, LVOT obstruction is defined as an instantaneous peak Doppler LVOT pressure gradient of 30 mm Hg or more at rest or during physiological provocation such as Valsalva maneuver, standing, and exercise. A gradient of 50 mm Hg or more is usually considered to be the threshold at which LVOT obstruction becomes hemodynamically important.

Myocardial Ischemia

Severe myocardial ischemia and even infarction can occur in HCM and is frequently unrelated to atherosclerotic epicardial coronary artery disease. Microvascular ischemia can be induced by a supply-demand mismatch. Increased demand is usually related to increased muscle mass, as well as increased wall stress due to elevated diastolic pressures.

Reduced supply can be precipitated by impaired vasodilator reserve, myocardial bridging and compression of intramural vessels, LVOT obstruction, abnormalities in intramural coronary arterioles, reduced capillary density relative to the myocardial mass, and microvascular dysfunction.¹ Bursts of focal myocardial ischemia result in repeated cycles of myocyte death with consequent replacement fibrosis and occasionally extensive scarring.

Ventricular Arrhythmias

The arrhythmogenic substrate responsible for ventricular tachycardia (VT) occurrence in HCM has not been completely defined. Myofibrillar disarray, as well as diffuse interstitial myocardial fibrosis or replacement scar (likely caused by focal ischemia), which potentially predispose to disordered conduction patterns and increased dispersion of electrical depolarization and repolarization, have been suggested as factors contributing to reentry and ventricular arrhythmogenesis.

Molecular Genetics

HCM is familial in approximately half of the cases and sporadic in the other half. The disease is transmitted as an autosomal dominant trait with variable expressivity and age-related (incomplete) penetrance. Sporadic cases can be due to *de novo* (new) mutations present in the proband (and absent in the parents), which then initiates a new familial disease. Furthermore, apparently sporadic cases can arise because of incomplete penetrance (absence of clinical expression despite the presence of a mutation) in a parent, inaccurate family history, or, less commonly, autosomal recessive inheritance.^{1,5}

Fig. 28.2 Cardiac Sarcomere Showing the Location of Known Hypertrophic Cardiomyopathy (HCM) Disease-Causing Genes. Prevalence for each of the 11 genes derived from studies in unrelated HCM probands with positive genotyping are shown in parentheses. Not shown are genes previously linked to HCM, but with lesser evidence for pathogenicity: alpha-myosin heavy chain, titin, muscle LIM protein, telethonin, vincalin/metavinculin, junctophilin 2. (From Maron BJ, Omman SR, Semsarian C, Spirito P, Olivetto I, Maron MS. Hypertrophic cardiomyopathy: present and future, with translation into contemporary cardiovascular medicine. *J Am Coll Cardiol.* 2014;64:89–99.)

There is a substantial diversity in the genetic causes of HCM. To date, more than 1500 disease-causing mutations have been identified in genes that encode proteins of the thick and thin contractile myofibrillar components of the cardiac sarcomere or the adjacent Z-disc (Fig. 28.2).⁶ These mutations have been localized to 11 sarcomere genes, 6 Z-disc genes, and 2 calcium-handling genes. Among these genes, mutations in *MYH7* (encoding beta-myosin heavy chain) and *MYBPC3* (encoding cardiac myosin binding protein-C) are the most common, each accounting for one-quarter to one-third of all cases (Fig. 28.3). Other sarcomeric mutations (including genes encoding troponin T, troponin I, alpha-tropomyosin, actin, regulatory light chain, and essential light chain) are less common. For each gene, several different mutations have been identified. Approximately 5% of patients with HCM have two or more mutations in the same gene or different genes.^{1,2} The vast majority of those mutations are missense (whereby a single normal amino acid is replaced for another). Frameshift mutations (insertion or deletion of one or more nucleic acids) are less common.

HCM is a complex and clinically heterogeneous disease that demonstrates remarkable diversity in disease course, age of onset, severity of symptoms, LVOT obstruction, and risk for sudden cardiac death (SCD). The characteristic diversity of the HCM phenotype is attributable to the *intergenetic* heterogeneity (with a variety of mutations encoding protein components of the cardiac sarcomere) and the *intra-genetic* heterogeneity (with multiple different mutations identified in each gene),

as well as the potential influence of modifier genes and environmental factors. Of note, no definitive genotype-phenotype relationships have been established between individual sarcomere mutations and the type or extent of morphological expression in HCM. The clinical outcome may not be predicted based on individual mutations, and the extent and distribution of LV hypertrophy can be dramatically different among relatives with the same disease-causing sarcomere mutation.⁷

EPIDEMIOLOGY AND NATURAL HISTORY

HCM is the most common genetic cardiovascular disease, with a prevalence of approximately 0.2% of the general population for the disease phenotype (i.e., LV hypertrophy recognized by echocardiography). Some investigators suggested that the combined prevalence of clinically expressed HCM and gene carriers (at risk for developing the disease phenotype) is likely higher and estimated that up to 0.6% of the population may carry disease-causing sarcomere mutations. However, this estimate has been debated.^{2,6,8,9}

The major causes of death in HCM are SCD, heart failure, and stroke. SCD accounts for approximately half of total mortality in patients with HCM. Progressive heart failure is responsible for the death of one-third of patients, usually after middle age (more than 55 years), and atrial fibrillation (AF)-associated stroke is responsible for the death of 13% of the patients at a higher age, usually older than 65 years.

(From Elliott PM, Anastakis A, Borger MA, et al. 2014 ESC guidelines on diagnosis and management of hypertrophic cardiomyopathy: the task force for the diagnosis and management of hypertrophic cardiomyopathy of the European Society of Cardiology [ESC]. *Eur Heart J*. 2014;35:2733–2779.)

Approximately 10% to 20% of individuals with HCM have a lifetime-increased risk for SCD, most likely resulting from VT and ventricular fibrillation (VF). SCD can be the first manifestation of the disease. HCM is the most common cause of SCD in the young and is the leading single cause of SCD in competitive athletes in the United States, accounting for approximately one-third of athletic field deaths in high school and college students engaged in organized sports. Although SCD occurs most often in adolescents or adults younger than 35 years, it can occur at any age. However, SCD is uncommon in young children and very uncommon in patients older than 60 years, even among those with established risk factors.²

Individuals with HCM who are at the highest risk can have a greater than 3% to 5% annual rate of SCD. However, studies on broader-based populations suggest that the prognosis is typically more favorable and most affected individuals probably achieve a normal life expectancy with little functional disability. Individuals in the general HCM population have 0.5% to 1% annual risk of SCD and 1.4% annual total cardiovascular mortality.²

Compared with patients with LVOT obstruction, HCM patients without the capacity to physiologically generate LVOT obstruction appear to have a more favorable prognosis, with lower risk for developing most HCM-related complications, including progressive heart failure, SCD, or embolic stroke, and with an HCM-related mortality rate of 0.5% per year.¹⁰

Approximately 2% to 9% of HCM patients progress to end-stage (or “burned-out”) phase of the disease, marked by LV systolic dysfunction (ejection fraction less than 50%) and occasionally progressive LV dilatation and wall thinning. Progression to end-stage disease is likely related to extensive myocardial scarring, and it can occur at a young age (approximately 50% of the patients are less than 40 years of age). The only known predictor of end-stage HCM is a family history of end-stage disease. The transition to end-stage HCM carries an ominous prognosis; over a 3-year interval, approximately two-thirds of these patients die secondary to severe heart failure or SCD or require cardiac transplantation. Posttransplantation survival is favorable (75% at 5 years; 60% at 10 years).²

Contemporary medical and invasive management strategies, including implantable cardioverter-defibrillator (ICD) implantation and septal reduction procedures, as well as heart transplantation, have significantly altered the natural history of HCM, currently resulting in an annual disease-related total mortality rate of only 0.5%.¹¹

Men are overrepresented in published HCM patient cohorts, suggesting a higher penetrance of HCM-causing mutations in male patients. Moreover, at the time of diagnosis, women were on average 9 years older than men. In addition, the extent of myocardial fibrosis is higher in male patients; nonetheless, diagnosed women tend to be more symptomatic, more likely to have LVOT obstruction, and fare worse than men. There appears to be no gender impact on the risk of

SCD or the incidence of atrial or ventricular arrhythmias in patients with HCM.³

CLINICAL PRESENTATION

The clinical presentation of HCM is characterized by extreme variability in disease course, age of onset, severity of symptoms, and risk for SCD. Many patients are either asymptomatic or mildly symptomatic, and the diagnosis is frequently made as a result of family screening, detection of a murmur during routine examination, or the identification of an abnormal electrocardiogram (ECG). The majority of patients present during adolescence or young adulthood, but symptoms can develop at any age. Symptoms can be related to LV diastolic dysfunction, LVOT obstruction, myocardial ischemia, cardiac arrhythmias, or a combination of those mechanisms. Nonetheless, there is no predictable correlation between clinical symptoms and the presence or severity of LVOT obstruction or the extent of LV hypertrophy. The extent of LV hypertrophy does not typically change once early adulthood is reached.

Heart Failure

Variable degrees of heart failure occur in more than 50% of HCM patients. Shortness of breath, particularly exertional, is the most common symptom of HCM. The most common mechanism of heart failure is LVOT obstruction, but diastolic LV dysfunction can precipitate heart failure symptoms even in the absence of LVOT obstruction. Although left ventricular ejection fraction (LVEF) is typically preserved or even hyperdynamic, a minority of patients can progress to the end-stage phase of HCM, marked by LV systolic dysfunction and occasionally progressive LV dilatation and wall thinning. These patients can develop advanced heart failure symptoms of pulmonary and systemic venous congestion (orthopnea, paroxysmal nocturnal dyspnea, edema), which can become refractory to medical therapy and require cardiac transplantation.

Left Ventricular Outflow Obstruction

Approximately 20% to 30% of individuals with HCM demonstrate LVOT obstruction at rest, and a similar proportion exhibit LVOT obstruction only in response to maneuvers that decrease LV preload or afterload or increase contractility or heart rate ("dynamic" LVOT obstruction). LVOT obstruction is the most common cause of heart failure symptoms (dyspnea) in HCM patients but can also precipitate chest pain and syncope. LVOT gradients and related symptoms can be aggravated by exercise, dehydration, low blood volume, large meals, excess alcohol intake, and certain drugs (such as vasodilators, diuretics, digoxin). On physical examination, LVOT obstruction can manifest as a dynamic ejection systolic murmur (with increasing intensity in response to Valsalva maneuver, during or immediately after exercise, or on standing), mitral regurgitation murmur, and an arterial pulse with bisferiens contour. Squatting reduces the LVOT gradient and intensity of the systolic murmur.

Myocardial Ischemia

Exertional chest discomfort occurs in 25% to 30% of patients with HCM, usually in the setting of a normal coronary arteriogram, and likely is related to microvascular angina caused by supply/demand mismatch. Some patients also experience atypical chest pain, frequently precipitated or worsened by heavy meals. A subset of patients can also have obstructive epicardial coronary artery disease, which heralds an adverse outcome.

Syncope

Syncope occurs in 15% to 25% of patients with HCM. Another 20% complain of presyncope. Different mechanisms can precipitate syncope

in HCM patients, including arrhythmias (VT or AF), neurocardiogenic syncope, and hypotension during exercise caused by LVOT obstruction or by abnormal vascular responses. Changes in LV loading conditions during exercise, heavy meals, and dehydration often provoke symptoms.^{12,13}

Syncope typically occurs in younger patients with small LV end-diastolic volume. Syncope during exertion is more common in patients with LVOT obstruction than in patients without obstruction, whereas unexplained syncope at rest and neurally mediated syncope do not appear to be related to LVOT obstruction.

Neurocardiogenic syncope is characterized by classic prodromal symptoms, including lightheadedness, warmth, nausea, and tunnel vision. Individuals tend to slump to the ground rather than drop suddenly. Syncope is brief, and patients awake nauseous and exhausted. On the other hand, syncope during exertion, or immediately following palpitation or chest pain, suggests a cardiac mechanism. Ventricular arrhythmias are an uncommon cause of syncope but should be suspected when loss of consciousness occurs suddenly, without a prodrome, particularly when it occurs at rest or on minimal effort. Occasionally, paroxysmal atrial arrhythmias with rapid ventricular rates can precipitate syncope, particularly in patients with preserved atrial function and high filling pressures.

Atrial Fibrillation

AF is the most common arrhythmia observed in HCM, with an annual incidence of approximately 1% to 2% and a prevalence of approximately 20% to 25%.¹⁴ The incidence of AF increases with age, occurring most frequently after the age of 55 years (but approximately 10 years earlier than in the general population), and is very uncommon in patients younger than 25 years. The high incidence of AF in HCM is likely related to increased left atrium (LA) atrial pressure and size, caused by LV diastolic dysfunction. In fact, LA size is one of the most important determinants of AF occurrence. In addition, the extent of LV myocardial fibrosis (as determined by cardiac magnetic resonance [CMR]) and interatrial conduction delay (as reflected by longer P wave duration) seem to correlate with higher incidence of AF. Furthermore, certain HCM mutations appear to predispose to AF, possibly by causing intrinsic atrial myopathy.³ Notably, the presence or severity of LVOT obstruction does not appear to be associated with an increased incidence of AF.

Due to the underlying ventricular hypertrophy and impaired relaxation, rapid ventricular rates and loss of atrial contribution to ventricular filling during AF are usually poorly tolerated. In fact, paroxysmal episodes of AF can precipitate acute clinical deterioration, resulting in syncope or acute heart failure, particularly in patients with severe diastolic dysfunction and LVOT obstruction. In addition, AF in HCM is associated with increased risk of stroke and thromboembolic complications (eightfold increase in risk compared with HCM patients without AF), with a prevalence and annual incidence of 27.1% and 3.8%, respectively.¹⁵ AF is associated with a fourfold increase in HCM-related mortality, predominantly driven by the higher occurrence of heart failure and stroke-related death. Of note, AF does not appear to be associated with an increased risk of SCD.

Ventricular Arrhythmias

The predominant arrhythmia syndrome associated with HCM is sudden cardiac arrest, presumably due to polymorphic VT or VF. SCD occurs with an annual rate of approximately 6% in referral-based populations and 1% in community-based studies. However, certain patient subgroups can have much higher rates, surpassing the American College of Cardiology/American Heart Association (ACC/AHA) guideline definition of high risk for SCD ($\geq 2\%$ annual risk).

HCM is the most common cause of SCD in young people, including competitive athletes, in the United States. SCD occurs throughout life,

with a peak in adolescence and young adulthood (less than 35 years of age), and can be the initial disease presentation. Although SCD occurs most commonly during mild exertion or sedentary activities, an important proportion of such events is associated with vigorous exertion. In HCM patients with ICDs, more than half of the ventricular arrhythmias identified and appropriate ICD therapies were associated with moderate or competitive physical activity.¹⁶

Ambulatory cardiac monitoring frequently reveals premature ventricular complexes (PVCs) (in more than 80% of patients) and nonsustained VT (25% to 30%). Nonsustained VT is associated with severity of LV hypertrophy and symptom class. Stable sustained monomorphic VT is rare but has been observed particularly in patients with LV apical aneurysms. Among ICD recipients for primary or secondary prevention, appropriate ICD therapies in response to ventricular arrhythmias occur in approximately 5.5% of HCM patients per year.¹

INITIAL EVALUATION

The initial evaluation is aimed at establishing the diagnosis of HCM, excluding other potential causes of LV hypertrophy, assessing the extent of the disease, and evaluating the underlying mechanisms of symptoms (e.g., chest pain, syncope), as well as risk stratification for SCD.

Clinically, HCM in adults is defined by a wall thickness ≥ 15 mm in one or more LV myocardial segments (as measured by echocardiograph or CMR), in the absence of an identifiable hemodynamic cause (such as coronary artery disease, valvular heart disease, hypertension, or congenital heart disease) capable of producing the observed myocardial abnormality (Fig. 28.4). With borderline wall thickness (13 to 14 mm), the diagnosis of HCM requires evaluation of other features including family history, noncardiac symptoms and signs, ECG abnormalities, laboratory tests, and multimodality cardiac imaging.

It is important to understand that any degree of wall thickness is compatible with the presence of the HCM genetic substrate. Because of the age-dependent and incomplete penetrance, many mutation carriers may not exhibit phenotypic expression (i.e., LV hypertrophy). These individuals are usually referred to as being “genotype positive/phenotype negative” or as having “subclinical HCM.”¹

Fig. 28.4 Echocardiographic Appearance of Hypertrophic Cardiomyopathy (HCM). Parasternal long-axis view from a patient with HCM demonstrating asymmetrical septal hypertrophy. The interventricular septum (marked by arrow) measures 2.1 cm, the posterior wall measures 0.99 cm. Ao, Aorta; IVS, interventricular septum; LA, left atrium; LV, left ventricle; MV, mitral valve; PW, posterior wall; RV, right ventricle.

Electrocardiography

The ECG is abnormal in more than 90% of patients with HCM and in 75% of asymptomatic relatives. An abnormal ECG in the young is a sensitive—although nonspecific—marker of early disease expression.¹

The surface ECG in HCM patients can show a wide variety of abnormal patterns; however, ECG abnormalities do not correlate with severity or pattern of LV hypertrophy, and no particular ECG pattern is characteristic or predictive of future events. LA enlargement, repolarization abnormalities (ST-T changes including marked T wave inversion), and deep and narrow Q waves (mimicking myocardial infarction, most commonly in the inferolateral leads) are the most frequent ECG findings and may precede manifest evidence of LV hypertrophy (Fig. 28.5). Voltage criteria for LV hypertrophy alone are nonspecific and are often seen in normal young adults. Giant negative T waves in the midprecordial leads are characteristic of hypertrophy confined to the LV apex.

Ambulatory Cardiac Monitoring

Ambulatory 24-hour (Holter) cardiac monitoring is recommended as part of the initial evaluation for asymptomatic and symptomatic HCM patients because the detection of ventricular tachyarrhythmias is important for risk stratification. PVCs occur during ambulatory ECG monitoring in the vast majority of patients, nonsustained VT in 25% to 30%, and paroxysmal supraventricular arrhythmias in 38%. It is reasonable to perform serial 24-hour Holter monitoring every 1 to 2 years in patients who are stable and had no VT on previous evaluation.¹ Reevaluation with ambulatory cardiac monitoring is also recommended to evaluate patients with palpitations, lightheadedness, or syncope.

Echocardiography

Echocardiography is central to the diagnosis of HCM (see Fig. 28.4). Comprehensive transthoracic echocardiography should be performed in the initial evaluation of all patients with suspected HCM, as well as during follow-up, particularly when there is a change in the clinical status or symptoms. Echocardiography can help assess the nature, distribution, and extent of hypertrophy, systolic and diastolic function, LVOT obstruction, and identify apical aneurysms.¹

Exercise Testing

Exercise testing can help assess blood pressure responses to exercise. In addition, combining exercise testing with Doppler echocardiography is useful for determining the presence of dynamic LVOT obstruction. Metabolic stress testing (i.e., determination of maximum oxygen consumption) may be considered when a more precise assessment of functional capacity is clinically required.¹

Electrophysiological Testing

Invasive electrophysiological (EP) testing is indicated in patients with documented or suspected supraventricular or ventricular arrhythmias when catheter ablation is being considered. However, programmed ventricular stimulation to evaluate inducibility of ventricular arrhythmias has little predictive value for SCD in HCM and is not recommended for SCD risk stratification. Similarly, the routine use of EP study for evaluation of patients with syncope is not recommended.¹

Cardiac Magnetic Resonance

CMR should be considered when the echocardiogram is inconclusive or suboptimal. CMR also can provide valuable additional information in the diagnosis of HCM, including more precise LV wall thickness measurements, defining extent and location of myocardial scars, and identification of regional wall hypertrophy and LV apical aneurysms.

Delayed hyperenhancement magnetic resonance images from a patient with symptomatic obstructive HCM demonstrating areas of extensive scarring in the basal interventricular septum (A, arrow). Notice also the areas of patchy scarring in the posterior wall (B, arrow). The image on the left is a short-axis view, and the image on the right is a three-chamber view. LV, Left ventricle. (From Kwon DH, Smedira NG, Rodriguez ER, et al. Cardiac magnetic resonance detection of myocardial scarring in hypertrophic cardiomyopathy: correlation with histopathology and prevalence of ventricular tachycardia. *J Am Coll Cardiol.* 2009;54:242–249.)

In addition, CMR can help differentiate apical HCM from LV noncompaction.² Furthermore, late gadolinium enhancement on contrast CMR can help to define the presence, severity, and distribution of myocardial fibrosis (Fig. 28.6). Late gadolinium enhancement is present in 65% of HCM patients, typically in a patchy mid-wall pattern in areas of hypertrophy. More extensive late gadolinium enhancement can be associated with more severe disease and worse prognosis.¹⁷

Genetic Testing

Given the lack of strong evidence of specific genotype-phenotype associations, the knowledge of the underlying gene and mutation has a limited role in risk stratification and management of the individual patient. Nonetheless, genetic testing is recommended for patients with established clinical diagnosis of HCM in whom mutation-specific confirmatory testing would help to confirm or exclude the diagnosis in

at-risk family members. Similarly, postmortem genetic analysis should be considered in deceased patients with pathologically confirmed HCM, to enable cascade genetic screening of their relatives.^{1,5}

Genetic analysis should include the most commonly implicated sarcomere protein genes. Overall, the yield of genetic testing in probands with HCM is approximately 60% because some genes causing HCM have not yet been identified and are absent from testing panels. The likelihood of finding a causal mutation depends on patient selection, being highest in patients with familial disease and lowest in older patients and individuals with nonclassical features.⁵

Genetic testing is not recommended as a diagnostic test of HCM in patients with nondiagnostic clinical features (e.g., athletes and those with hypertension) because the absence of a sarcomere mutation cannot rule out familial HCM. Furthermore, finding variants of uncertain significance are difficult to interpret.

Genetic counseling is recommended for all patients with HCM, to explain the potential risks and benefits and enhance understanding of the medical and familial implications of test results. Even when genetic testing is not undertaken, genetic counseling about the potential for familial transmission of HCM is medically important.^{1,5}

DIFFERENTIAL DIAGNOSIS

Phenocopies of Hypertrophic Cardiomyopathy

LV hypertrophy is a relatively nonspecific phenotype that may reflect the final common pathway for a number of different disease processes. It does not indicate etiology or reveal underlying pathophysiology. In infants, older children, and young adults, LV hypertrophy mimicking sarcomeric HCM is often associated with congenital malformations and syndromes (e.g., Noonan, LEOPARD, and Costello syndromes), inherited metabolic storage disorders (e.g., Anderson-Fabry disease, Danon disease, PRKAG2 syndrome, Pompe disease, Forbes disease), mitochondrial cytopathies (e.g., MELAS, MERRE, LHON), and neuro-

muscular diseases (e.g., Friedreich ataxia). These clinical entities are distinct from HCM caused by sarcomere protein mutations, despite the shared feature of LV hypertrophy (Table 28.1).^{5,18}

The incidence of phenocopy in patients with the clinical diagnosis of HCM is estimated at 5% to 10%. The distinction between sarcomeric HCM and its phenocopies is important, given the differences in the inheritance pattern, natural history, prognosis, and, in some cases, management strategies. Both cardiac and extracardiac traits contribute to clinical recognition of phenocopies. A phenocopy should be suspected when an atypical feature of classic HCM or multiorgan involvement is present. HCM can be distinguished from these disorders by dysmorphological examination, neuromuscular examination, metabolic screening, family history, and genetic testing (Table 28.1).

It is recommended to limit the use of the term *hypertrophic cardiomyopathy* or *HCM* to those patients in whom overt disease expression (with LV hypertrophy) appears to be confined to the heart and the definitive mutation is either one of a gene encoding proteins of the cardiac sarcomere or alternatively when the genotype is unresolved using

current genetic testing. On the other hand, LV hypertrophy that occurs in the context of multisystem disorders or nonsarcomeric genetic diseases is considered a phenocopy of the sarcomeric HCM and is described as “LV hypertrophy” rather than “hypertrophic cardiomyopathy.”¹

Athlete's Heart

Intensive and long-term athletic training can lead to constellation of physiological cardiovascular adaptations, including increased LV wall thickness and cavity size. Such remodeling, termed *athlete's heart*, permits enhanced filling of the LV in diastole and augmentation of stroke volume, allowing generation of a large and sustained cardiac output even at rapid heart rates. Compared with nonathletes, athletes have 15% to 20% greater LV wall thickness and 10% to 15% larger LV size. However, the absolute increases in LV wall thickness are usually modest and fall within the normally accepted range for the general population.^{19,20}

A minority (approximately 2%) of adult male athletes, predominantly those involved in endurance sports, demonstrate extreme physiological adaptation with LV wall thickness measurements of 13 to 15 mm, which overlaps with measurements observed in morphologically mild HCM. Although the majority of individuals with HCM have a mean LV wall thickness of 18 to 20 mm, 8% have milder degrees of LV hypertrophy,

especially in the setting of incomplete phenotypic expression of HCM during periods of rapid growth.¹⁹

The distinction between physiological LV hypertrophy and HCM is critical; an incorrect diagnosis has far-reaching implications. A false-positive diagnosis can potentially lead to erroneous disqualification from competition, whereas a false-negative diagnosis may result in devastating SCD, especially when one considers that HCM is the most common cause of exercise-related SCD in young athletes.

In the majority of athletes, differentiating physiological from pathological LV hypertrophy is possible using ECG and echocardiography. If the diagnosis is still uncertain, CMR, cardiopulmonary exercise testing, and genetic testing can provide further information (Table 28.2).^{19,21}

Demographics

The magnitude of expected LV wall thickening varies with age, gender, ethnicity, body surface area, and degree and type of athletic training. Athletes participating ultra-endurance sport with a high isotonic and isometric component such as rowing, canoeing, swimming, cycling, and ultra-endurance running exhibit the greatest increases in LV wall thickness. On the other hand, athletes participating in pure isometric sports (such as weightlifting or wrestling) rarely exhibit LV wall thickness

TABLE 28.2 Differences Between Hypertrophic Cardiomyopathy and Athlete's Heart

	Favors Athlete's Heart	Favors HCM
Age	—	<16 years
Sex	Male	Female
Ethnicity	Black	—
Type of sport	High-intensity endurance sport	Low-intensity sport
Family history of HCM or SCD	Absent	Present
Symptoms	Absent	Dyspnea, chest pain, presyncope, syncope, palpitations, fatigue
Physical examination	Unremarkable	Dynamic systolic murmur
Electrocardiogram	No abnormalities	Pathological Q waves
	Isolated LVH criteria	ST-segment depression
		T-wave inversions in anterolateral leads
		LBBB
LV hypertrophy	Symmetrical, uniform	Asymmetric
		LVWT >15 mm
		LVWT >13 mm in female and adolescent athletes
Echocardiogram	Normal or improved LV diastolic function	LV diastolic dysfunction
	LVEDD >55 mm	LVEDD <45 mm
	Balanced RV dilation	LVOT obstruction
		Disproportionate LA dilatation
Cardiopulmonary exercise testing	VO _{2max} >45 mL/kg/min	VO _{2max} lower than predicted
	VO _{2max} >120% of predicted	
Gadolinium-enhanced CMR	Absence of late enhancement or nonspecific pattern	Typical late enhancement
Deconditioning	Reduction in LVWT by 2–5 mm	No reduction in LVWT
Genetic testing	Negative	Positive for HCM-causing sarcomere mutation

CMR, Cardiac magnetic resonance; HCM, hypertrophic cardiomyopathy; LA, left atrium; LBBB, left bundle branch block; LV, left ventricular; LVEDD, left ventricular end-diastolic diameter; LVH, left ventricular hypertrophy; LVOT, left ventricular outflow tract; LVWT, left ventricular wall thickness; RV, right ventricle; SCD, sudden cardiac death.

exceeding 12 mm. In addition, an athlete's body surface area of more than 2.0 m² increases the probability of identification of LV hypertrophy.

Black male athletes appear to be more prone to develop greater degrees of physiological LV hypertrophy than are white athletes. In one report, 18% of black athletes exhibited LV wall thickness exceeding 12 mm compared with only 4% of white athletes of similar age, size, and sporting caliber. In addition, 3% of the black athletes, but none of the whites, exhibited LV wall thickness of 15 to 16 mm.²² In another report, LV wall thickness exceeding 12 mm was observed in 3.3% black female athletes (all 12 to 13 mm), but none of their white counterparts had LV wall thickness exceeding 11 mm.

Furthermore, LV wall thickening exceeding 12 mm is extremely rare in female or adolescent athletes. Athletes with LV wall thickness of more than 12 mm are invariably males older than 16 years, and the identification of such degrees of LV hypertrophy in a female athlete, any adolescent athlete aged younger than 16 years, or any athlete participating in low-intensity endurance sports is highly suggestive of HCM.

Electrocardiography

The ECG changes that develop as part of the cardiovascular adaptation in an endurance athlete include sinus bradycardia, increased QRS voltage, tall peaked T wave, J point elevation, and U waves. However, pathological Q waves, left axis deviation, and T wave inversion strongly favor a diagnosis of HCM.²¹

Although both LV hypertrophy and HCM are associated with large QRS complexes in LV leads, *isolated* QRS voltage criteria for LV hypertrophy are commonly observed in athletes but occur in only 2% of individuals with HCM. In contrast, pathological Q waves, ST segment depression, deep T wave inversions (greater than 0.2 mV), and left bundle branch block (LBBB) are highly suggestive of HCM.

Echocardiography

Physiological LV hypertrophy is homogeneous and associated with concomitant LV dilation and normal indexes of diastolic function. In contrast, individuals with HCM often show asymmetrical patterns of LV hypertrophy, small chamber size, abnormal indexes of LV diastolic filling, and impaired relaxation, independent of whether heart failure or outflow obstruction is present. LVOT obstruction and SAM of mitral valve leaflets are inconsistent with athlete's heart and strongly suggest HCM.²⁰

LV cavity size is the single most important discriminator between physiological LV hypertrophy and HCM. More than 90% of athletes with physiological LV hypertrophy have concomitant enlargement of the LV cavity (LV end-diastolic dimension of 55 to 65 mm). In contrast, the majority of patients with HCM have a small LV cavity (LV end-diastolic dimension less than 45 mm).²¹

Cardiac Magnetic Resonance

CMR provides accurate characterization of the severity, extent, and distribution of myocardial hypertrophy, particularly of apical LV segments. In addition, the identification of myocardial fibrosis (as indicated by late gadolinium enhancement) favors the diagnosis of HCM.²¹

Cardiopulmonary Exercise Testing

Elite athletes have efficient LV filling and stroke volume augmentation during exercise. Consequently, during cardiopulmonary exercise testing, athletes achieve high peak oxygen consumption (VO₂) values that exceed normal levels. In contrast, patients with HCM have low peak VO₂ (irrespective of symptoms) secondary to impaired myocardial relaxation and failure to augment stroke volume effectively during exercise. Thus a peak VO₂ of more than 50 mL/kg per minute or more than 120% of

that predicted for age and size favors physiological LV hypertrophy over HCM. Of note, cardiopulmonary exercise parameters were found to reliably distinguish HCM from endurance athletes (middle/long distance runners) but not from strength trained athletes (weightlifters).²¹

Genetic Testing

Genetic analysis has a high positive predictive value but a low negative predictive value. The identification of a disease-causing sarcomere mutation in an athlete with a maximal LV wall thickness in the “gray zone” establishes the diagnosis of HCM. However, there is significant potential for false-negative test results in which a HCM diagnosis cannot be excluded.²¹

Deconditioning

Deconditioning (detraining) can help to differentiate physiological from pathological LV hypertrophy. Elite athletes with LV hypertrophy may show regression in wall thickness measurements (of approximately 2 to 5 mm) on serial echocardiography or CMR over short periods (approximately 3 months) of deconditioning. In one report, complete normalization of LV wall thickness occurred in elite athletes after 5.6 ± 3.8 years of deconditioning. Reverse LV remodeling (wall thickness reduction) with detraining is inconsistent with pathological hypertrophy of HCM. Compared with echocardiography, CMR can be more accurate for comparison of serial LV wall thickness measurements.^{20,21}

RISK STRATIFICATION

The incidence of SCD in an unselected HCM patient population is approximately 0.7% per year. However, certain subgroups of patients can have a greater than 3% to 5% annual risk for SCD. Because ICD implantation offers the only effective means of preventing SCD, it is critical to identify high-risk patients who are appropriate for prophylactic ICD therapy. Risk stratification models currently used to guide ICD implantation in HCM patients are based on observational, retrospective cohort studies that have determined the relationship between clinical characteristics and prognosis. Randomized trials or statistically validated prospective prediction models are lacking.^{1,5}

Established Risk Markers

Cardiac Arrest/Sustained Ventricular Arrhythmias

Patients who survived a cardiac arrest or experienced an episode of spontaneous sustained VT have the highest risk for subsequent cardiac events (approximately 10% per year), with 41% risk of SCD or ICD-discharge in 5 years and 33% mortality in 7 years. Nonetheless, some of these patients may have no recurrence of cardiac events for years or decades.^{1,5}

Stable sustained monomorphic VT is rare but can occur particularly in patients with midventricular obstruction or apical LV aneurysms. The recurrence rate of VT in HCM patients is relatively high (56%), and electrical storm can occur.

Importantly, inducibility of ventricular arrhythmias with programmed ventricular stimulation has little predictive value for SCD in HCM and has no advantage over the traditional noninvasive risk stratification.

Nonsustained Ventricular Tachycardia

Ambulatory cardiac monitoring frequently reveals PVCs (in more than 80% of patients) and nonsustained VT (25% to 30%). Nonsustained VT is more frequent in patients with pronounced LV hypertrophy, LVOT obstruction, LA enlargement, and AF. Nonsustained VT appears to be associated with severity of hypertrophy and symptom class.

The predictive value of nonsustained VT detected on 24-hour ambulatory monitors or during stress testing remains controversial. Some

studies demonstrated that nonsustained VT is associated with an eightfold increase in SCD risk, but with a low (26%) positive predictive value. Rare, isolated brief episodes of nonsustained VT, especially in patients older than 30 years, do not appear to predict SCD risk. On the other hand, prolonged (greater than 7 to 10 beats), fast (greater than 200 beats/min), or repetitive episodes of nonsustained VT, particularly in younger patients (less than 30 years), may predict a high arrhythmogenic substrate for SCD. Until more data are available, it is probably more appropriate to consider duration, rate, and frequency of nonsustained VT, rather than just the presence or absence of the arrhythmia, although this strategy has not been validated.^{1,5,23}

Family History of Sudden Death

SCD events tend to cluster in families. However, there has not been a universal agreement regarding the prognostic implications of a positive family history of SCD. A single SCD is seen in up to 25% of HCM families, and it seems to have a low positive predictive value. Nonetheless, a family history of SCD (presumably caused by HCM) is considered more significant when the SCD has occurred in one or more first-degree relatives younger than 40 years (with or without a diagnosis of HCM) or in a first-degree relative at any age with an established diagnosis of HCM. Of note, families with multiple SCD under the age of 40 years are uncommon (approximately 5%). Family history is most useful when considered within the context of the overall risk profile.¹

Syncope

As noted, syncope occurs in 15% to 25% of patients with HCM. Syncope can be related to arrhythmias (VT or AF), neurocardiogenic syncope, and hypotension during exercise caused by LVOT obstruction or by abnormal vascular responses. However, in the majority of cases, no likely mechanism can be identified despite extensive investigation.

Syncopal episode of unexplained origin (i.e., not neurally mediated) or thought to be consistent with ventricular arrhythmias is often regarded as a marker of high risk for SCD. The occurrence of unexplained syncope is associated with a 1.8-fold higher probability of SCD; however, the prognostic significance of syncope is influenced by timing of the syncope event and patient's age. Patients with a recent (within 6 months before initial evaluation) episode of unexplained syncope had a fivefold relative risk of SCD higher than patients without syncope and an eightfold relative risk if they were younger than 18 years. In contrast, remote (greater than 5 years before initial evaluation) episodes of syncope in patients older than 40 years showed no association with SCD. Prognostic implications of syncopal events occurring within the time frame between recent and remote syncope are not clear. Therefore assessment should be individualized, depending on the patient's overall clinical profile.^{1,5,12}

The prognostic value of syncope in HCM patients is further supported by the fact that patients who received ICDs with unexplained syncope as the sole risk marker had a 5% annual rate of appropriate interventions compared with an annual rate of 3.5% in the overall study group with primary prevention ICDs.

Extreme Left Ventricular Hypertrophy

Marked hypertrophy (wall thickness ≥ 30 mm) in any part of the LV is an independent risk factor for SCD (particularly in patients younger than 18 years). Up to 10% of HCM patients exhibit this severe degree of LV hypertrophy, and those patients exhibit a threefold higher risk of SCD compared with those with less severe hypertrophy. Importantly, the risk of SCD increases in a linear fashion with increasing LV wall thickness. Therefore it may not be appropriate to use the 30-mm threshold in a binary manner (i.e., as either greater than 30 mm or less than

30 mm) in all cases; rather, the complete individual risk profile should be considered.^{1,5}

Abnormal Blood Pressure Response to Exercise

Approximately 20% to 40% of the patients with HCM exhibit an abnormal blood pressure response during exercise (defined as either a failure of systolic blood pressure to rise more than 20 mm Hg or a fall in systolic blood pressure during effort). Often these patients are younger than 40 years and have a small LV cavity. The mechanism of this abnormal blood pressure response is either inability to increase stroke volume in response to exercise (secondary to dynamic LVOT obstruction) or inappropriate drop in systemic vascular resistance (mediated by extensive systemic vasodilatation). Autonomic dysregulation can potentially underlie an abnormal reflex response (hypotension and bradycardia) to LVOT obstruction.¹ The prognostic significance of abnormal blood pressure response during exercise is not clearly defined but is likely more important in patient younger than 40 years and those with a family history of premature SCD.¹

Possible Risk Modifiers

End-Stage Hypertrophic Cardiomyopathy

End-stage HCM (characterized by LV ejection fraction less than 50%, wall thinning, and chamber enlargement) is observed in 2% to 9% of patients, with an annual incidence of less than 1%. The transition to end-stage HCM carries an ominous prognosis; within 3 years from the time of diagnosis, two-thirds of patients with end-stage HCM die from heart failure or SCD or require heart transplantation. Patients awaiting heart transplantation have a substantial arrhythmia-related event rate of 10% per year.^{1,11}

Left Ventricular Apical Aneurysm

LV apical aneurysms occur in 2% of HCM patients, particularly those with midventricular hypertrophy or, less commonly, apical hypertrophy. In small series, patients with LV apical aneurysms were found to exhibit a substantial (up to 10%) annual event rate, including SCD, progressive heart failure, evolution into the end-stage phase, stroke, and cardiovascular mortality. Therefore LV aneurysms may warrant consideration in SCD risk-assessment strategies, but prophylactic ICD implantation is not recommended in the absence of other clinical features that suggest an increased risk of SCD.^{1,11}

Previous Alcohol Septal Ablation

Percutaneous alcohol septal ablation appears to augment the risk of SCD in patients with HCM. Alcohol septal ablation typically creates a sizable transmural scar occupying on average 30% of the ventricular septum and 10% of the overall LV mass. Alcohol-induced infarcts can potentially compound preexisting myocardial electrical instability, resulting in increased arrhythmogenicity and higher risk of malignant ventricular arrhythmias.

The results of studies regarding the effect of alcohol septal ablation on long-term prognosis are conflicting. Several studies have documented the occurrence of sustained ventricular arrhythmias and SCD following septal ablation in approximately 10% to 20% of patients with or without SCD risk factors. Long-term outcome and survival following alcohol ablation is fourfold less favorable compared with myotomy/myectomy (which leaves no intramyocardial septal scar), and the rate of appropriate ICD therapy among alcohol ablation patients with primary prevention ICDs is threefold more frequent than in other patients (10.3% per year vs. 3.6% per year). On the contrary, other studies have shown no increase in the risk of SCD or ICD discharges after alcohol ablation. Therefore previous septal alcohol ablation is not currently considered an independent prognostic factor for SCD in HCM.

Extensive Late Gadolinium Enhancement

Late gadolinium enhancement on contrast CMR reflects myocardial fibrosis, which represents a potential substrate for ventricular arrhythmias. In fact, studies have demonstrated a linear correlation between the extent of late gadolinium enhancement and the risk of ventricular arrhythmias. HCM patients with evidence of late gadolinium enhancement on CMR tend to have more markers of risk of SCD, as well as higher mortality, than do patients without late gadolinium enhancement. Late gadolinium enhancement of 15% or more of LV mass showed a twofold increase in SCD event risk. However, available data are currently insufficient to consider late gadolinium enhancement as an independent risk marker of SCD. Nonetheless, late gadolinium enhancement can serve an arbitrator in HCM. When the level of SCD risk remains uncertain after standard stratification, the presence of extensive late gadolinium enhancement supports the benefit of ICD implantation, whereas minimal or only focal late gadolinium enhancement suggests low risk.^{5,11,24}

Left Ventricular Outflow Obstruction

Up to two-thirds of HCM patients demonstrate either resting or provokable LVOT obstruction. Although LVOT obstruction is a determinant of progressive heart failure and increased overall cardiovascular mortality, it does not specifically predict arrhythmic death. Furthermore, reduction of obstruction by septal myectomy or alcohol ablation is not considered a primary strategy for mitigating SCD risk. Similarly, the severity of clinical symptoms such as dyspnea, chest pain, and effort intolerance has not been correlated with increased risk of SCD. It is important to note that it can be challenging to use the LVOT gradient as a risk marker in individual patients, given the dynamic nature of the obstruction, characterized by spontaneous variability on a day-to-day (or even hourly) basis and influenced by factors that alter myocardial contractility and loading conditions. The 2011 ACC/AHA guidelines include marked LVOT obstruction only as a potential SCD risk modifier to be considered in borderline situations. In contrast, the 2014 European Society of Cardiology (ESC) guidelines on HCM consider LVOT obstruction as a major clinical feature associated with increased risk of SCD.^{1,5}

Genetic Testing

Adult patients with HCM and an established pathogenic mutation have worse long-term prognosis (cardiovascular mortality, stroke, and severe heart failure) compared with genotype-negative HCM patients. However, genetic testing appears to have little clinical application for risk stratification for SCD. Although certain mutations (e.g., some beta-myosin heavy chain and troponin T mutations) responsible for HCM can be associated with a higher risk for SCD compared with other mutations, there is substantial overlap between different disease gene groups, and exceptions are common. Hence the prognostic value of disease-causing mutations in HCM for risk stratification remains questionable.

On the other hand, the presence of more than one HCM-associated sarcomere mutation appears to be associated with greater disease severity and malignant ventricular arrhythmia, as well as SCD. Thus the identification of double to triple mutations on genetic testing can potentially be considered for risk stratification.

Age at Diagnosis

In HCM the risk of SCD is greatest in patients younger than 30 years and decreases thereafter. HCM patients older than 60 years appear to have low annual event rate (0.6% disease-related mortality and 0.2% SCD), despite the fact that 30% of patients have one or more risk factors for SCD. Hence the prognostic implications of the traditional SCD risk markers are of greater significance in young and middle-aged patients than in older patients with HCM.

Conventional Risk Stratification Model

The traditionally acknowledged noninvasive risk stratification strategy for primary prevention uses five clinical markers that have been defined in several retrospective and observational studies (Box 28.1). These primary prevention risk factors (applicable to HCM patients without prior cardiac arrest) are: (1) premature SCD (presumably caused by HCM) in one or more relatives; (2) unexplained syncope (particularly if recent and in young patients); (3) nonsustained VT on ambulatory (Holter) monitoring (particularly when the bursts of VT are multiple, repetitive, or prolonged); (4) severe LV hypertrophy (maximal wall thickness ≥ 30 mm); and (5) abnormal blood pressure response during exercise.¹

The relative weight that can be assigned to each of the traditional risk markers has not been defined. Although the absence of risk factors identifies a low-risk group (negative predictive value of 85% to 95%), the positive predictive value of any single risk factor is limited (approximately 10% to 20%). Risk for SCD is increased in proportion to the absolute number of risk factors.

It is also important to recognize that the absence of all risk factors does not convey immunity to SCD; the traditional risk stratification strategy in HCM remains imprecise, and a few SCDs have been reported in young patients judged to be at low risk without any of the acknowledged risk predictors.

Age is an important factor in considering patients at risk. The risk associated with each of the established risk factors is greatest in adults younger than 50 years. This risk stratification model is not easily translated to children, although a marked degree of LV hypertrophy or syncope have proven the most reliable markers in this age group. Similarly, this model may not apply to adults older than 50 years. HCM patients who have achieved an age of 60 years or more are at very low risk for disease-related adverse events, including SCD, even in the presence of conventional risk factors. However, it is important to note that even achieving this measure of longevity does not confer immunity to SCD.

In unselected HCM patient populations, approximately 60% of the patients have none of the five conventional risk factors, 20% have one risk factor, 14% have two, 3.5% have three, and 3.5% had four risk factors.

Surprisingly, in one study, neither the nature nor the number of risk factors predicted appropriate ICD therapies among ICD recipients

for primary prevention. Approximately 35% of patients with appropriate ICD interventions for VT/VF had undergone implantation for only a single risk factor, and the likelihood of appropriate discharge was similar in patients with 1, 2, or 3 or more risk markers. However, in another study, during an average of 3.6 years of follow-up, the rate of SCD was 3%, 5%, 17%, and 57%, when 1, 2, 3, or 4 risk factors were present, respectively. It is also important that during the same period only 3% of the patients without any risk factor displayed SCD. Nonetheless, it is reasonable to assume that SCD risk increases according to the number of risk factors, and risk stratification based on incorporation of multiple risk factors, as well as other “nonconventional” potential risk modifiers (Box 28.1), would likely improve positive predictive accuracy and better guide clinical decisions regarding prophylactic ICD implantation, particularly in patients in the “gray zone” of risk stratification.¹ The recognition that SCD can occur in the absence of classic risk factors should prompt the continuing search of other, unexplored risk markers.

“HCM Risk-SCD” Model

The ESC has incorporated a new, mathematical approach to risk stratification (the “HCM Risk-SCD” model) into their 2014 guidelines (Table 28.3). Instead of the conventional model that is based on the sum of the established risk factors, the “HCM Risk-SCD” model calculates individual 5-year SCD risk estimates. The algorithm is based on a Cox proportional hazards model based on data obtained from a retrospective, multicenter, longitudinal cohort study involving 3675 consecutively presenting patients.^{5,25}

The biggest changes in the HCM Risk-SCD model, compared with the risk stratification models proposed by the older guidelines, are the following: (1) abnormal blood pressure response during exercise is no longer included in the risk stratification; (2) increasing age is a protective factor; (3) LV wall thickness is no longer regarded as dichotomous, but as a continuous variable; and (4) LA diameter and LVOT gradient are added as continuous risk factors.^{5,26}

The seven continuous or binary risk factors (Table 28.3) are used to stratify patients into one of three groups based on 5-year risks of SCD (the ESC calculator is available at <http://www.doc2do.com/hcm/webHCM.html>). If the 5-year risk was calculated at less than 4%, an ICD would not be recommended; if the calculated risk is in the range 4% to 6%, it would be contingent; and if greater than 6%, ICD

BOX 28.1 Risk Factors for Sudden Death in Hypertrophic Cardiomyopathy

Established Risk Factors

1. Massive left ventricular hypertrophy (maximal wall thickness ≥ 30 mm)
2. Unexplained syncope in the past 6 months
3. Family history of premature sudden death in a first-degree relative <50 years of age
4. Nonsustained ventricular tachycardia (multiple, repetitive)
5. Abnormal blood pressure response on exercise

Possible Risk Factors or Arbitrators

1. End-stage hypertrophic cardiomyopathy (left ventricular ejection fraction <50%)
2. Left ventricular apical aneurysm
3. Extensive late gadolinium enhancement on cardiac magnetic resonance
4. Significant left ventricular outflow tract gradient at rest
5. Multiple sarcomere mutations
6. Previous alcohol septal ablation
7. Modifiable factors (intensive exercise, coronary artery disease)

TABLE 28.3 Prespecified Predictor Variables Assessed at Baseline Evaluation

Predictor Variable	Coding
Age	Continuous, years
History of SCD in one or more first-degree relatives <40 years of age or SCD in a first-degree relative with confirmed HCM at any age	Binary (yes = 1/no = 0)
Maximal LV wall thickness	Continuous, mm
LA diameter (determined by M-mode or 2-D echocardiography in the parasternal long axis plane)	Continuous, mm
Maximal LVOT gradients determined at rest and with Valsalva provocation	Continuous, mm Hg
Nonsustained ventricular tachycardia	Binary (yes = 1/no = 0)
Unexplained syncope	Binary (yes = 1/no = 0)

2-D, Two-dimensional; HCM, hypertrophic cardiomyopathy; LA, left atrial; LVOT, left ventricular outflow tract; SCD, sudden cardiac death.

implantation would be recommended. So far, two studies have examined how the guidance would have performed in their patients and arrived to opposing conclusions, emphasizing the need for new methods to identify patients at risk of SCD.^{5,25}

PRINCIPLES OF MANAGEMENT

No treatments to prevent or modify disease progression currently exist. Therefore current treatment focuses on symptom management, assessment for risk of SCD, and family screening.

Treatment of Heart Failure and Left Ventricular Outflow Obstruction

Pharmacological Therapy

In patients with LVOT obstructive symptoms or heart failure, beta-blockers are the mainstay of pharmacological therapy. The negative chronotropic and inotropic effects of beta blockade help alleviate symptoms related to diastolic dysfunction, LVOT obstruction, and myocardial ischemia. Verapamil or diltiazem can be used as an alternative or in conjunction with beta-blocker therapy. For refractory cases, disopyramide (a class IA antiarrhythmic agent with negative inotropic properties) can potentially reduce both resting and provokable gradients and may be added to beta-blockers or verapamil therapy. The initiation of disopyramide requires in-hospital cardiac monitoring for potential arrhythmias and QT prolongation.²

It is also important to avoid factors that exacerbate the degree of LVOT obstruction such as dehydration (e.g., aggressive diuresis) and arterial and venous dilator drug therapy (including nitrates and phosphodiesterase type 5 inhibitors).

Treatment of patients with end-stage disease (with LVEF $\leq 50\%$) is similar to that of other types of heart failure with LV systolic dysfunction (including angiotensin-converting enzyme inhibitors, angiotensin receptor blockers, beta-blockers, and other indicated drugs).

Septal Reduction Therapy

Septal reduction therapy is recommended for severely symptomatic patients who have substantial LVOT gradients (greater than 50 mm Hg at rest or provoked) and are refractory to medical therapy. Surgical septal myectomy is generally preferred when septal reduction is indicated. Alcohol septal ablation (eFig. 28.1) may be considered in patients with serious comorbidities or when surgery is contraindicated or not preferred. Following alcohol septal ablation, the annual mortality rate is 2.4%, whereas the risk of SCD is 1% per year.²⁷

Importantly, AV and intraventricular conduction abnormalities often complicate septal reduction procedures. Right bundle branch block (RBBB) develops in 36% of patients following alcohol septal ablation. Complete heart block requiring pacemaker implantation develops in 10% to 15%. In addition, LBBB develops in approximately 40% of patients undergoing surgical septal myectomy, and 3% develop complete heart block.^{2,27,28}

Permanent Pacing

RV pacing modifies the LV excitation pattern by changing the depolarization synchrony of LV contraction and can potentially reduce LVOT gradient and improve symptoms. Although the initial observational studies in patients with HCM showed promising results, subsequent randomized clinical studies failed to show a significant benefit of permanent pacing, and there are currently no data available to support the contention that pacing alters the clinical course of the disease or improves survival or long-term quality of life. Hence routine implantation of dual-chamber pacemakers is no longer recommended, except in a subset of symptomatic patients who have substantial LVOT gradients

refractory to medical therapy and are suboptimal candidates for surgical myectomy or alcohol septal ablation (eFig. 28.2).¹ A trial of dual-chamber pacing may also be considered for the relief of symptoms attributable to LVOT obstruction in HCM patients who already have dual-chamber cardiac devices implanted (pacemakers or defibrillators).

When permanent pacing is used, it is recommended to position the pacing lead in the RV apex, to promote excitation of the interventricular septum prior to the remainder of the LV. In addition, an atrial-synchronous ventricular pacing mode is selected, and the AV delay is optimized (usually in the range of 100 to 120 milliseconds) to shorten the ventricular peak filling time and reduce the preload. In addition, increasing the heart rate (using the DDD pacing mode with a lower rate of 60 to 70 beats/min) can help to further reduce LVOT gradient. Further adjustments of pacing parameters in the individual patient and assessment of the therapeutic effects using echocardiography will need to be considered to maximize the benefit of pacing therapy.²⁹

Treatment of Atrial Fibrillation

For patients with AF, the goal is to restore and maintain sinus rhythm because the loss of AV synchrony can precipitate or worsen symptoms. Amiodarone is the most effective. Disopyramide can also be considered, given its negative inotropic effects and additional potential benefit in reducing LVOT obstruction. Sotalol, dofetilide, and dronedarone are second line agents but may be considered as initial therapy in patients with ICDs. Flecainide and propafenone are not recommended. Catheter ablation can be considered in patients with drug-refractory AF. Surgical ablation can also be performed in AF patients undergoing surgical myectomy for LVOT obstruction. Anticoagulation is recommended in all HCM patients with AF (regardless of the CHA₂DS₂-VASc score), because of the high risk for thromboembolic complications in this patient population.

Treatment of Ventricular Arrhythmias

Pharmacological Therapy

There is currently no indication for any medication for primary prevention of SCD in HCM patients. Similarly, pharmacological therapy is not recommended in patients with asymptomatic PVCs or nonsustained VT for the purpose of arrhythmia suppression. However, beta-blockers, sotalol, and amiodarone may be considered as adjunctive therapy in ICD patients who experience frequent symptoms or device discharges triggered by ventricular arrhythmias.^{1,2}

Catheter Ablation

Sustained monomorphic VT is highly unusual in HCM patients and is more likely to occur in patients with LV apical aneurysms. In those patients the VT exhibits RBBB and superior axis on the surface ECG. Catheter ablation can be considered in patients with frequently recurring or incessant VT that is refractory to antiarrhythmic drug therapy. Macroreentry is the likely mechanism of VT, and catheter ablation techniques similar to those described for postinfarction VT can be used. Preprocedural CMR is helpful to identify the apical aneurysm, as well as areas of myocardial scarring that can potentially harbor the substrate for VT. Of note, an epicardial approach can be warranted in a significant proportion of patients.^{1,2}

Implantable Cardioverter-Defibrillator

ICD therapy is the most effective and reliable approach for reduction of the risk of SCD in patients with HCM, both for primary and secondary prevention. On the other hand, prophylactic pharmacological treatment alone (amiodarone, beta-blockers, or verapamil) does not offer HCM patients reliable protection against SCD and is generally not indicated. Of note, the interval from ICD implantation to first appropriate

eFig. 28.1 Left Coronary Angiography in a Patient With Asymmetrical Septal Hypertrophic Cardiomyopathy. A right lateral oblique view is shown. The septal perforator branch (marked by *arrows*) of the left anterior descending artery is the target for alcohol septal ablation. A temporary pacing wire is positioned in the right ventricle and a pigtail catheter is positioned in the left ventricle.

eFig. 28.2 Reduction of Left Ventricular (LV) Outflow Obstruction by Ventricular Pacing. The four panels show electrocardiogram and hemodynamics (femoral arterial [FA] and LV) under different conditions in a patient with hypertrophic cardiomyopathy and dynamic LV outflow obstruction. *Panels from left to right:* Baseline sinus rhythm showing a peak LV-FA gradient of almost 40 mm Hg. During atrial pacing at 100/min, the gradient increases to 50 mm Hg. With addition of right ventricular pacing at 100/min and an atrioventricular (AV) interval of 110 milliseconds, the gradient is almost eliminated; finally, when the AV interval is shortened, the gradient increases again to approximately 30 mm Hg.

device intervention is quite variable and often of considerable length. Even ICD recipients for secondary prevention after a cardiac arrest can survive for many years without the aid of ICD therapies. Previous reports found that ICD shocks occur randomly during the day without defined circadian periodicity, often unassociated with physical activity and sometimes during sleep.² However, in a recent report of HCM patients with ICDs, more than half of appropriate ICD interventions occurred during moderate to strenuous physical activity.¹⁶

ICD implantation is recommended for secondary prevention in patients with prior cardiac arrest or sustained VT, because of the relatively high recurrence rates in this subgroup. ICD implantation is also recommended for primary prevention in patients with (1) massive LV thickness (≥ 30 mm), (2) family history of SCD (including appropriate ICD therapy for ventricular tachyarrhythmias), or (3) personal history of recent unexplained syncope (Fig. 28.7). For those with nonsustained VT or abnormal blood pressure response to exercise, management decisions should be individualized, taking into consideration other markers of disease severity, as well as the desires of the fully informed patient and family. In these patients, other less-established risk factors (including LVOT obstruction, late gadolinium enhancement on CMR,

LV apical aneurysm, presence of multiple genetic mutations) may be used as arbitrators and to help resolve otherwise uncertain ICD decision making.¹

Appropriate ICD discharges in HCM patients occur annually in 10% to 14% of ICD recipients for secondary prevention after cardiac arrest and in 2.6% to 4% of ICD recipients for primary prevention. The incidence of appropriate ICD therapy does not increase with the aggregation of risk factors. Of note, arrhythmogenic events do not necessarily portend other adverse clinical outcomes. Specifically, appropriate ICD discharges do not appear to predict the occurrence of heart failure or the need for other invasive therapies (e.g., surgical myectomy or septal ablation).^{30–32}

The absence of risk factors for SCD accurately identifies a cohort of patients with a low risk of SCD. Nevertheless, regular periodic (every 12 to 24 months) reassessment of low-risk adults with Holter monitoring, exercise testing, and echocardiography is recommended. In addition, changes in symptoms, particularly sustained palpitations or syncope, at any age, should prompt urgent reevaluation.

It is important to recognize that ICD implantation is an invasive measure and carries a definite rate of complications, as well as the need

Fig. 28.7 Guidelines for Implantation of Implantable Cardioverter-Defibrillators (ICDs) in Patients With Hypertrophic Cardiomyopathy. ^aSudden cardiac death (SCD) risk modifiers include established risk factors and emerging risk modifiers (see text). Regardless of the level of recommendation put forth in these guidelines, the decision for placement of an ICD must involve prudent application of individual clinical judgment, thorough discussions of the strength of evidence, the benefits, and the risks (including but not limited to inappropriate discharges, lead and procedural complications) to allow active participation of the fully informed patient in ultimate decision making. BP, Blood pressure; LV, left ventricular; SD, sudden death; VT, ventricular tachycardia. (From Gersh BJ, Maron BJ, Bonow RO, et al. 2011 ACCF/AHA Guideline for the Diagnosis and Treatment of Hypertrophic Cardiomyopathy: a report of the American College of Cardiology Foundation/American Heart Association Task Force on Practice Guidelines. Developed in collaboration with the American As. *J Am Coll Cardiol.* 2011;58:e212–e260.)

for recurring device service and generator changes. Furthermore, inappropriate ICD shocks are common, occurring in up to 28% of HCM patients (5.3% per year), particularly in younger patients and those with AF. The negative psychological impact of an implanted device and inappropriate shocks should not be underestimated. Therefore the benefit of ICD implantation should be carefully weighed against the risks of such a procedure in this young patient population.

Of note, in a recent report of HCM patients with ICDs, ventricular tachyarrhythmias were more commonly monomorphic VT or ventricular flutter than VF, and antitachycardia pacing ICD therapies was successful in arrhythmia termination in two-thirds of episodes, thereby avoiding the need for delivery of ICD shocks. Therefore programming the ICD to deliver antitachycardia pacing therapy, even for those arrhythmias with rapid rates, can potentially reduce the risk of appropriate ICD shocks. Furthermore, these data suggest that transvenous ICD systems are likely preferable subcutaneous ICDs for HCM patients because subcutaneous ICDs do not possess antitachycardia pacing capability.¹⁶

Exercise Restriction

The physical and metabolic stresses associated with intense exercise (including catecholamine surge, hyperpyrexia, dehydration, electrolyte imbalances) can serve as triggers of fatal arrhythmias in patients with HCM. In fact, engagement in intense competitive sports is itself an acknowledged risk factor in these patients. However, this is a modifiable risk factor and by itself is not considered an indication for prophylactic ICD implantation. ICD indications for competitive athletes with HCM should not differ from those in other HCM patients, and using ICDs for the explicit purpose of allowing organized sports participation is inadvisable.^{31,33}

Therefore it is recommended that patients with HCM not participate in intense competitive sports, even when conventional markers are absent, and regardless of age, sex, race, magnitude of LV hypertrophy, presence or absence of LVOT obstruction, presence or absence of myocardial fibrosis on CMR, prior septal reduction therapy, and even in patients with ICDs.

In a recent report of HCM patients with ICDs, the majority of appropriate (and inappropriate) ICD therapies occurred during moderate to strenuous physical activity. Importantly, the increased risk for ventricular arrhythmias during exercise and high adrenergic tone can be coupled with the potential for failure of arrhythmia termination with appropriate device therapy, presenting an argument against participation of HCM patients with ICDs in competitive sports.¹⁶ Nonetheless, exclusion from competitive sports is not absolute; the ultimate decision should be made by the fully informed athletes and their families in concert with their physician and third-party interests.^{16,33}

Participation in low-intensity competitive sports (e.g., golf and bowling) and recreational sporting activities (of lesser intensity than that of competitive sports) is reasonable and should be tailored to the individual’s desires and abilities. In general, aerobic exercise is preferred to isometric exercise. It is also prudent to avoid activities associated with abrupt increase in heart rate or during extreme environmental conditions.³³

Family Screening

All HCM patients and relatives should have access to some form of genetic counseling. As expected in an autosomal dominant disease, every offspring has a 50% chance of inheriting the disease-causing mutation. However, because of the age-dependent penetrance, many mutation carriers may not exhibit phenotypic expression early in life, and many others may express the phenotype but remain asymptomatic and hence remain undiagnosed unless screened.

When the causative mutation in the index patient is identified, all first-degree relatives should first be genetically tested and then clinically evaluated if they are found to carry the same mutation. Genetic testing can have particular advantages over clinical screening because ECG and echocardiographic abnormalities may be absent or subtle, or develop late in life. Furthermore, genetic testing affords permanent reassurance to those family members who test gene-negative. Mutation-negative family members and their descendants have no risk for developing HCM and do not need further evaluation.^{2,5}

When genetic testing is not performed in the proband, or when genetic analysis fails to identify a definite disease-causing mutation (or reveals one or more genetic variants of unknown significance), it is recommended that all first- and second-degree genetically related family members of patients with HCM should undergo clinical screening with detailed history and physical examination, 12-lead ECG, and echocardiogram. CMR may also be considered for screening, particularly if the ECG is abnormal. As noted, because penetrance is age dependent, many family members may not express the phenotype at the time of examination and may be falsely considered “unaffected.” Thus periodic evaluation of the “unaffected” family members is necessary because some may develop HCM later in life. Annual screening should be considered in adolescents and young adults (ages 12 to 20 years), in athletes, and in those with a family history of early-onset disease. Screening every 3 to 5 years in other individuals may be adequate because of the rare possibility of adult-onset hypertrophy and phenotypic conversion later in life between 20 and 50 years of age (Table 28.4).^{2,5}

Individuals who have nondiagnostic clinical features consistent with early disease (e.g., ECG abnormalities, increased LVEF, delayed myocardial relaxation, or myocardial fibrosis on CMR) should be followed initially at intervals of 6 to 12 months and then less frequently if there is no progression. In addition, those who develop new cardiac symptoms should be reevaluated promptly.

Genotype-Positive/Phenotype-Negative Patients

Family members testing positive for pathogenic (disease-causing) sarcomere mutations (i.e., genotype-positive) should undergo a comprehensive cardiac evaluation and risk stratification similar to patients with known HCM, even in the absence of clinical evidence of LV hypertrophy on echocardiography and CMR (i.e., phenotype-negative). The clinical expression of HCM in this population is unpredictable. When

TABLE 28.4 Clinical Family Screening Strategies for Detection of HCM Phenotype

Age of Family Member	Screening Strategy
<12 year old	Screening optional unless: <ul style="list-style-type: none">• Family history of premature HCM-related death or other adverse complications• Competitive athlete in an intense training program• Onset of symptoms• Other clinical suspicion of early left ventricular hypertrophy
12 to 18–21 year old	Every 12–18 months
>18–21 year old	<ul style="list-style-type: none">• At onset of symptoms or at least every 5 years through midlife• More frequent intervals with a family history of late-onset HCM and/or malignant clinical course

HCM, Hypertrophic cardiomyopathy.

LV hypertrophy develops, it typically manifests between 12 and 20 years of age and much less frequently later in life. ECG abnormalities, increased LVEF, delayed myocardial relaxation, or myocardial fibrosis on CMR can precede the onset of LV hypertrophy and indicate early emergence of clinical disease.^{2,5}

Genotype-positive/phenotype-negative individuals should also undergo periodic screening (with clinical examination, ECG, echocardiogram, or CMR) for detecting development of clinical disease with LV hypertrophy. The frequency of screening is similar to that described for clinical family screening (Table 28.4). Exercise stress testing or Holter monitoring to screen for ventricular arrhythmias may also be considered in individuals of families with high risk for SCD.

At present, there is no compelling evidence to suggest an increased risk for SCD in asymptomatic, genotype-positive/phenotype-negative HCM patients; therefore participation in competitive athletics is not prohibited, particularly in the absence of a family history of HCM-related SCD.³³

Prophylactic pharmacological therapy in asymptomatic carriers of HCM genes is ineffective and not recommended.

PATHOPHYSIOLOGY

Arrhythmogenic right ventricular cardiomyopathy (ARVC), also referred to as “arrhythmogenic cardiomyopathy,” is an inherited desmosomal cardiomyopathy with incomplete penetrance and variable expressivity. ARVC is characterized by ventricular arrhythmias and structural abnormalities of the right ventricle (RV) (and left ventricle [LV] more manifest during the latter stages of the disease). The hallmark pathological findings are progressive myocyte loss and fibrofatty (fibrous and adipose) tissue replacement, with a predilection for the RV, but the LV also can be affected. Fibrofatty replacement of the myocardium produces “islands” of scar that can lead to reentrant ventricular tachycardias (VTs) and increased risk of sudden cardiac death (SCD).^{1–3}

Molecular Genetics

Familial disease occurs in approximately 30% to 60% of cases of ARVC. The remainder of patients with ARVC have undiscovered genetic abnormalities or have the disease *de novo*. Two patterns of inheritance have been described: autosomal dominant disease with incomplete penetrance (most common) and autosomal recessive disease (rare). Autosomal recessive forms of ARVC include Naxos disease (also known as familial palmoplantar keratosis and “mal de Meleda” disease) and Carvajal syndrome (a disorder of LV cardiomyopathy), both of which are associated with skin and hair abnormalities.⁴

The autosomal dominant nonsyndromic ARVC-1 to ARVC-12 as well as the two rare recessive forms (Naxos disease and Carvajal syndrome) have been mapped to 12 genetic loci, with mutations in eight gene loci identified (Table 29.1). Although some identified gene mutations such as ryanodine receptor 2 (RYR2) may be phenocopies of ARVC, a common theme of *desmosomal protein mutations* has been emerging. In fact, five of the eight gene loci encode desmosomal proteins (plakophilin-2 [PKP2], desmoglein-2 [DSG2], desmoplakin [DSP], desmocollin-2 [DSC2], and junctional plakoglobin [JUP]) have been found in association with the ARVC phenotype in up to 50% of cases. Among genotype-positive probands, mutations in PKP2 appear to be the most common causes of ARVC, accounting for approximately 73% to 79% of cases. Mutations in DSG2 and DSP account for approximately 10% to 14% and 3% to 8% of cases, respectively. Therefore ARVC is currently considered to be, at least in a subset, a disease of the cardiac desmosome.^{2,5}

The majority of disease-causing mutations are insertion/deletion or nonsense mutations, which are expected to cause premature termination of the encoded proteins. Data from the North American ARVC registry showed that 86% of patients had a single heterozygous gene mutation, 7% showed compound heterozygosity, 7% had digenic heterozygosity, and 1% had homozygous mutation. Patients with multiple mutations seem to have early disease onset and a worse arrhythmic course.⁶ Mutations can be inherited from a parent or can be the result

TABLE 29.1 Known Genetic Loci for Arrhythmogenic Right Ventricular Cardiomyopathy-Dysplasia

Locus Name	Causative Gene	Mode of Inheritance	% of Mutations
ARVC-1	Transforming growth factor- β_3	Autosomal dominant	
ARVC-2	Cardiac ryanodine receptor (RYR2)	Autosomal dominant	
ARVC-3	Unknown	Autosomal dominant	
ARVC-4	Unknown	Autosomal dominant	
ARVC-5	Transmembrane protein-43	Autosomal dominant	
ARVC-6	Unknown	Autosomal dominant	
ARVC-7	Unknown	Autosomal dominant	
ARVC-8	Desmoplakin (DSP)	Autosomal dominant	3%–8%
ARVC-9	Plakophilin-2 (PKP2)	Autosomal dominant	73%–79%
ARVC-10	Desmoglein-2 (DSG2)	Autosomal dominant	10%–14%
ARVC-11	Desmocollin-2	Autosomal dominant	
ARVC-12	Plakoglobin (JUP)	Autosomal dominant	
Naxos disease	Plakoglobin (JUP)	Autosomal recessive	Rare
Carvajal syndrome	Desmoplakin (DSP)	Autosomal recessive	Rare

ARVC, Arrhythmogenic right ventricular cardiomyopathy;
JUP, junctional plakoglobin.

of a new mutation. Approximately 20% to 30% of patients with ARVC have a family history of ARVC or of SCD.

Mutations in several nondesmosome genes have also been reported to cause ARVC: Transmembrane protein 43 (*TMEM43*), transforming growth factor-beta3 (*TGF β 3*), desmin (*DES*), lamin A/C (*LMNA*), titin (*TTN*), and phospholamban (*PLN*). A mutation in *TMEM43*, encoding a transmembrane protein with ties to an adipogenic transcription factor, was reported as the cause for ARVC-5, a subtype of ARVC with prominent LV involvement.

Furthermore, mutations in *RYR2*, encoding the cardiac ryanodine receptor (the major calcium release channel of the sarcoplasmic reticulum in cardiomyocytes, also implicated in familial catecholaminergic polymorphic ventricular tachycardia [CPVT]), result in a form of arrhythmogenic cardiomyopathy (ARVC-2) characterized by exercise-induced polymorphic VT that does not appear to have a reentrant mechanism, occurring in the absence of significant structural abnormalities. Patients do not develop characteristic features of ARVC on the 12-lead electrocardiogram (ECG) or signal-averaged ECG, and global RV function remains unaffected. ARVC-2 shows a closer resemblance to familial CPVT in both etiology and phenotype, and its inclusion under the umbrella term of ARVC remains controversial.^{7–9}

Genotype–phenotype studies have identified an association of genotype with clinical course and disease expression, including the onset of overt disease, LV involvement, and the severity of heart failure. In a multicenter study, 80% of individuals had a single copy of a *PKP2* mutation whereas 4% of individuals carried two or more pathogenic mutations. *PKP2* mutation carriers are more likely to experience an earlier onset of both symptoms and arrhythmias. *PLN* mutation carriers presented at a significantly older age yet had worse long-term prognosis, with more LV dysfunction and heart failure. Also, individuals harboring DSP were considerably more likely to develop heart failure and more

prominent LV involvement, and are more likely to present with SCD rather than other mutation carriers.¹⁰

Carriers of single pathogenic mutations in any of the genes appear to exhibit a similar high risk of developing a life-threatening arrhythmia, with no significant differences in survival from life-threatening VT/ventricular fibrillation (VF) among the different genes. Conversely, patients with more than one mutation have considerably worse clinical course with a significantly earlier onset of symptoms and first sustained VT or VF, a greater chance of developing sustained VT or VF, and a fivefold increase in the risk of developing LV dysfunction and heart failure than those carrying a single mutation.^{6,10}

Pathogenesis

Cardiac desmosomes are specialized, multiprotein complexes in the intercalated disks that anchor intermediate filaments to the cytoplasmic membrane in adjacent cardiomyocytes, thereby forming a three-dimensional (3-D) scaffolding and providing mechanical strength and cohesion of cardiomyocytes in the beating heart (Fig. 29.1). Cardiac desmosomes are also responsible for regulating the transcription of genes involved in adipogenesis and apoptosis as well as maintaining proper electrical conductivity through the regulation of gap junctions and calcium homeostasis.

Cardiac desmosomes are composed of three groups of proteins: the cadherin family, the Armadillo family, and the plakin family. The cadherin family is composed of three desmocollins and three desmogleins, which are primarily responsible for anchoring the structure to the membrane. The Armadillo family is composed of plakoglobin and three plakophilins, which form the core structure and possess signaling capabilities. The plakin family is composed of DSP, envoplakin, periplakin, plectin, and pinin, which are responsible for the attachment of the desmosomes to intermediary filaments.

The mechanisms by which the affected desmosomes cause myocyte apoptosis, fibrogenesis, adipogenesis, and slow ventricular conduction, thus leading to impaired RV function and increased arrhythmogenicity, remain to be determined. Mutations in desmosomal genes alter the number or integrity of desmosomes and thereby lead to impaired mechanical coupling and the failure of cell-to-cell adhesion structures during exposure to physical strain, resulting in cardiomyocyte detachment and degeneration, with subsequent inflammation and replacement by fibrofatty tissue. This course may be triggered or aggravated by inflammatory processes (superimposed myocarditis), autonomic dysfunction, or mechanical stretch of the myocardium (e.g., during intense exercise) and lead to myocardial damage, inflammation, and cell death.^{2,11} The reason behind the preferential involvement of the RV in ARVC remains elusive; nonetheless, several factors can make the RV particularly vulnerable to impaired mechanical cellular coupling, more so than the LV, including thinner RV free wall, high distensibility, and variations in preload and stretch. These factors expose the RV to disproportionately greater strain during exercise compared with the LV.^{12,13}

Fibrofatty replacement is a nonspecific repair process also observed in the muscular dystrophies. The architecture of thin surviving myocardial bundles within the fibrofatty tissue creates lengthened conduction pathways, conduction slowing at pivotal points, and conduction block, creating an electrophysiological (EP) substrate for reentry and VT. Furthermore, fibrofatty replacement of the myocardium results in abnormal structure, morphology, geometry, and wall motion of the ventricle.¹¹

In addition, impaired desmosomal structure and function can affect other cell-to-cell contact structures in the myocardium. Mutations in desmosomal proteins can impair the expression of interacting proteins at the intercalated disk (e.g., gap junction or sodium channel proteins), giving rise to the impairment of intercellular conductance and promoting ventricular arrhythmogenesis, even in the absence of fibrofatty tissue

Fig. 29.1 Molecular Structure of the Cardiac Desmosome. The desmosomal cadherins desmocollin and desmoglein form classic homotypic and heterotypic interactions between cells. These membrane-bound proteins are linked through the Armadillo family members, plakoglobin, and plakophilin to the intermediate filament-binding protein desmoplakin. This complex anchors the desmosome to the cytoskeleton of the cell, and thus indirectly to the sarcomere, the nuclear membrane, and the dystrophin-associated glycoproteins. (From Ellinor PT, MacRae CA, Thierfelder L. Arrhythmogenic right ventricular cardiomyopathy. *Heart Fail Clin.* 2010;6:161–177.)

replacement. In particular, connexin-43 (Cx43) remodeling in the gap junctions, which contributes to delayed conduction and ventricular arrhythmogenesis, is often observed in ARVC patients. Also, a reduction in Cx43 protein can potentially lead to reduced sodium channel expression and function. Abnormal electrical coupling and ion channel dysfunction, leading to electrical instability, can promote arrhythmias and predispose patients to a high risk of SCD, even in the early disease stages, prior to the development of significant ventricular dysplasia and scarring.^{14–16}

In the early disease phase, VF likely reflects acute ventricular electrical instability secondary to acute myocyte death and reactive

inflammation, which is often characterized by dynamic T wave inversion, ST segment elevation, and myocardial enzyme release.² In later disease stages of ARVC, fibrofatty replacement of RV myocardium creates scar regions that provide the arrhythmogenic substrate for VT. In fact, scar-related macroreentry in areas of abnormal myocardium (similar to that observed in the post-myocardial infarction [MI] setting) is the most common mechanism of VT in ARVC patients. Most reentrant circuits cluster around the tricuspid annulus and the right ventricular outflow tract (RVOT). The critical isthmus contained in these reentry circuits often is a narrow path of tissue with abnormal conduction properties, typically bounded by two approximately

parallel conduction barriers that consist of scar areas, the tricuspid annulus, or both.

Of note, among ARVC patients with frequent premature ventricular complexes (PVCs) at baseline, a high degree of association has been reported between induced sustained VT and the clinical PVCs. VT in these patients exhibited features suggestive of a focal mechanism. The site of origin of those catecholamine-facilitated VTs was uniformly the border region of scar, typically in the RVOT and RV basal regions.¹⁷

Pathology

The most striking morphological feature of ARVC is the diffuse or regional loss (atrophy) of myocardium with subsequent replacement by fibrofatty tissue, leading to localized ventricular wall thinning, sacculations, aneurysms (eFig. 29.1), and segmental hypokinesia. Fibrofatty replacement usually begins in the subepicardium or midmural layers and progresses to the subendocardium. Patchy inflammatory infiltrates can be present in areas of myocardial damage. Myocarditis can reflect an active phase of ARVC during which worsening of ventricular systolic function or ventricular arrhythmia can develop.¹⁸

In ARVC, the muscle cells affected initially are primarily in the RV, but the LV can be involved later in the course of ARVC or occasionally be an early or predominant site of the disease. The sites of involvement can be localized, and in early disease they are often confined to the so-called triangle of dysplasia—namely, the RVOT, RV apex, and inferolateral wall near the tricuspid valve (which is considered a pathognomonic feature of ARVC, although it is not necessarily present in all cases). More recent evidence suggests that, unlike the other two areas, the RV apex is usually not involved in arrhythmogenesis; histopathologically, myocardium at the apex is often thin and replaced by fat (but not fibrosis) in older persons without ARVC. Thus some of the early reports of ARVC probably included patients with age-related apical thinning and fatty replacement that was mistaken for apical involvement with the disease.

RV trabeculae are not primarily affected by the atrophic process and tend to show a compensatory hypertrophy, resulting in an aspect of increased trabeculation and fissuring of the RV walls. Involvement of the interventricular septum is minimal. In more advanced stages of ARVC, diffuse myocardial involvement leads to global RV dilation and dysfunction.¹¹ End-stage disease typically exhibits biventricular involvement, usually with multiple aneurysms and a parchment-like appearance of the ventricular free wall. Although several hypotheses have been put forth, currently there is no unifying hypothesis that explains the patchy, yet predictable pattern of RV involvement in ARVC.

Although the dysplastic tissue predominantly involves the RV, the increasing use of advanced imaging studies (cardiac magnetic resonance [CMR]) revealed that LV involvement is common from the early disease stage, but is often clinically subtle.¹⁹ The fibrofatty pattern exhibits a predilection for the LV posteroseptal and posterolateral areas, typically extending from the epicardium to the mid-myocardium, with sparing of the endocardium. In a recent report in a cohort of genetically confirmed ARVC patients, regional cardiac involvement in ARVC mutation carriers had a characteristic pattern involving the RV basal inferior wall, the RV basal anterior wall, and the LV posterolateral wall. RV apical involvement was only observed in advanced cases of ARVC, typically as a part of global RV disease.²⁰ These findings support the adoption of the broader term “arrhythmogenic cardiomyopathy.”²¹ Furthermore, the ARVC phenotype can vary depending on the desmosomal component affected by the primary mutation. Genotype–phenotype correlations have shown “nonclassical” clinical variants in genetically predisposed ARVC patients exhibiting early and more extensive LV involvement, which may either parallel (“biventricular” variant) or exceed (“left dominant” variant) the severity of RV disease.^{19,22}

In ARVC, the regions of abnormal myocardium do not always follow the pattern of dense scar surrounded by a ring of abnormal myocardium, which is often referred to as the scar border zone. Sometimes, abnormal voltages are found alone without a dense scar defining the regions. This is because ARVC is a different process from scarring caused by MI. Infarction causes dense scar surrounded by a border zone because of the ischemic penumbra that surrounds the infarcted territory. However, in ARVC, the process is patchy and can cause inhomogeneous scarring in anatomically disparate areas. Nonetheless, previous data have shown that it is still possible to identify well-demarcated borders around these abnormal regions.

EPIDEMIOLOGY AND NATURAL HISTORY

The incidence and prevalence of ARVC are uncertain. The prevalence of the disease in the general population is estimated at 0.02%, but it varies geographically. In certain regions of Italy (Padua, Venice) and Greece (the island of Naxos), a prevalence as high as 0.4% to 0.8% for ARVC has been reported.³ Approximately 50% of affected patients have a positive family history. ARVC exhibits incomplete penetrance (i.e., not all carriers of the pathogenic mutation will develop a phenotypic expression) and limited phenotypic expression, which probably account for the underestimation of the prevalence of familial disease.³

ARVC occurs in young adults; about 80% of familial ARVC patients are younger than 50 years, and the mean age at diagnosis is 31 years. The disease is almost never diagnosed in infancy and rarely before the age of 10 years.²³ The high risk of life-threatening arrhythmias in patients with ARVC spans from adolescence to advanced age, reaching its peak (4.0 per 100 person-years) between the ages of 21 and 40 years.²⁴ Of note, the phenotypic first presentation with SCD or VF appears to occur at a significantly younger age (median 23 years) than presentation with sustained monomorphic VT (median 36 years).¹⁰ Late clinical presentation is not uncommon and does not confer a benign prognosis; about 21% of all ARVC patients present after 50 years of age, predominantly with sustained VT.²⁵

Because ARVC is an autosomal-dominant disease, an equal number of men and women are genetically affected. However, a predominance of male gender exists in phenotypically affected individuals. In worldwide cohorts, men seem more likely to develop a more severe disease phenotype, present with SCD, be symptomatic at presentation, and have worse long-term prognosis.¹⁰ However, in the North American ARVC Registry, no gender differences were found in the clinical expression of ARVC.²⁶ In one study of patients with sporadic ARVC, men had a significantly higher risk of VT/VF, whereas women had a significantly higher risk of heart failure death or heart transplantation. However, the other clinical manifestations, including ECG findings and LV and RV function, as well as total cardiac mortality, were comparable in both genders.²⁷

Some patients are asymptomatic and ARVC is only suspected by the finding of ventricular ectopy and other abnormalities on routine ECG or other testing because of a positive family history. In one report, 10% of those initially unaffected subjects developed structural signs of disease on echocardiography during a mean follow-up of 8.5 years; almost 50% had symptomatic ventricular arrhythmias. Progression from mild to moderate disease occurred in 5% of patients, and progression from moderate to severe disease occurred in 8%.

The estimated overall mortality rate in ARVC patients varies among different studies, ranging from 0.08% to 3.6% per year.² Mortality is predominantly related to arrhythmic SCD, mostly in young people and athletes, which is the first clinical manifestation of ARVC in 50% of afflicted individuals. In fact, up to 5% of SCDs in young adults in the United States are attributed to ARVC. In northeast Italy, ARVC is

eFig. 29.1 Right Ventricular (RV) Aneurysm. This cardiac computed tomography angiogram shows thinning and aneurysmal dilation of the RV anterior wall and outflow tract (*arrows*) in a patient with arrhythmogenic right ventricular cardiomyopathy and ventricular tachycardia. Ao, Aorta; LV, left ventricle; PA, pulmonary artery; RV, right ventricle.

responsible for 22% of SCDs in young athletes and 8% of SCDs in nonathletes. In advanced disease, progressive RV or biventricular heart failure contributes to poor outcome.¹

CLINICAL PRESENTATION

The clinical presentation varies widely because ARVC includes a spectrum of different conditions rather than a single entity. Different pathological processes can manifest a diversity of symptoms. In addition, ARVC can have a temporal progression and, hence, present differently according to the time of presentation.

Phases of Clinical Disease Expression

Four clinicopathological stages of ARVC can be considered: (1) “concealed” phase, (2) “overt electrical disorder,” (3) phase of “RV failure,” and (4) phase of “biventricular failure.” Although ARVC is a genetically transmitted disease, it is associated with a long asymptomatic lead time and individuals in their teens may not have any characteristics of ARVC clinically or on screening tests. Early ARVC is often asymptomatic (the “concealed” phase), and is occasionally associated with minor ventricular arrhythmias and subtle RV structural changes. Nonetheless, these patients are still at risk of SCD, especially during intense physical exertion.

With disease progression, the “overt electrical disorder” typically causes symptomatic ventricular arrhythmia (manifesting as palpitations, effort-induced syncope, or cardiac arrest) and more obvious morphological abnormalities detectable by cardiac imaging. Further disease extension results in RV dilation and dysfunction (the “phase of RV failure”), precipitating symptoms and signs of right heart failure. Unless SCD occurs, progressive impairment of cardiac function can result in biventricular heart failure late in the evolution of ARVC, usually within 4 to 8 years after typical development of complete right bundle branch block (RBBB). End-stage disease is often indistinguishable from dilated cardiomyopathy and manifests with congestive heart failure, atrial fibrillation (AF), and an increased incidence of thromboembolic events. Overall, judging the accurate position of the patient on the time scale of the spectrum can be difficult, and some patients can remain stable in the same phase of the disease for several decades.²

Ventricular Arrhythmias

ARVC is one of the most arrhythmogenic human heart diseases known. Unlike other cardiomyopathies, electrical instability is present at the very early stages of ARVC; ventricular arrhythmias and SCD are often presenting symptoms before the development of any overt myocardial dysfunction. Ventricular arrhythmias range from isolated ectopy to sustained VT or VF. Approximately 50% of patients with ARVC present with symptomatic ventricular arrhythmias, most commonly sustained and nonsustained monomorphic VT, which are manifested by palpitations, dizziness, or syncope. Importantly, unlike other forms of cardiomyopathies and channelopathies, most syncopal episodes in ARVC are attributable to ventricular arrhythmias (rather than vasovagal or nonarrhythmic causes) and are associated with a poor prognosis. In fact, unexplained syncope is an independent predictor of SCD, with a sensitivity of 40% and a specificity of 90%.

The frequency of ventricular arrhythmias in ARVC varies with the severity of the disease, ranging from 23% in patients with mild disease to almost 100% in patients with severe disease. Ventricular arrhythmias characteristically occur during exercise; up to 50% to 60% of patients with ARVC develop monomorphic VT during exercise testing.^{2,14}

One of the unfortunate features of ARVC is SCD, which is the first clinical manifestation of ARVC in 50% of afflicted individuals. In most patients, the mechanism of SCD in ARVC is the acceleration of VT,

with ultimate degeneration into VF. In addition, RV failure and LV dysfunction are independently associated with cardiovascular mortality.²¹

Supraventricular Arrhythmias

Supraventricular arrhythmias are observed in approximately 14% of patients with ARVC, and in up to 25% of those referred for treatment of ventricular arrhythmias. In decreasing order of frequency, supraventricular tachyarrhythmias in these patients include AF, atrial tachycardia (AT), and atrial flutter (AFL). The presence of atrial arrhythmias is associated with increasing disease severity and heart failure. Often, atrial arrhythmias in this population can be asymptomatic, detected only on implantable cardioverter-defibrillator (ICD) interrogation or following an inappropriate ICD shock.²⁸

Thromboembolism

Thromboembolic complications occur in approximately 0.5% of ARVC patients annually, and are likely related to thrombus formation in ventricular aneurysms and sacculations, or global ventricular dilatation.²

INITIAL EVALUATION

ECG, Holter monitoring, signal-averaged ECG (if available), echocardiography, and CMR provide optimal clinical evaluation of patients suspected of having ARVC. Electrical abnormalities often precede structural changes in ARVC, and therefore ECG, signal-averaged electrocardiogram (SAECG), exercise stress testing, and Holter monitoring may have more diagnostic utility than CMR in the early stages of ARVC. If noninvasive work-up is suggestive but not diagnostic of ARVC, further testing should be considered to establish the diagnosis, including RV angiography, endomyocardial biopsy, and invasive EP testing.^{11,21}

The noninvasive diagnosis of ARVC can be exceedingly difficult. Several factors, including marked phenotypic variation, incomplete and low (30%) penetrance, and age-related disease development and progression contribute to the complexity of the clinical diagnosis. Particularly problematic is recognition of the early stages of ARVC when overall RV function may be normal, with local or regional wall-motion abnormalities that are difficult to quantify; nonetheless, the absence of clinical features does not necessarily confer low risk.

Diagnostic Criteria

There is no single test that is conclusively diagnostic (gold standard) of ARVC in the disease's early stages. At initial presentation, the ECG can be normal in up to 50% of ARVC patients. Furthermore, up to 36% of ARVC patients presenting with a history of sustained ventricular arrhythmias or cardiac arrest exhibit no major or minor criteria on cardiac imaging (CMR or echocardiogram).

Therefore the diagnosis of ARVC is currently guided by the modified task force criteria, a composite of clinical, imaging, pathological, and ECG features (Table 29.2). According to this scheme, the diagnosis of ARVC is fulfilled by the presence of (1) two major or one major and two minor criteria, or by four minor criteria (definite diagnosis); (2) one major and one minor or three minor criteria (borderline diagnosis); or (3) one major or two minor criteria from different categories (possible diagnosis).²⁹

Echocardiography, CMR, and angiography are the current imaging modalities incorporated into the modified task force criteria. Because ARVC is a rare disease, when performing and analyzing these studies it is important to recognize the importance of expert interpretation of the complex-shaped RV and the need for quantitation of RV structure and function, as well as specific protocols for optimal evaluation. Referral to centers with expertise in this field should be considered.²⁹

TABLE 29.2 Revised Task Force Criteria for the Diagnosis of ARVC

Major Criteria	Minor Criteria
I. Imaging By 2-D echo: Regional RV akinesia, dyskinesia, or aneurysm And 1 of the following (end diastole): PLAX RVOT ≥ 32 mm (corrected for body size [PLAX/BSA] ≥ 19 mm/m ²) PSAX RVOT ≥ 36 mm (corrected for body size [PSAX/BSA] ≥ 21 mm/m ²) Fractional area change $\leq 33\%$ By CMR: Regional RV akinesia or dyskinesia or dyssynchronous RV contraction And one of the following: Ratio of RV end-diastolic volume to BSA ≥ 110 mL/m ² (male) or ≥ 100 mL/m ² (female) RV ejection fraction $\leq 40\%$ By RV angiography: Regional RV akinesia, dyskinesia, or aneurysm	By 2-D echo: Regional RV akinesia or dyskinesia And 1 of the following (end diastole): PLAX RVOT ≥ 29 to <32 mm (corrected for body size [PLAX/BSA] ≥ 16 to <19 mm/m ²) PSAX RVOT ≥ 32 to <36 mm (corrected for body size [PSAX/BSA] ≥ 18 to <21 mm/m ²) Fractional area change $>33\%$ to $\leq 40\%$ By CMR: Regional RV akinesia or dyskinesia or dyssynchronous RV contraction And one of the following: Ratio of RV end-diastolic volume to BSA ≥ 100 to <110 mL/m ² (male) or ≥ 90 to <100 mL/m ² (female) RV ejection fraction $>40\%$ to $\leq 45\%$
II. Endomyocardial Biopsy Residual myocytes (60% by morphometric analysis or 50% if estimated), with fibrous replacement of the RV free wall myocardium in ≥ 1 sample, with or without fatty replacement of tissue on endomyocardial biopsy	Residual myocytes (60% to 75% by morphometric analysis or 50% to 65% if estimated), with fibrous replacement of the RV free wall myocardium in ≥ 1 sample, with or without fatty replacement of tissue on endomyocardial biopsy
III. Repolarization Abnormalities Inverted T waves in right precordial leads (V ₁ , V ₂ , and V ₃) or beyond in individuals >14 years of age (in the absence of complete RBBB QRS ≥ 120 msec)	Inverted T waves in leads V ₁ and V ₂ in individuals >14 years of age (in the absence of complete RBBB) or in V ₄ , V ₅ , or V ₆ Inverted T waves in leads V ₁ , V ₂ , V ₃ , and V ₄ in individuals >14 years of age in the presence of complete RBBB
IV. Depolarization/Conduction Abnormalities Epsilon wave (reproducible low-amplitude signals between end of QRS complex to onset of the T wave) in the right precordial leads (V ₁ to V ₃)	Late potentials by SAECD in ≥ 1 of 3 parameters in the absence of a QRS duration of ≥ 110 msec on the standard ECG Filtered QRS duration (fQRS) ≥ 114 msec Duration of terminal QRS <40 μ V (low-amplitude signal duration) ≥ 38 msec Root mean square voltage of terminal 40 msec ≤ 20 μ V Terminal activation duration of QRS ≥ 55 msec measured from the nadir of the S-wave to the end of the QRS, including R', in V ₁ , V ₂ , or V ₃ , in the absence of complete RBBB
V. Arrhythmias Nonsustained or sustained ventricular tachycardia of left bundle-branch morphology with superior axis (negative or indeterminate QRS in leads II, III, and aVF and positive in lead aVL)	Nonsustained or sustained ventricular tachycardia of RV outflow configuration, LBBB morphology with inferior axis (positive QRS in leads II, III, and aVF and negative in lead aVL), or of unknown axis >500 ventricular extrasystoles per 24 h (Holter)
VI. Family History ARVC confirmed in a first-degree relative who meets current TFC ARVC confirmed pathologically at autopsy or surgery in a first-degree relative Identification of a pathogenic mutation categorized as associated or probably associated with ARVC in the patient under evaluation	History of ARVC in a first-degree relative in whom it is not possible or practical to determine whether the family member meets current TFC Premature sudden death (<35 years of age) due to suspected ARVC in a first-degree relative ARVC confirmed pathologically or by current TFC in a second-degree relative

Diagnostic terminology: definite diagnosis: two major or one major and two minor criteria, or four minor from different categories; borderline: one major and one minor or three minor criteria from different categories; possible: one major or two minor criteria from different categories. 2-D, 2-Dimensional; ARVC, arrhythmogenic right ventricular cardiomyopathy; BSA, body surface area; CMR, cardiac magnetic resonance; ECG, electrocardiogram; echo, echocardiography; LBBB, left bundle branch block; PLAX, parasternal long-axis view; PSAX, parasternal short-axis view; RBBB, right bundle branch block; RV, right ventricle/ventricular; RVOT, right ventricular outflow tract; SAECD, signal averaged electrocardiogram; TFC, task force criteria.

From Etom Y, Govindapillai S, Hamilton R, et al. Importance of CMR within the task force criteria for the diagnosis of ARVC in children and adolescents. *J Am Coll Cardiol*. 2015;65:987–995.

Endomyocardial Biopsy

Definitive diagnosis of ARVC requires histological confirmation. A myocardial biopsy showing myocyte loss (<45% residual myocytes) with fibrosis and fatty infiltration (>40% fibrous tissue and >3% fat) confirms the diagnosis. However, myocardial biopsy lacks sufficient sensitivity (67% in one report) owing to the patchy nature of the disease. For safety reasons, the biopsy is performed mostly in the interventricular septum, which is histopathologically rarely involved in the disease process. Biopsy sampling performed on the RV free wall may improve the ability to diagnose ARVC. However, because of the frequently observed wall thinning with aneurysms or diverticula, free wall sampling is associated with risk of cardiac perforation, particularly when performed at random sites. Therefore the role of endomyocardial biopsy in the diagnosis of ARVC remains controversial.

Electroanatomic voltage mapping, which seems to be an effective technique to detect RV low-voltage regions reflecting fibrofatty myocardial atrophy in ARVC patients, has been shown to improve the diagnostic accuracy of myocardial biopsy by reducing the sampling errors. Endomyocardial biopsies are obtained from low-voltage areas, preferably from the border zone, to minimize the risk of perforation.

Immunohistochemical analysis of conventional biopsy samples to detect a change in the distribution of desmosomal proteins can also improve the sensitivity and specificity of endomyocardial biopsy. Reduced immunoreactive signal levels of plakoglobin at intercalated discs were found to be a consistent feature in patients with ARVC. Nonetheless, more recent studies revealed that sarcoidosis and giant cell myocarditis can cause similar patterns.³⁰

Genetic Testing

Molecular genetic analysis can potentially facilitate timely diagnosis, guide interpretation of borderline investigations, and corroborate clinical suspicion of disease in an index case. Although the patient with an established clinical diagnosis of ARVC may not personally benefit from genetic testing (since the presence or absence of a gene defect would not alter the treatment), genetic testing is still recommended because it can enable cascade screening of relatives and the early identification of asymptomatic carriers who must be considered at risk, because the disease is progressive and can appear later, due to the age-related penetrance.^{6,31}

However, sequence analysis of the known desmosomal ARVC-related genes only identifies a responsible mutation in approximately 50% of ARVC probands. Nevertheless, recent studies support the use of genetic testing as a new diagnostic tool in ARVC and suggest a prognostic impact, as the severity of the disease appears different according to the underlying gene or the presence of multiple mutations. Importantly, genetic testing is not recommended for patients with only a single minor criterion according to the 2010 task force criteria.

In a significant proportion of probands, more than one disease-causing mutation can be found (mostly in different genes). Therefore it is recommended that all desmosome genes be tested simultaneously in the proband. Whenever a pathogenic mutation is identified, it becomes possible to establish a presymptomatic diagnosis of the disease among family members and to provide them with genetic counseling to monitor the development of the disease and to assess the risk of transmitting the disease to offspring.³²

Invasive Electrophysiological Testing

The value of invasive EP testing with programmed ventricular stimulation for the diagnosis and risk stratification in ARVC patients appears to be limited and, hence, is rarely indicated. The inducibility of VT or VF in an EP study was not found to reliably predict arrhythmic events or appropriate ICD therapies.

Nonetheless, electroanatomic voltage mapping can help identify and quantify an electroanatomical scar area (which correlates with fibrofatty myocardial replacement), and was found to be more sensitive than CMR in identifying an RV scar.³³ The extent of RV low-voltage areas appear to predict increased risk of arrhythmic events.²⁴ In addition, this technique has been shown to be especially useful in distinguishing subclinical ARVC from idiopathic RVOT VT.²¹ Substrate mapping can also be used to guide and improve the diagnostic accuracy of myocardial biopsy. Therefore EP testing may be considered in individual patients, but it is not recommended as a routine diagnostic tool.

Importantly, an arrhythmogenic response to high-dose intravenous (IV) isoproterenol (45 µg/min for 3 minutes, regardless of heart rate) can potentially help diagnose ARVC, particularly in the early stages of the disease. The occurrence of polymorphic ventricular arrhythmias (PVCs and sustained and nonsustained VT) with predominant left bundle branch block (LBBB) morphology (different from the typical pattern observed in RVOT VT) during isoproterenol testing (during or within 10 minutes after the cessation of isoproterenol infusion) is highly suggestive of ARVC in the absence of other structural heart disease (sensitivity, 91%; negative predictive value, 99%). In contrast, a sustained monomorphic RVOT VT response during isoproterenol testing is considered a negative response.³⁴

DIFFERENTIAL DIAGNOSIS

Differential diagnosis of ARVC include idiopathic RVOT VT, dilated cardiomyopathy (DCM), cardiac sarcoidosis, Brugada syndrome, myocarditis, RV infarction, and congenital heart disease, and pulmonary hypertension. In addition, other forms of VT with an LBBB pattern need to be considered, including bundle branch reentry (BBR) VT, reentrant VT following surgical repair of congenital heart disease, and postinfarction VT originating from the LV septum, as well as AVRT using an atriofascicular bypass tract (BT).

Idiopathic Right Ventricular Outflow Tract Tachycardia

In clinical practice, the disease that most frequently mimics ARVC is idiopathic RVOT VT. Although RVOT VT is associated with a benign prognosis with no familial basis, it can be extremely difficult to distinguish from the concealed phase of ARVC, in which typical ECG and imaging abnormalities are absent. Similar to RVOT VT, the VT in ARVC also affects young adults, is commonly catecholamine-facilitated, and can originate from the RVOT. The distinction between the two entities has important prognostic and therapeutic implications (Box 29.1).

Electrocardiogram During Sinus Rhythm

In ARVC, the resting 12-lead ECG in normal sinus rhythm (NSR) typically shows characteristic depolarization and repolarization abnormalities (see below). In contrast, the resting ECG in NSR is typically normal in patients with idiopathic RVOT VT, with no epsilon wave, QRS widening or fragmentation, or other markers of delayed activation of the RV. Patients with idiopathic VT also have a normal SAECG in NSR.

Nevertheless, the ECG also can be normal in up to 50% of patients with ARVC at presentation, but in almost no patients 6 years after initial diagnosis. Furthermore, approximately 10% of patients with idiopathic RVOT VT can have complete or incomplete RBBB during NSR.

Electrocardiogram During Ventricular Tachycardia

Patients with idiopathic RVOT VT typically present with a single-morphology VT. The presence of multiple VT morphologies and RV sites of origin of the VT that are inconsistent with idiopathic RVOT VT (e.g., LBBB with superior axis) should prompt the consideration of ARVC. Nonetheless, it should be recognized that patients with several

BOX 29.1 Findings Favoring Arrhythmogenic Right Ventricular Cardiomyopathy Over Idiopathic Right Ventricular Outflow Tract Ventricular Tachycardia

Electrocardiogram During Sinus Rhythm

- Depolarization abnormalities: epsilon waves, RBBB, QRS fragmentation, localized QRS widening, and terminal S wave prolongation in right precordial leads
- Repolarization abnormalities: T wave inversion in the right precordial leads

Electrocardiogram During Ventricular Tachycardia

- Multiple VT morphologies and RV sites of origin
- LBBB with superior axis
- QRS duration in lead I ≥ 120 msec
- Late precordial transition (at lead V₅ or V₆)
- Notching in the QRS in multiple leads (especially in leads I and aVL)
- LBBB morphology with a superior axis is very unlikely in idiopathic RVOT VT

Signal-Averaged Electrocardiogram

- Late potentials and fragmented electrical activity

Isoproterenol Testing

- Inducibility of polymorphic ventricular arrhythmias (PVCs, sustained or non-sustained VT) with predominant LBBB morphology (different from the typical pattern observed in RVOT VT) during high-dose isoproterenol testing

Invasive Electrophysiological Testing

- Reproducible initiation of VT by programmed stimulation
- Lack of response of VT to adenosine
- Induction of VTs with different QRS morphologies
- Fractionated diastolic electrograms recorded during VT or sinus rhythm at the VT site of origin
- Electroanatomical scars on voltage mapping

Cardiac Imaging

- RV dilation, aneurysm, or systolic dysfunction

idiopathic VT morphologies have been reported, and patients with ARVC can initially present with only one VT morphology consistent with an RVOT origin.³⁵

During VTs with LBBB and inferior axis, certain features of the QRS complex favor ARVC over RVOT VT including: (1) later precordial transition (at lead V₅ or V₆); (2) QRS notching in at least two leads (in particular, leads I and aVL); and (3) QRS duration in lead I exceeding 120 to 125 milliseconds. The most specific finding was late precordial transition (100% specificity at lead V₆ and 90% specificity at lead V₅ or later), and the most sensitive was the duration of QRS in lead I exceeding 120 milliseconds, followed by the presence of any notching on the QRS complex. QRS notching and longer QRS duration in ARVC reflect the abnormal myocardial substrate underlying the VT, which is lacking in idiopathic RVOT VT.^{36–38}

Invasive Electrophysiological Testing

The response during EP testing is also helpful in distinguishing idiopathic RVOT VT from ARVC. Reentry is the mechanism of VT in the

majority of the ARVC patients, whereas RVOT VT almost always displays features of triggered activity. The repetitive initiation of VT by programmed stimulation suggests a reentrant mechanism. In one report, programmed electrical stimulation induced VT in all but 1 of 15 patients with ARVC compared with only 2 patients with idiopathic RVOT VT (93% vs. 3%). Unlike RVOT VT, the VT in ARVC does not terminate with adenosine. Furthermore, the induction of VT with different QRS morphologies is common in ARVC (observed in 73% of patients in one report) and is very rare with RVOT VT (except for minor variations in QRS axis). In addition, fractionated diastolic electrograms recorded during VT or NSR at the VT site of origin or other RV sites, or late potentials in NSR, are inconsistent with idiopathic RVOT VT but are typical for ARVC.³⁵

In addition, electroanatomic voltage mapping can help distinguish early or concealed ARVC from idiopathic VT by detecting RV electroanatomical scars that correlate with the histopathological features pathognomonic of ARVC.

Isoproterenol Testing

As noted earlier, the inducibility of polymorphic ventricular arrhythmias with predominant LBBB morphology (not typical for RVOT VT) during high-dose isoproterenol testing favors ARVC over RVOT VT (sensitivity, 91%; and negative predictive value, 99%). Induction of a single monomorphic VT morphology favors RVOT VT.³⁴

Cardiac Imaging

Patients with idiopathic VT have normal imaging studies (echocardiography, CMR, contrast ventriculography) of RV size and function. The presence of RV dilation or aneurysm is consistent with ARVC.

Cardiac Sarcoidosis

In the absence of a previous diagnosis of extracardiac sarcoidosis, sarcoid heart disease can present a diagnostic challenge and can mimic the clinical presentation of ARVC with respect to arrhythmic, ECG, and structural cardiac findings. In fact, cardiac sarcoid patients often fulfill the revised task force diagnostic criteria for ARVC (63% in one report). Furthermore, cardiac sarcoidosis is diagnosed in about 15% of patients who are initially suspected to have ARVC.³⁵

Several similarities exist between sarcoid heart disease and ARVC. Cardiac sarcoidosis is associated with the replacement of myocytes with noncaseating granulomas. RV involvement (with confluent regions of endocardial and, more predominantly, epicardial RV scarring) is common and appears to be particularly arrhythmogenic. Multiple scar-related monomorphic VTs (predominantly due to scar-related macroreentry) are frequent, and commonly originate from the RV and, hence, exhibit LBBB morphology. The surface ECG during NSR commonly exhibits RBBB, QRS fragmentation, T wave inversion in the right precordial leads, and PVCs. Epsilon waves can be observed with a similar frequency in both ARVC and cardiac sarcoidosis. Furthermore, about 14% to 56% of the patients with cardiac sarcoidosis have detectable abnormalities on echocardiogram, such as LV or RV systolic dysfunction, wall-motion abnormalities, ventricular aneurysm, or basal septum thinning.^{39,40} In contrast to ARVC, a disorder largely confined to the RV free wall, cardiac sarcoidosis typically spares the free wall and involves the septum.

One report suggested that a reduced left ventricular ejection fraction (LVEF) should raise suspicion of cardiac sarcoidosis even if ARVC diagnostic criteria are fulfilled. Compared to patients with ARVC, those with cardiac sarcoidosis tend to have a significantly lower LVEF, significantly wider QRS complexes, and more different morphologies of inducible monomorphic VT, which originate more commonly in the apical region of the RV.^{35,41} In addition, screening for cardiac sarcoidosis should be considered in young patients (<60 years) with unexplained

Mobitz II or third-degree AV block, in those with unexplained monomorphic VT, and in those with unexplained nonischemic cardiomyopathy presenting with ventricular arrhythmias.^{39,42} Initial testing typically includes computed tomography (CT) scan of the chest for pulmonary sarcoid and advanced cardiac imaging (CMR or positron emission tomography [PET]). Abnormal finding on those tests should prompt definitive histological diagnosis.⁴³

Dilated Cardiomyopathy

ARVC is distinguished from DCM by the greater degree of arrhythmogenicity. Although ventricular arrhythmia is a relatively common finding in DCM, it is rare in the absence of significant ventricular dysfunction, and SCD is seldom the mode of presentation. In contrast, ARVC is associated with a propensity toward ventricular arrhythmias even in the absence of significant ventricular dysfunction. SCD is the first clinical manifestation of the disease in more than 50% of ARVC probands. In addition, regional involvement and aneurysm formation, which are characteristic of ARVC, argue against the diagnosis of DCM.

Athlete's Heart

The term *athlete's heart* refers to a constellation of electrical and structural cardiac adaptations in response to intensive and long-term athletic training. Such physiological cardiac remodeling allows the generation of a large and sustained cardiac output even at rapid heart rates. Although athletic adaptation of the left side of the heart has been well recognized, recent evidence revealed that the athlete's RV undergoes structural and functional adaptation in synergy with the LV. Physiological remodeling of the RV can manifest electrical and structural changes that mimic those observed in ARVC, including RV enlargement (typically in conjunction with LV enlargement and normal ventricular wall motion), anterior precordial T wave inversion (typically biphasic T wave morphology with preceding convex ST segment elevation), and PVCs of RV origin.^{44,45}

Distinguishing physiological remodeling of the athlete's RV (generally considered benign and nonarrhythmogenic) from ARVC (which is responsible for as many as 22% of SCDs in young athletes in Europe) has important management and prognostic implications. A false-positive diagnosis can potentially lead to erroneous disqualification from competition, whereas a false-negative diagnosis can result in devastating SCD.

RV dilatation in conjunction with convex ST segment elevation and biphasic anterior T wave inversion, and concomitant enlargement of the left and right sides of the heart with normal wall motion, appear to be benign findings and should not trigger further evaluation for ARVC in asymptomatic athletes without an adverse family history (Fig. 29.2). Conversely, the presence of symmetrical anterior T wave inversion that extends beyond lead V₁, preceded by isoelectric or downsloping ST segments, depolarization abnormalities (e.g., Epsilon waves or terminal QRS activation delay), reduced limb lead voltages, PVCs with LBBB morphology and superior axis, and global RV systolic dysfunction or regional wall motion abnormalities, should prompt careful investigation to exclude ARVC.^{44,45}

Exercise-Induced Arrhythmogenic Right Ventricular Cardiomyopathy

A relationship has been postulated between intense endurance exercise and an "acquired" ARVC-like phenotype without an identifiable genetic predisposition (sometimes referred to as "exercise-induced ARVC"). In favor of this hypothesis is the lower than expected prevalence of desmosomal gene mutations (13% vs. 50%) identified in endurance athletes with complex ventricular arrhythmias of RV origin and definite or suspected ARVC diagnosis according to the revised task force criteria. Furthermore, 3% of black and 0.3% of white athletes were found to

meet the criteria for ARVC, but further investigation did not detect any pathological findings.^{14,46–49}

Intense endurance exercise is associated with increased hemodynamic load (increased afterload, wall stress, work, and oxygen demand), which is proportionally greater for the RV than for the LV, and can result in transient exercise-induced RV dysfunction. Consecutive bouts of RV dilatation and dysfunction can potentially alter the RV interstitial matrix and lead to chronic RV remodeling, generating a substrate for serious arrhythmias in the absence of a known genetic predisposition.^{14,47,48}

Uncertainty exists regarding why a small fraction of athletes develop this profound degree of nonphysiological, arrhythmogenic RV remodeling. Impaired balance between cellular stress and repair and a milder degree of yet unidentified genetic predisposition have been hypothesized.^{47–49}

RISK STRATIFICATION

Once the diagnosis of ARVC is established, evaluation should be directed to assessing the patient's risk of arrhythmic events and SCD. Those deemed at low risk at initial evaluation should undergo periodic evaluation (every 1 to 2 years or whenever clinical symptoms develop or worsen) with ECG, echocardiography, 24-hour Holter monitoring, and exercise testing to reassess the risk of SCD and to optimize the treatment.

Factors identifying ARVC patients at risk for SCD have not yet been defined in large prospective studies focusing on survival. Nonetheless, three categories of risk for SCD (high, intermediate, and low) have been determined by consensus based on observational studies or registries of ARVC patients (Box 29.2).^{2,26,50–52}

The *high-risk* category (estimated annual rate of malignant arrhythmic events >10%) includes patients who experienced cardiac arrest due to VF or sustained VT, or those with severe RV dysfunction (RV fractional area change ≤17% or RV EF ≤35%) or LV dysfunction (LVEF ≤35%). This group of patients has an estimated annual rate of life-threatening arrhythmic events >10%.^{24,52–54}

The *intermediate-risk* category (estimated annual rate of malignant arrhythmic events 1% to 10%) includes patients with one or more of the risk factors recognized by consensus experts. Those risk factors are classified as either "major" or "minor." Major risk factors include a syncopal episode of unexplained origin (i.e., not neurally mediated) or thought to be consistent with ventricular arrhythmia, nonsustained ventricular tachycardia (NSVT), and moderate RV dysfunction (RV fractional area change of 17% to 24% or right ventricular ejection fraction [RVEF] of 36% to 40%) or LV dysfunction (LVEF of 36% to 45%). The prognostic implications of minor risk factors remain uncertain.^{2,21,52}

The *low-risk* category (estimated annual rate of malignant arrhythmic events <1%) includes ARVC patients and relatives without risk factors as well as healthy gene carriers. Of note, family history of arrhythmic events does not appear to influence risk in other family members.

PRINCIPLES OF MANAGEMENT

Pharmacological Therapy

Beta-Blockers

The current consensus recommends the use of beta-blockers (titrated to the maximally tolerated dose) in most patients diagnosed with ARVC, given the multiple potential benefits in this patient population. First, the inhibition of sympathetic activity can potentially reduce the risk of effort-induced ventricular arrhythmias. Second, beta-blockers can reduce the risk of inappropriate ICD therapies triggered by sinus tachycardia or supraventricular arrhythmias. Third, beta-blockers have a proven benefit in heart failure management. Another potential value

(From Zaidi A, Sheikh N, Jongman JK, et al. Clinical differentiation between physiological remodeling and arrhythmogenic right ventricular cardiomyopathy in athletes with marked electrocardiographic repolarization anomalies. *J Am Coll Cardiol*. 2015;65:2702–2711.)

of beta-blocker therapy is retarding the progression of disease in individuals who are asymptomatic (by lowering RV wall stress); however, this has not been proven. Importantly, there is no proof that beta-blocker therapy confers protection against SCD.^{2,3,55}

Antiarrhythmic Drugs

Although antiarrhythmic drug therapy does not lower the risk of SCD in ARVC, it is indicated to reduce the frequency of symptomatic ventricular arrhythmias (PVCs, sustained and nonsustained VT) and as an adjunct therapy to ICD to reduce the frequency of ventricular arrhythmias in patients with unacceptably frequent ICD therapies. Antiarrhythmic agents can also be considered as an adjunct therapy to catheter ablation without a back-up ICD in patients with recurrent, hemodynamically stable VT. Prophylactic antiarrhythmic drug therapy alone (without ICD implantation) in asymptomatic ARVC patients does not offer reliable protection against SCD and is generally not indicated.^{2,24}

Amiodarone, alone or in combination with beta-blockers, is the most effective drug for preventing symptomatic ventricular arrhythmias.² Sotalol can also be considered; however, evaluation of its efficacy with programmed electrical stimulation or with cardiac monitoring needs to be considered.^{55,56}

Heart Failure Therapy

For patients with RV or biventricular heart failure, standard pharmacological treatment with angiotensin-converting-enzyme inhibitors, angiotensin II receptor blockers, beta-blockers, and diuretics is recommended. Although angiotensin-converting enzyme inhibitors are well known for slowing progression in other cardiomyopathies, their value in ARVC patients is yet to be proven.

Anticoagulation Therapy

Long-term oral anticoagulation is generally indicated for secondary prevention in patients with documented intracardiac clots or venous

BOX 29.2 Risk Categories for Sudden Cardiac Death in ARVC**High Risk**

- Prior sustained ventricular arrhythmias
- Severe dysfunction of RV, LV, or both (EF $\leq 35\%$)
- Aborted sudden cardiac death

Intermediate Risk**Major Risk Factors**

- Syncope
- NSVT
- Moderate dysfunction of RV, LV, or both (RV fractional area change between 24% and 17% or RVEF between 40% and 36% and/or LV EF between 45% and 36%)

Minor Risk Factors

- Young age
- Male gender
- Complex genotype

Minor Risk Factors—cont'd

- Presence of more than one mutation
- Compound or digenic heterozygosity of desmosomal-gene mutations
- Desmoplakin mutation
- Proband status
- Inducible VT/VF
- Extent of RV scar on electroanatomic mapping
- Fragmented electrograms on electroanatomic mapping
- Extent of TWI across precordial leads or in inferior leads
- QRS fragmentation
- Precordial QRS amplitude ratio
- CMR abnormalities
- Heart failure/transplantation

Low Risk

- No risk factors
- Healthy gene carriers

The high-risk category includes patients with prior sustained ventricular arrhythmias, severe dysfunction of RV, LV, or both (ejection fraction $\leq 35\%$), or aborted sudden cardiac death. The estimated rate of life-threatening arrhythmic events is greater than 10% per year, and therefore ICD implantation is considered a class I indication in this group. The low-risk group includes probands and relatives without risk factors and healthy gene carriers who have a less than 1% per year life-threatening arrhythmic event rate. These patients do not require ICD implantation (class III). The intermediate group had an estimated annual event rate between 1% and 10% and was composed of ARVC patients with one risk factor. There was general agreement that patients with one major risk factor, which includes syncope, NSVT, and moderate ventricular dysfunction (RVEF between 36% and 40% or LVEF between 36% and 45%) should undergo prophylactic ICD implantation (class IIa).

or systemic thromboembolism. However, prophylactic anticoagulation for primary prevention of thromboembolism on the basis of ventricular dilatation or dysfunction, either global or regional, is not recommended.²

Catheter Ablation

Endocardial catheter ablation of monomorphic VT has a 60% to 80% acute success rate in patients with ARVC, but long-term recurrences are frequent (50% to 70%). Additional antiarrhythmic drug therapy and repeated ablation procedures are frequently required to provide clinical control of VT. Some reports show that epicardial catheter ablation is substantially more effective acutely, and has better long-term success than endocardial ablation. At present, catheter ablation of VT is considered palliative rather than curative, and is recommended mainly for patients with recurrent VT causing frequent ICD shocks and for those with VT storm or incessant VT refractory to antiarrhythmic drug therapy.²

Importantly, VT ablation does not appear to reduce the risk of SCD in ARVC. Therefore catheter ablation should not be considered as an alternative to ICD therapy in ARVC patients with VT. Nonetheless, catheter ablation may be considered as first choice therapy without a back-up ICD for selected patients with drug-refractory, hemodynamically stable, single-morphology VT (class IIb indication).^{2,21,57}

Implantable Cardioverter-Defibrillator

ICD therapy is the most effective and reliable approach for reduction of the risk of SCD in ARVC patients, both for primary and secondary prevention, with an estimated 24% to 35% mortality reduction at 36 months of follow-up. ICD implantation is recommended for secondary prevention in patients with prior cardiac arrest or sustained VT because of the relatively high recurrence rates in this subgroup.

Candidates for primary prevention ICDs are categorized into high-risk, intermediate-risk, and low-risk groups (Box 29.2; Fig. 29.3). Prophylactic ICD implantation is recommended in patients with high risk factors (severe RV dysfunction [RV fractional area change $\leq 17\%$ or RVEF $\leq 35\%$] or LV dysfunction [LVEF $\leq 35\%$]) irrespective of arrhythmias. Conversely, prophylactic ICD implantation is not recommended in asymptomatic ARVC patients with no risk factors, or healthy gene carriers. Among patients in the intermediate-risk group, ICD implantation should be considered in patients with “major” risk factors such as unexplained syncope, NSVT, or moderate RV dysfunction (RV fractional area change of 17% to 24% or RVEF of 36% to 40%) or moderate LV dysfunction (LVEF of 36% to 45%). The value of ICD therapy in those with “minor” risk factors is not well established, but may be considered after a careful discussion of the long-term risks and benefits of ICD implantation in the individual patient and considering the desires of the fully informed patient and family.⁵⁵

The rate of appropriate ICD therapy is high (24% to 78%) in the first few years after implantation, with an annualized rate of about 9.5%. Multiple ICD discharges and VT storm are not uncommon. Of note, the interval from ICD implantation to first appropriate device intervention is quite variable, and typically exceeds 1 year in a large proportion of patients.²

It is important to recognize that ICD implantation is an invasive measure and carries a definite rate of complications as well as the need for recurring device service and generator changes. In particular, lead-related adverse events are relatively common in this patient population. More than 6% of patients experience major complications requiring the revision of the implant over a 7-year follow-up period.²⁴ The thin RV wall can predispose to lead perforation. In addition, the progressive loss of myocardium with fibrofatty replacement can result in suboptimal

Fig. 29.3 Risk Stratification and Indications of Implantable Cardioverter-Defibrillator (ICD) Implantation in Arrhythmogenic Right Ventricular Cardiomyopathy. Based on the available data on annual mortality rates associated with specific risk factors, the estimated risk of major arrhythmic events in the high-risk category is greater than 10% per year, in the intermediate ranges from 1 to 10% per year, and in the low-risk category is less than 1% per year. Indications to ICD implantation were determined by consensus taking into account not only the statistical risk, but also the general health, socioeconomic factors, the psychological impact, and the adverse effects of the device. ^aSee the text for distinction between *major* and *minor* risk factors. LV, Left ventricle; NSVT, nonsustained ventricular tachycardia; RV, right ventricle; SCD, sudden cardiac death; VF, ventricular fibrillation; VT, ventricular tachycardia. (From Corrado D, Wichter T, Link MS, et al. Treatment of arrhythmogenic right ventricular cardiomyopathy/dysplasia: an international task force consensus statement. *Eur Heart J*. 2015;36:3227–3237.)

ventricular sensing and pacing functions, especially for RV apical lead placement. Septal positioning of the RV lead appears to improve long-term lead performance.⁵⁸

Furthermore, inappropriate ICD interventions occur in 10% to 25% of ARVC patients (annualized rate of about 3.7%), mostly at a young age, and are usually caused by sinus tachycardia or atrial tachyarrhythmia.²¹ Strategic ICD programming can help reduce the incidence of inappropriate interventions.⁵⁹ The vast majority of ventricular arrhythmias in ARVC patients are monomorphic VTs, which can be successfully terminated by antitachycardia pacing therapy. Therefore ICDs should be programmed for antitachycardia pacing therapy, even for rapid VT.⁵² In addition, beta-blocker therapy can help prevent excessive sinus tachycardia and rapid ventricular rates during atrial arrhythmias. Dual-chamber devices can improve the discrimination of ventricular from supraventricular arrhythmias but at the expense of additional potential complications of adding an atrial lead.^{2,59,60}

Therefore the benefit of ICD implantation should be carefully weighed against the risks of such a procedure in this young patient population. The negative psychological impact of an implanted device and inappropriate shocks should not be underestimated.⁵⁹

Participation in Sports

Intense exercise can serve as a trigger for fatal arrhythmias and has been shown to double the risk of SCD in adolescent and young adults with ARVC, likely related to acute volume overload with RV stretching and adrenergic stimulation during exercise. Further, mechanical stress

can potentially promote the development and progression of the ARVC phenotype.²⁴

In fact, sports disqualification *per se* is a life-saving measure. Therefore individuals with a definite, borderline, or possible diagnosis of ARVC should not participate in most competitive sports, with the possible exception of low-intensity class 1A sports.⁶¹ Furthermore, any activity, competitive or not, that causes symptoms of palpitations, presyncope, or syncope should be avoided. Although the restriction of moderate- to high-intensity-level recreational activities is generally recommended, a recent report suggested that recreational sport participation was not associated with the earlier presentation of symptoms or the increased risk of ventricular arrhythmias or death when compared with inactive ARVC probands.¹³

The issue of exercise restriction is challenging in family members of ARVC patients. Restriction from competitive sports activity is reasonable in healthy gene carriers without symptoms or overt clinical disease.^{2,62} For family members of probands without an identified mutation, the benefit of exercise restriction is uncertain. Exercise stress testing (to evaluate for exertional ventricular arrhythmias) can potentially help guide exercise prescription. In those preferring to participate in competitive sports, frequent screening for ARVC should be considered.⁶³

Family Screening

Since ARVC is primarily caused by an autosomal dominant genetic defect, every offspring has a 50% chance of inheriting the disease-causing mutation. However, because of the age-dependent penetrance, many

mutation carriers may not exhibit phenotypic expression early in life, and many others may express the phenotype but remain asymptomatic and, hence, remain undiagnosed unless screened.²⁴

When the causative mutation in the index patient is identified, genetic testing is recommended in all first-degree relatives. Mutation-negative family members and their descendants have no risk for developing ARVC and do not need further evaluation.⁶ Family members who test positive for an ARVC genetic mutation may not exhibit clinical manifestations of the disease, given the lack of association of the genotype with the phenotypic expression of the disease. Therefore cardiac evaluation is required in mutation-positive patients to identify those with the disease. Clinical evaluation may start at the age of 10 to 12 years; clinical expression of the disease and SCD are extremely rare at less than 10 years of age.^{4,64} Due to the age-related penetrance of ARVC, healthy gene carriers should also be offered repeat clinical assessment (every 2 to 3 years), especially during adolescence and young adulthood.

When genetic testing is not performed in the proband, or when genetic analysis fails to identify a definite disease-causing mutation (or reveals one or more genetic variants of unknown significance), genetic testing in the related family members is not recommended. Instead, it is recommended that all first-degree genetically related family members undergo clinical screening with detailed history and physical examination, 12-lead ECG, echocardiography, Holter monitoring, and CMR imaging. Given the low penetrance observed in most families, screening should be extended throughout the kindred to at least one generation beyond the last affected individual. Importantly, no single test is capable of excluding the diagnosis of ARVC. Therefore a full baseline evaluation remains necessary in determining an at-risk individual's phenotype. Approximately, one-third of at-risk relatives fulfill diagnostic 2010 task force criteria for ARVC at the first evaluation.^{4,64}

Asymptomatic family members with a normal comprehensive evaluation are less likely to experience life-threatening arrhythmias during short-term (4 years) follow-up, and are less likely to have inherited the gene defect. Nevertheless, these individuals should undergo follow-up at regular intervals until definitive diagnostic tools are available.⁵⁰ It is suggested that clinical screening be performed every 2 to 3 years between the ages of 10 and 20 years, and every 5 years after the age of 20 years. Screening may be stopped at the age of 50 to 60 years because the disease uncommonly presents after that. Importantly, the overall rate of progression in relatives of ARVC probands is typically slow, and only minimal changes may be observed on any single testing modalities between baseline and last follow-up. Electrical progression on ECG, Holter monitoring, or SAECG is observed to a much greater extent than structural progression on CMR.^{4,6,64}

Among family members of ARVC patients, approximately one-third eventually develop disease, and 10% develop sustained ventricular arrhythmias. The risk is higher in genotype-positive family members, who have double the risk of developing ARVC and an eightfold increased risk of developing sustained ventricular arrhythmias in comparison to family members of probands without a desmosomal mutation.

ELECTROCARDIOGRAPHIC FEATURES

Electrocardiogram During Sinus Rhythm

ECG abnormalities are present in the majority of patients with ARVC and often precede structural abnormalities. Although a normal ECG can be present in up to 40% of ARVC patients at presentation, by 6 years, almost all patients have one or more of several characteristic findings on ECG during NSR. Significant differences exist in most ECG features among ARVC patients according to the degree of RV involvement, and they are more prevalent in diffuse ARVC than in the localized form of the disease.³⁵

ECG abnormalities during ARVC can be subdivided into abnormalities of repolarization or depolarization. Depolarization abnormalities are caused by cellular uncoupling and altered tissue architecture due to fibrofatty infiltration, and typically manifest on the ECG as epsilon waves, RBBB, QRS fragmentation, localized QRS widening, and terminal S wave prolongation in right precordial leads (Fig. 29.4). Repolarization abnormalities typically manifest as T wave inversion in the right precordial leads.^{65,66}

Repolarization Abnormalities

Repolarization abnormalities are the most common ECG features, with T wave inversion in leads V₁ through V₃ observed in 87% of patients with ARVC (prevalence has been reported as 55% to 94% in different series). T wave inversion in ARVC is likely secondary to the regional conduction delay and RV dilatation, rather than a primary repolarization abnormality. The extent of right precordial T wave inversion relates to the degree of RV involvement, and was found to predict an increased risk of arrhythmic events.^{35,51,67}

T wave inversion in leads V₁ through V₃ or beyond (in the absence of complete RBBB) in individuals older than 14 years is considered a major diagnostic criterion for ARVC. On the other hand, inverted T waves *only* in leads V₁ and V₂ (in the absence of complete RBBB) or in leads V₁ through V₄ (in the presence of RBBB) in individuals older than 14 years are considered as minor diagnostic criteria for ARVC.⁶⁸ The absence of negative T waves beyond lead V₁ characterizes a low-risk subgroup of ARVC patients with a more favorable clinical course because of a low rate of arrhythmic events.⁶⁹

However, T wave inversion in the right precordial leads is non-specific and can be observed in a multitude of conditions such as athlete heart, Brugada syndrome, and occasionally in the normal adult female.^{68,70}

Depolarization Abnormalities

Epsilon wave. The epsilon wave, the hallmark feature of ARVC, is a marker of delayed activation of the RV free wall and outflow tract and is considered a major diagnostic criterion for ARVC. The epsilon wave has the appearance of a reproducible distinct wave (low-amplitude small deflections) between the end of QRS complex to the onset of the T wave in the right precordial leads, particularly in lead V₁ (Figs. 29.5 and 29.6).^{70,71}

Epsilon waves represent low-amplitude potentials caused by delayed excitation of islands of surviving cardiomyocytes bordered by or embedded in interstitial fibrous and fatty tissue of some portion of the RV. Epsilon waves appear to be associated with significant endocardial scarring in addition to an epicardial scar, thus signifying extensive disease. Of note, the timing of epsilon waves on the surface ECG correlated with electrical activation of in the RV inflow and perivalvular regions (rather than RVOT or the RV apex).⁶⁶

The bipolar Fontaine precordial ECG leads I to III may be also used to enhance the recording of epsilon waves by applying placement of the right arm electrode on the manubrium, the left arm electrode on the xiphoid, and the left leg lead in V₄ location. The sensitivity of recording epsilon waves by using the Fontaine lead positions can be further accentuated when the ECG is taken at double paper speed and sensitivity, and a filter setting of 40 Hz.⁷⁰

Although the epsilon wave has been considered highly specific for ARVC, ECG markers that reflect ventricular conduction delay in ARVC (including the epsilon wave) are frequently observed in subjects with a spontaneous or drug-induced type 1 ECG pattern of Brugada syndrome and in association with diseases that involve the RV (such as RV infarction or sarcoidosis). In addition, this criterion is of limited sensitivity, observed in only 10% to 37% of ARVC patients when

Fig. 29.4 Representative of Total Endocardial and Epicardial Bipolar Activation and the Area of Activation During the Delayed Depolarization Period of QRS Complex in Different Electrocardiographic (ECG) Features in Arrhythmogenic Right Ventricular Cardiomyopathy Patients. The gradual color-coded model showed the sequence activation patterns of each ECG features. The two-color coded model with red for the activation before the abnormal depolarization and purple for activation during abnormal depolarization showed the area of activation during abnormal depolarization. *Abn*, Abnormal; *CRBBB*, complete right bundle branch block; *Depol*, depolarization; *ECG*, electrocardiogram; *IRBBB*, incomplete right bundle branch block; *LAO*, left anterior oblique view; *RAO*, right anterior oblique view; *TAD*, terminal activation duration. (From Tanawuttiwat T, Te Riele AS, Philips B, et al. Electroanatomic correlates of depolarization abnormalities in arrhythmogenic right ventricular dysplasia/cardiomyopathy. *J Cardiovasc Electrophysiol*. 2016;27:443–452.)

Fig. 29.5 Epsilon Wave. Surface electrocardiogram of sinus rhythm in a patient with arrhythmogenic right ventricular dysplasia-cardiomyopathy. *Inset:* Magnified view of a single complex in V_1 showing epsilon waves (arrow).

Fig. 29.6 Examples of Epsilon Waves in Patients With Arrhythmogenic Right Ventricular Cardiomyopathy. (A–D) Right precordial surface electrocardiographic leads obtained from four different patients. (From Platonov PG, Calkins H, Hauer RN, et al. High interobserver variability in the assessment of epsilon waves: implications for diagnosis of arrhythmogenic right ventricular cardiomyopathy/dysplasia. *Heart Rhythm*. 2016;13:208–216.)

evaluated by standard ECG. The use of highly amplified (20 mV) precordial leads and modified limb leads can increase the detection of epsilon potentials to 75%, but is rarely utilized.^{14,35}

Right bundle branch block. Incomplete or complete RBBB can be observed in 18% and 15% of patients, respectively. Epicardial mapping suggests that these patterns are usually caused by parietal block (due to the irregular and delayed propagation of activation in the zones of dysplasia), rather than by disease of the bundle branch itself. In the presence of an RBBB pattern, selective prolongation of the QRS duration in leads V_1 to V_3 compared with lead V_6 (>25 milliseconds, parietal block) is an important hallmark of ARVC (sensitivity of 52% to 64%). Increased QT dispersion (i.e., interlead variability of the QT interval) has been observed in ARVC.⁷⁰

Localized prolongation of QRS duration. Localized QRS widening (>110 milliseconds) in the right precordial leads can indicate an activation delay in the diseased region of the RV. QRS duration greater than 110 milliseconds in lead V_1 has a sensitivity of 26% to 75% and a

specificity of 100% in patients suspected of having ARVC based on historical features. To discriminate localized QRS prolongation from RBBB, the ratio of the sum of the QRS durations in leads $(V_1 + V_2 + V_3)/(V_4 + V_5 + V_6)$ is calculated. A ratio of ≥ 1.2 is considered abnormal and has a sensitivity of 35% to 98%.^{68,70}

Prolongation of S wave upstroke. Prolongation of the upstroke of the S wave (≥ 55 milliseconds from the nadir of the S wave to the isoelectric line) in leads V_1 through V_3 in the absence of RBBB was found in the original report to be a very sensitive ECG criterion for ARVC (present in all cases with diffuse ARVC and in 90% in the localized form of the disease). However, the sensitivity of this criterion was less than 60% in several other reports. This measurement has the highest diagnostic usefulness for differentiating the localized form of ARVC from idiopathic RVOT VT, correlates with the degree of RV involvement, and is an independent predictor of VT induction. It is recognized that a prolonged S wave upstroke directly relates to the QRS width in the right precordial leads; nonetheless, it is superior to localized QRS

prolongation in distinguishing the mild form of ARVC from idiopathic RVOT VT.^{35,68}

Prolonged terminal activation duration. Another ECG marker of abnormal depolarization in ARVC is the “terminal activation delay.” This parameter is measured from the nadir of the S wave to the end of all depolarization deflections, thereby including not only the S wave upstroke but also both late fractionated signals and epsilon waves, to the completion of the QRS complex. This criterion is only applicable in the absence of complete RBBB. A prolonged terminal activation delay (≥ 55 milliseconds) was observed in 71% of ARVC patients and only 4% of controls.⁶⁸

QRS fragmentation. QRS fragmentation in standard ECG leads is defined as deflections (slurs or notches) at the beginning of the QRS complex, on top of the R wave or in the nadir of the S wave, or as total QRS complex having four or more spikes. QRS fragmentation presenting in multiple leads is likely pathological, reflecting regional delay in ventricular depolarization. QRS fragmentation is highly prevalent in ARVC, especially when using amplified and modified ECG recording techniques (including the use of the Fontaine Leads System), with a sensitivity of 61% to 85%.³⁵ However, QRS fragmentation is not specific for ARVC and is prevalent in other types of cardiomyopathy, both ischemic and nonischemic.⁷⁰

QRS fragmentation can be of value in the stratification of the high-risk ARVC patients for arrhythmic events. In one report, the presence of QRS fragmentation in three or more of the standard 12-lead ECG predicted arrhythmic events with a sensitivity of 56% and a specificity of 99.7%.

Furthermore, a recent study found a strong correlation between QRS fragmentation on the surface ECG and the extent and anatomical distribution of abnormal RV endocardial and epicardial scarring (as identified on electroanatomic substrate mapping) in patients with ARVC.⁷²

Late potentials. “Late potentials” refer to the low-amplitude, high-frequency, and altered frequency components in the terminal QRS complex. These signals are too small to be visible on the surface ECG, but can be detected by high resolution SAECG. The SAECG is a highly amplified and signal-processed ECG that can detect microvolt-level electrical potentials. Late potentials, which reflect the slow conduction in the ventricular myocardium and electrical potentials that extend beyond the activation time of normal myocardium, typically arise from scarred myocardium, an anatomical substrate potentially responsible for reentrant ventricular arrhythmias.^{67,70}

The SAECG and its three components (filtered QRS duration, low-amplitude signal duration, and root-mean-square voltage of the last 40 milliseconds of the QRS) are highly associated with the diagnosis of ARVC. Late potentials and fragmented electrical activity can be detected by SAECG in 50% to 80% of patients with ARVC.^{67,70}

Although there are no guidelines for abnormal SAECG in patients with ARVC, it is common practice to categorize the SAECG as abnormal if two or more of these parameters are abnormal. In one report, the sensitivity of using SAECG for the diagnosis of ARVC was increased from 47% using two of the three criteria to 69% by using any one of the three criteria, while maintaining a high specificity of 90% to 95%. Abnormal SAECG was strongly associated with dilated RV volumes and decreased RV ejection fraction detected by CMR. SAECG abnormalities did not vary with clinical presentation, and had limited correlation with ECG findings. In addition, SAECG abnormalities appear to correlate with the presence of low-voltage areas selectively in the RVOT as observed during electroanatomic voltage mapping, whereas surface ECG abnormalities are associated with a more diffuse RV involvement. However, the value of SAECG for predicting inducible VT in ARVC remains uncertain.⁶⁷

Electrocardiogram During Ventricular Tachycardia

Ventricular ectopy in ARVC usually arises from the basal peri-valvular region in the RV and therefore has an LBBB pattern with superior, inferior, or indeterminate axis. Most sustained VTs arise from the RV free wall, most VTs display LBBB configuration with poor R-wave progression in the precordial leads. Nonetheless, VT with RBBB morphology can be observed in patients with LV disease or when advanced structural RV disease distorts normal ventricular geometry within the thorax (Fig. 29.7). The QRS axis during VT is typically between -90 and $+110$ degrees; an extreme rightward direction of the QRS axis is uncommon.⁷⁰

Leads I and aVR can help localize the VT exit site within the RV. The QRS complex is typically positive in lead I during VTs originating from the RV basal regions, but is isoelectric or negative in VTs with more apical sites of origins. Inferior RV exit sites exhibit a positive QRS in lead aVR, usually with a superior axis. Furthermore, the presence of a Q wave or QS configuration in leads I and V_2 (anterior RV epicardial sites) or Q waves leads II, III, or aVF (inferior RV epicardial sites) on the surface ECG during VT suggests the presence of an epicardial source of VT.⁷³

Importantly, patients with ARVC frequently demonstrate the presence of more than one VT morphology, either spontaneously (64%) or during an EP study (88%).

ELECTROPHYSIOLOGICAL FEATURES

Induction of Tachycardia

The most commonly used stimulation protocol applies pacing output at twice the diastolic threshold current and a pulse width of 1 to 2 milliseconds. Single ventricular extrastimuli (VESs) during NSR and at pacing drive cycle lengths (CLs) of 600 and 400 milliseconds are delivered, first from the RV apex and then from the RVOT. The prematurity of extrastimuli is increased until refractoriness or induction of sustained VT is achieved. If these measures fail to induce VT, double and then triple VESs are used in the same manner. If VT still cannot be induced, rapid ventricular pacing is started at a pacing cycle length (PCL) of 400 milliseconds, gradually decreasing the PCL until 1:1 ventricular capture is lost or a PCL of 220 milliseconds is reached. Repeating the protocol at other pacing drive CLs, at other RV sites, or after administration of isoproterenol is then attempted.

VT can be induced with programmed electrical stimulation in the majority of ARVC patients with clinical VT. Isoproterenol infusion facilitates VT induction in many patients. In patients with frequent PVCs at baseline, induction of VT with identical morphology to the clinical PVCs has been reported and frequently requires high-dose isoproterenol (up to 30 $\mu\text{g}/\text{min}$) combined with ventricular burst pacing. In these patients, salvos of nonsustained monomorphic VT may precede the emergence of sustained monomorphic ventricular tachycardia (SMVT) with an identical morphology.¹⁷

Tachycardia Features

Reentry in areas of abnormal myocardium is the most common mechanism of VT in ARVC. Most reentrant circuits cluster around the tricuspid annulus and the RVOT. Multiple morphologies of inducible VT are common. A variety of different reentry circuit sites can be identified with entrainment mapping. A single region can give rise to multiple VT morphologies. The VT burden is exceptionally high in this patient population, with a median of four distinct VTs (clinical and inducible) per patient.⁷⁴

The response of VT to programmed stimulation and resetting and entrainment maneuvers, is consistent with macroreentry, similar to post-MI VT (see Chapter 22 for detailed discussion).

VT-1

VT-2

Fig. 29.7 Surface Lead Electrocardiograms of Ventricular Tachycardia (VT) in a Patient With Arrhythmogenic Right Ventricular Cardiomyopathy. Both VTs have left bundle branch block-type morphology but with very different frontal axes.

A focal mechanism of VT has been observed in a minority of ARVC patients. Among patients with frequent PVCs at baseline, a high degree of association has been reported between catecholamine-facilitated induced sustained VTs and the clinical PVCs. VT in these patients exhibited features suggestive of a focal mechanism and had a QRS morphology identical to that of clinical PVCs. The site of origin of those VTs was mapped to the border region of the scar, typically in the RVOT and RV basal regions.¹⁷

MAPPING

VTs in ARVC share many features observed in post-MI VTs. First, the tachycardias typically are monomorphic and have a macroreentrant mechanism. Second, the circuits are composed of zones of abnormal conduction, characterized by low-amplitude abnormal electrograms, with identifiable exit regions to the surrounding myocardium. Third, outer loops, which can be broad portions of the reentry circuit in communication with the surrounding myocardium, have also been observed. Fourth, the ablation targets in post-MI VT (critical isthmus) are similar to those in ARVC. Therefore mapping techniques for ARVC-related VT are similar to those used for post-MI VT (see Chapter 22 for detailed discussion).

Electroanatomic mapping with CARTO (Biosense Webster, Diamond Bar, CA, United States), ESI-NavX (St. Jude Medical, St. Paul, MN, United States), or Rhythmia (Boston Scientific, Cambridge, MA, United States) is generally used for the mapping and ablation of VT associated with ARVC. Electroanatomic 3-D mapping can help in the precise description of VT reentrant circuits, the rapid visualization of the sequence of ventricular activation during the VT, and the identification of slow-conducting pathways and appropriate sites for entrainment mapping. Local activation times are assigned according to the onset of the bipolar electrogram registered at the tip of the mapping catheter, and are color-coded. These systems also help in the navigation of the ablation catheter, the planning of ablation lines, and the maintaining a log of sites of interest (e.g., sites with favorable entrainment or pace mapping findings), which can then be revisited with precision. In addition, voltage (scar) mapping is a helpful feature of some of the electroanatomic mapping systems (see later).

Activation Mapping

Most reentrant circuits cluster around the inferolateral tricuspid annulus, the RVOT, and less commonly the RV apex, which are the typical areas of fibrous and fatty infiltration in ARVC. Hence, these areas are targeted first by activation mapping. Because the VT circuit is composed of zones of abnormal conduction, which are characterized by low-amplitude abnormal electrograms with identifiable exit regions to the surrounding myocardium, endocardial activation mapping during VT typically detects abnormal fragmented or split low-voltage electrograms, with diastolic potentials (eFig. 29.2).

During activation mapping, particular sites of interest include: (1) sites with abnormal local bipolar electrogram (amplitude, ≤ 0.5 mV; duration, ≥ 60 milliseconds); (2) sites at which the local electrogram precedes the QRS complex by at least 50 milliseconds (activation times are taken from the onset of the bipolar electrogram); and (3) sites with the earliest local activation closest to mid-diastole, isolated mid-diastolic potentials, or continuous activity. Once identified, these sites are targeted by entrainment mapping (see later) to establish their relationship to the tachycardia circuit.

Detailed mapping will usually reveal more than one site of presystolic activity. Therefore it is essential to demonstrate that the presystolic site recorded is in fact the earliest site. A normal presystolic bipolar electrogram (amplitude, >3 mV; duration, <70 milliseconds) should prompt

further search for earlier activity. If, after very detailed mapping, the earliest recorded site is not at least 50 milliseconds presystolic, this suggests that either the map is inadequate (most common) or the VT arises deeper than the subendocardium, in the midmyocardium, or even incorporating the subepicardium. VTs in patients with ARVC exhibiting a focal activation pattern have also been described; however, an epicardial reentrant circuit with a defined endocardial exit may explain a focal activation pattern of the RV endocardium.

An isolated mid-diastolic potential is defined as a low-amplitude, high-frequency diastolic potential separated from the preceding and subsequent ventricular electrograms by an isoelectric segment. It is likely that isolated mid-diastolic potentials that cannot be dissociated from the VT are generated in segments of the zone of slow conduction or common pathway (isthmus), which are integral components of the reentry circuit. It is important to recognize that not all presystolic activity recorded during VT is related to the mechanism; it could represent delayed activity not related to the tachycardia mechanism, dead-end pathways, or even an artifact. Therefore it is important to confirm that presystolic activity is related to the reentrant circuit. Demonstration of a fixed relationship of the diastolic electrograms to the subsequent VT QRS, despite spontaneous or induced oscillations of the tachycardia cycle length (TCL), helps exclude the possibility that those electrograms reflect late activation from unrelated dead-end pathways.

Successful activation mapping of VT has several prerequisites, including the inducibility of VT at the time of EP testing, hemodynamic stability of the VT (which usually requires a relatively slow VT rate), and stability of the VT reentry circuit (i.e., stable VT morphology and TCL). If the tachycardia is not stable (morphologically or hemodynamically), mapping can still be performed by starting and stopping the VT after data acquisition at each site. In addition, poorly tolerated rapid VTs sometimes can be slowed by antiarrhythmic drugs to allow for mapping. The use of 20-pole catheter (PentaRay; 2-6-2 mm interelectrode spacing, 1 mm electrodes; Biosense-Webster), the mini-basket catheter (Orion, Boston Scientific), and noncontact mapping can also provide large amounts of activation mapping data during nonsustained or unstable VT. The use of percutaneous LV assist devices is unlikely to be beneficial in ARVC patients, given the generally preserved LV function.⁷³

Entrainment Mapping

Entrainment mapping during reentrant VT is used to verify whether a site recording diastolic activity (regardless of where in diastole it occurs, its position, and its appearance on initiation of VT) is functionally involved in the VT circuit. Pacing is performed during VT at a PCL 10 to 30 milliseconds shorter than the VT CL, at RV sites identified during activation mapping, demonstrating continuous activity or isolated mid-diastolic potentials.^{75,76}

Once the presence of entrainment is verified, several criteria can be used to indicate the relation of the pacing site to the reentrant circuit. The first entrainment criterion to be sought is concealed fusion. Entrainment with concealed fusion indicates that the pacing site is in a protected isthmus located within or attached to the reentrant circuit. Whether this protected isthmus is crucial to the reentrant circuit or is just a bystander site needs to be verified by other entrainment criteria including the postpacing interval (PPI) versus the TCL and the local electrogram-QRS interval during VT versus the S-QRS interval (see Fig. 22.20).⁷⁷

For stable SMVTs, the following three criteria are used to define the critical isthmus and predict the success of radiofrequency (RF) application in termination of the VT: (1) entrainment with concealed fusion; (2) PPI equal to the TCL (± 30 milliseconds); (3) and S-QRS interval equal to the local electrogram-to-QRS interval (± 20 milliseconds). Other

eFig. 29.2 Electrocardiogram and Intracardiac Recordings During Normal Sinus Rhythm (NSR) and Ventricular Tachycardia (VT) in a Patient With Arrhythmogenic Right Ventricular Cardiomyopathy. During NSR (*left*), a late potential is present (*arrow*); the same potential occurs during mid-diastole during VT (*right*). Abl, Ablation; RVA, right ventricular apex; RVOT, right ventricular outflow tract.

predictors of successful ablation sites include S-QRS interval-to-VT CL ratio less than 70%, long S-QRS interval, and alteration of the TCL and/or termination by subthreshold or nonpropagated stimuli. However, because of the diffuse nature of the disease in ARVC, isthmuses may sometimes be wide, and good entrainment maps can be obtained from a rather large area. In this case, linear RF applications across the diastolic pathway may be necessary.⁷⁸

When hemodynamic compromise during the VT is the main limitation for conventional activation and entrainment mapping methods, inductions of brief episodes of VT (with the mapping catheter at the optimal site, as identified by substrate and pace mapping approaches) can allow assessment of the relationship of the abnormal electrograms to the VT circuit. This can also allow entrainment maneuvers to be performed at those sites to help distinguish sites critical to the VT circuit from bystander sites. VT is then quickly terminated before significant hemodynamic compromise ensues. This approach can be facilitated by hemodynamic support with the use of IV vasopressors. However, it requires being able to reproducibly induce the same VT morphology.

Pace Mapping

Pace mapping can be used to complement activation and entrainment mapping findings and to confirm ablation target sites. At isthmus sites defined during VT, pace mapping during NSR is attempted after VT termination, with the mapping catheter being kept at the same location. Pace mapping is preferably performed with unipolar stimuli (10 mA, 2 milliseconds) from the distal electrode of the mapping catheter (cathode) and an electrode in the inferior vena cava (IVC) (anode).

The resulting 12-lead ECG paced morphology is compared with that of the tachycardia. ECG recordings should be reviewed at the same gain and filter settings. The greater the degree of concordance between the morphology during pacing and tachycardia, the closer the catheter is to the exit site of the tachycardia.

At best, a pace map that matches the VT would only identify the exit site to the normal myocardium, and can be distant from the critical sites of the circuit to be targeted by ablation. Thus pace mapping remains only a corroborative method of localizing VT. It can be used to focus initial mapping to regions likely to contain the reentrant circuit exit or abnormal conduction but is not sufficiently specific or sensitive to be the sole guide for ablation.

Pace mapping can also be used in conjunction with substrate mapping when other mapping techniques are not feasible, so that it can provide information on where ablation can be directed. The VT circuit's exit site is approximated by the site of pace mapping that generates QRS complexes similar to those of VT. From that point, evaluation of the S-QRS interval (measured to the onset of the earliest QRS on the 12-lead ECG) can help trace the course of the VT isthmus. Sites along the VT isthmus are associated with good pace maps but with progressively longer S-QRS intervals.

Substrate Mapping

In a subset of ARVC patients, conventional activation and entrainment mapping during VT can be limited by the changing multiple morphologies, the nonsustainability of the tachycardia, or the hemodynamic instability. Substrate-based voltage mapping during sinus rhythm can be used in these cases to identify regions of scar and abnormal myocardium and guide—in conjunction with pace mapping—the ablation of linear lesions to connect or encircle the abnormal regions.

The majority of VTs in ARVC patients are caused by macroreentry involving the dense myocardial scar interspersed with branching and merging bundles of viable myocytes with poor intercellular coupling and abnormal conduction properties. Buried in the arrhythmogenic substrate is the common central pathway (critical isthmus), which is a

narrow path of tissue with abnormal conduction properties, causing the slowing of impulse propagation and allowing reentry to occur. The isthmus itself can be surrounded by dead ends or branches that do not participate in the common pathway of the main reentrant circuit (bystander).⁷⁹

The dysplastic regions can be identified, quantified, and differentiated from healthy myocardium by the presence of electrograms with low amplitudes and longer durations, reflecting replaced myocardial tissue. Substrate mapping is performed during NSR and aims to identify: (1) scar location and distribution (as identified by voltage mapping and electric unexcitability); and (2) conducting channels within the scar, between two confluent scar areas, or between a scar and the tricuspid annulus that can potentially serve as isthmuses for reentrant VTs (as identified by local abnormal ventricular activity, late potentials, and long S-QRS interval during pacing).^{80,81}

Preprocedural Substrate Imaging

CT or CMR imaging can be used to identify the size, location, and transmural extent of the scar that potentially contains the arrhythmogenic substrate. In addition, integration of those imaging modalities into the 3-D electroanatomic mapping system can help visualize and display the LV substrate in a 3-D format and focus initial mapping efforts to those regions.

Scar Mapping

An electrical scar is defined by low-amplitude of local electrograms and tissue inexcitability during high-output pacing. Voltage mapping is performed during sinus rhythm, atrial pacing, or ventricular pacing. The peak-to-peak signal amplitude of the bipolar electrogram is measured automatically. RV endocardial regions with a bipolar electrogram amplitude greater than 1.5 mV are defined as normal, and dense scar areas are defined as those with an amplitude less than 0.5 mV. Abnormal myocardium is defined as an area of contiguous recordings with a bipolar electrogram amplitude between 0.5 and 1.5 mV. Of note, for the epicardium, normal myocardium is defined as regions with bipolar electrogram amplitude greater than 1.0 mV (to limit the influence of epicardial fat and coronary vasculature), and dense scar as regions with bipolar electrogram amplitude less than 0.5 mV. Because epicardial fat can decrease signal amplitude, low-voltage areas during epicardial mapping should also show abnormal electrogram configuration. At low-amplitude (<0.5 mV) sites, pacing is performed with 10-mA, 2-millisecond pulse width stimuli. A pacing threshold greater than 10 mA has been used to define unexcitable scar, provided electrode-tissue contact is adequate. A color-coded voltage map is then created (with the color range set between 0.5 and 1.5 mV) and superimposed on the anatomical model to show the amplitudes of all selected points.^{82,83}

As noted, in ARVC, the normal myocardium is replaced by fatty and then fibrous tissue, causing thinning and scarring, predominantly in the RV. Studies have found that regions of abnormal voltage suggestive of scar were observed in all ARVC patients. The endocardial bipolar voltage abnormalities tend to be perivalvular and, although predominantly affecting the RV free wall, involve some aspect of the septum in most patients (76%). This pattern is consistent with pathological studies demonstrating a predilection for scar to occur in these particular areas in ARVC. Whether an extensive perivalvular fibrotic process is specific for patients who present with sustained monomorphic VT in the setting of ARVC is yet to be determined. In contrast to the post-MI pattern of dense scar surrounded by a border zone, the regions of abnormal myocardium in ARVC are commonly patchy and inhomogeneous, occurring in anatomically disparate areas. Consequently, low-voltage identification in ARVC is less useful as a marker for ablation because it is very widespread. Nonetheless, evaluating the existence of different voltage areas

within the 0.5 mV scar (i.e., the voltage limits are reset to 0.3 to 0.5 mV as the upper limit and to 0.1 mV as the lower, representing dense scar) can potentially help visualize channels of slow conduction within scar tissue. The critical isthmus of each of the reentrant circuit typically is bounded by an area of low-voltage scar on one side and an anatomical barrier (tricuspid annulus) on the other side, or by two parallel lines of double potentials.

Importantly, fibrofatty replacement in ARVC typically begins in the subepicardium or midmural layers and progresses to the subendocardium. This contrasts with the VT substrate in post-MI patients, whereby the wave of necrosis progresses from subendocardium to epicardium, producing larger scar areas endocardially rather than epicardially, and intramural or epicardial substrate abnormalities are almost always associated with endocardial scar. Therefore bipolar voltage mapping from the endocardial surface likely underestimates the degree of abnormal

myocardium in ARVC patients (eFig. 29.3). Endocardial *unipolar* voltage mapping (with a cutoff of 5.5 mV for RV free wall scar detection, and 7.5 mV for the RV septum) can potentially provide a more global assessment of myocardial voltage and more closely approximate the degree and location of epicardial bipolar voltage abnormalities that serve as a substrate for VT in ARVC patients with no or limited endocardial bipolar voltage abnormalities. Endocardial unipolar voltage mapping was found to accurately predict the location and extent of epicardial involvement and may help in decision making related to proceeding to epicardial substrate mapping and ablation (eFig. 29.4).^{83,84}

Identification of Conducting Channels

Identification of the conducting channels within the scar region helps refine the area that potentially supports the VT circuit. Those channels can be identified by voltage channels, late potentials, or both. Recent

Fig. 29.8 Late Potential Conducting Channel Containing a Ventricular Tachycardia (VT) Isthmus Site. Epicardial bipolar voltage map during sinus rhythm (SR VG) from a patient with arrhythmogenic right ventricular cardiomyopathy and a low-voltage area in the epicardial right ventricular free wall. Two late potential channels are highlighted with white dotted lines. Electrograms (EGs) during sinus rhythm in the more basal channel are shown on the left. Epicardial activation mapping (VT LAT) and electrocardiogram of the clinical ventricular tachycardia are shown. The VT isthmus site (exit site) was identified by activation mapping during VT. This exit site is located in the transition from blue to red colors in the VT LAT map and could also be recognized because from this location to red dots marks the precise location of the radiofrequency delivery. This VT isthmus exit site is projected over the SR VG map (highlighted with a yellow dot) and coincides with the conducting channel-entrance electrogram identified during sinus rhythm. Ao, Ascending aorta; RCA, right coronary artery. (From Fernandez-Armenta J, Andreu D, Penela D, et al. Sinus rhythm detection of conducting channels and ventricular tachycardia isthmus in arrhythmogenic right ventricular cardiomyopathy. *Heart Rhythm*. 2014;11:747–754.)

eFig. 29.3 Voltage Mapping in Arrhythmogenic Right Ventricular Cardiomyopathy (ARVC). Right and left anterior oblique electroanatomic endocardial (*top*) and epicardial (*bottom*) voltage maps in a patient with ARVC. Red areas denote low voltage/scar. On the endocardial map, only a small area shows abnormal voltage (near lateral tricuspid valve, *red area*); however, on the epicardial map, substantially larger areas show abnormal low voltage. LAO, Left anterior oblique; RAO, right anterior oblique.

eFig. 29.4 Bipolar and Unipolar Voltage Mapping in Arrhythmogenic Right Ventricular Cardiomyopathy (ARVC). Unipolar endocardial voltage mapping identifies the location and greater extent of epicardial bipolar electrogram abnormalities in a patient with ARVC. Endocardial bipolar voltage map demonstrates a paucity of low-voltage regions (*left*). Endocardial unipolar voltage mapping reveals a much greater burden of abnormal myocardium (<5.5 mV) extending from the lateral tricuspid valve up to the pulmonic valve region and inferiorly across the right ventricular free wall (*center*). Epicardial bipolar voltage map confirms the extensive area of abnormal epicardium (*right*). Black dots represent wide, split, and/or late epicardial electrograms and help to identify low-voltage areas consistent with scar versus fat. (From Polin GM, Haqqani H, Tzou W, et al. Endocardial unipolar voltage mapping to identify epicardial substrate in arrhythmogenic right ventricular cardiomyopathy/dysplasia. *Heart Rhythm*. 2011;8:76–83.)

eFig. 29.5 Voltage Channels. Epicardial voltage map during sinus rhythm showing extensive scarring of the right ventricular free wall. (A) Voltage map with standard voltage threshold of 0.5 to 1.5 mV showing uniform extensive scarring of the right ventricular free wall. (B) Unmasked channel of relatively higher voltage (blue arrows) after the voltage threshold was reduced to 0.05 to 0.5 mV. (C) Unipolar and bipolar recordings from the epicardium with ablation catheter during sinus rhythm in the area of the channel (red tag) showing late potential. (From Kumar P, Mounsey JP, Chung EH. Adjusting voltage criteria can unmask conducting channels in a patient with arrhythmogenic right ventricular cardiomyopathy and ventricular tachycardia. *Heart Rhythm Case Rep.* 2015;1:275–278.)

evidence has shown that the technique using late potentials identifies a higher proportion of conducting channels and, more importantly, most conducting channels that serve as the substrate for VTs. Using only the bipolar voltage adjustment, more than 70% of the conducting channels and 60% of the VT isthmuses would not be identified.⁸⁵

Voltage channels. Conducting channels on the electroanatomic voltage map are identified corridors of voltage preservation (voltage channels) within denser regions of scar or corridors between a dense scar and the tricuspid annulus. Careful step-by-step manual adjustment of voltage upper and lower limits on the color-coded electroanatomic voltage map can help maximize the color contrast between adjacent myocardium with different electrogram voltage levels within the 0.5 mV scar and, thus, unmask channels of viable myocardium within a dense scar (eFig. 29.5).^{85,86}

Late potentials. Fractionated electrograms (i.e., near-field signals with three or more sharp spikes, either separated by an isoelectric interval or continuous) and late potentials (defined as bipolar electrogram with any component is recorded after the offset of the QRS complex on the surface ECG) can reflect local depolarization of surviving muscle bundles that are well insulated by dense scar. Sites recording abnormal electrograms are tagged on the electroanatomic map.^{83,85}

Late potential conducting channels are defined as a path of more than two adjacent late potentials connecting with healthy tissue (Fig. 29.8). Further, late potentials are classified as being an entrance or an inner part of a given conducting channel, depending on the local activation time of the near-field component. The entrance of a conducting channel is tagged as sites within the border zone (i.e., zone with 0.5 to 1.5 mV voltage) recording late potentials with the shortest delay between the far-field component of healthy/border zone muscle (low frequency, usually high voltage) and the near-field component (delayed, high frequency, usually fractionated and low voltage) corresponding to the local activation of myocardial fibers in the scar. Sites with longer delays likely reside farther along the conducting channel within the dense scar.⁸⁵

Often, late potentials are obscured by larger far-field electrograms. Therefore verification that a recorded electrogram is far-field rather than near-field is important and can be achieved by pacing at the local site. When the recorded electrogram is near-field, capture of the pacing stimulus results in capturing the tissue generating all components of the electrogram, so that no clear electrogram component is identifiable during pacing. Conversely, when the recorded electrogram is far-field, pacing may not capture local tissue (due to dense scar) or, when capture occurs, the far-field electrograms remain discernable during pacing (since they reflect activation of myocardium adjacent to the pacing site). Furthermore, changing the direction of depolarization approaching the mapping site (e.g., sinus rhythm vs. RV pacing) and premature

ventricular stimulation (causing decremental conduction) can help unmask some areas of block and slow conduction, expose late potentials by separating the local (near-field) from the far-field potentials.

Epicardial Mapping

As noted, the arrhythmogenic substrate in ARVC is more extensive epicardially. Several studies demonstrated that the scar and conducting channels supporting the VT circuit are more prevalent on epicardial compared to endocardial mapping, and are predominantly located in the subtricuspid region, followed by the RVOT region. This limits the success of purely endocardial mapping and ablation, since wall thickness in involved areas can be 1 cm or more.

Therefore patients with limited endocardial substrate (as demonstrated on voltage mapping), those with late VT termination with endocardial RF delivery, and certainly those with persistent VT despite aggressive endocardial ablation should be considered for an epicardial approach. In addition, unipolar voltage mapping from the endocardium can be used for evaluation of epicardial scar. Endocardial unipolar (rather than bipolar) voltage mapping can predict the presence of and more closely approximate the extent of epicardial involvement and, hence, the need for the epicardial approach. RV endocardial unipolar voltages less than 5.5 mV identify extensive RV epicardial bipolar abnormalities (eFig. 29.4).^{85,87}

Some studies have shown that a combined endocardial-epicardial mapping and ablation as a first-line strategy in patients with ARVC, and especially in those with failed prior endocardial ablation, can improve procedural success and mid-term outcomes.^{19,85} Furthermore, the presence of a Q wave or QS configuration in leads I and V₂ (anterior RV epicardial sites) or Q waves leads II, III, or aVF (inferior RV epicardial sites) on the surface ECG during VT suggests the presence of an epicardial source of VT, and can be helpful in identifying patients who should be considered for an epicardial approach with the initial procedure.

The approach to epicardial mapping is essentially the same as for endocardial ablation, including activation mapping, entrainment mapping, substrate mapping, and pace mapping, and is discussed in detail in Chapter 27.

ABLATION

Target of Ablation

Selective Ablation of the Critical Isthmus of the Reentrant Circuit

For each induced stable SMVT, reentry circuit isthmuses are the target of ablation and are defined by activation and entrainment mapping as sites with: (1) continuous activity or isolated mid-diastolic potentials

Fig. 29.9 Scar Dechanneling. (A) Endocardial (*left*) and epicardial (*right*) substrate voltage maps, before scar dechanneling. (B) In this patient, three conducting channels (CCs) were identified: (1) one long and branched late potential channel localized at the right ventricular free wall (*top*); (2) one voltage channel parallel to the tricuspid annulus (*bottom*); and (3) another short late potential channel perpendicular to the tricuspid annulus (*bottom*). (C) A low number of radiofrequency (RF) lesions at the CC entrance (*black dots*) were necessary to eliminate all the channels as follows: (1) RF applications were delivered at the right ventricular free wall CC entrance and required two additional RF applications in the scar core to be completely eliminated (*top*); (2) RF was delivered at the CC entrance to eliminate the voltage CC parallel to the tricuspid annulus (*bottom*); and (3) RF was delivered to eliminate the CC perpendicular to the tricuspid annulus (*bottom*). (D) An increase in the epicardial scar area can be observed in the postablation remaps. Of note, despite a very wide epicardial scar after the ablation, endocardial electrograms opposite these areas are normal in sites outside of the initial endocardial scar. (From Berruezo, A, Fernández-Armenta J, Mont L, et al. Combined endocardial and epicardial catheter ablation in arrhythmogenic right ventricular dysplasia incorporating scar dechanneling technique. *Circ Arrhythmia Electrophysiol.* 2012;5:111–121.)

that cannot be dissociated from the tachycardia; (2) entrainment with concealed fusion; (3) PPI equal to the TCL (± 30 milliseconds); (4) S-QRS interval equal to electrogram-to-QRS interval (± 20 milliseconds); and (5) ratio of S-QRS interval of the TCL between 30% to 70%. Alteration of the TCL or termination of VT by subthreshold or nonpropagated stimuli, and repeated VT termination occurring with catheter manipulation or pacing at the site, also suggest an isthmus location (eFig. 29.6). These findings are consistent with a central/proximal isthmus site.

For hemodynamically unstable VTs, substrate mapping during sinus rhythm followed by brief inductions of VT (with the mapping catheter at the optimal site, as identified by substrate and pace mapping) can allow assessment of the relationship of the abnormal electrograms to the VT circuit. This can also allow entrainment maneuvers to be performed at those sites to help distinguish sites critical to the VT circuit from bystander sites. VT is then quickly terminated before significant hemodynamic compromise ensues. This approach, however, requires being able to induce the same VT reproducibly. The use of noncontact mapping can be of value in these cases.

When the critical isthmuses of the reentrant circuit(s) can be identified, linear ablation lesions are delivered to sever those isthmuses. Terminating VT by targeting this area during ablation provides confirmatory evidence that it is a critical site for the arrhythmia. Isthmuses can be relatively broad and require transection with linear ablation lesions, usually connecting two regions of scar, or scar and an anatomical barrier, such as the tricuspid annulus.⁸⁸

Substrate-Based Ablation

Often, several VT morphologies are inducible in an individual patient, and usually only a minority of induced VTs are mappable using the conventional activation and entrainment mapping techniques. For unmappable VTs (due to poor inducibility, changing VT morphology or hemodynamic instability), RF ablation can be performed as linear lesions targeting potential exit sites and isthmuses of VT circuits based on the location of the best pace map, the location of valvular anatomical boundaries, and the conducting channels defined by substrate mapping. Typically, linear lesions are created over target regions by sequential point lesions designed to: (1) connect scar or abnormal myocardium to a valve continuity (e.g., tricuspid annulus); (2) connect scar or abnormal myocardium to another scar; or (3) encircle the scar or abnormal region, depending on the scar location and size.^{85,87}

In addition, “scar dechanneling” with combined endocardial and epicardial RF ablation of all conducting channels within the scar, has been reported to improve short- and long-term success rates. This strategy preferentially targets the entrance sites to the conducting channels, which are identified by substrate mapping as sites within the border zone recording late potentials with the shortest delay between the far-field component (low frequency, usually high voltage) component and the near-field local ventricular activity (typically delayed, high frequency, fractionated, and low voltage). The endpoint of this ablation strategy is conducting channel entrance conduction block, manifest as the disappearance of the inner point of the conducting channels or delayed activation of conducting channel inner points, usually with the activation sequence in reverse order (Fig. 29.9).⁸²

Given the high burden of clinical and inducible VTs in ARVC patients, a strategy that incorporates extensive substrate-based ablation (linear ablation or scar dechanneling) in addition to selective ablation of the critical isthmus of the clinical VT may be reasonable to improve the long-term outcome.^{74,82,85,89}

Ablation of Premature Ventricular Complexes

In ARVC patients with frequent PVCs whose morphology is identical to that of the clinical or induced VT, an ablation strategy selectively

targeting the focus of the PVCs (typically at the border region of scar in the RVOT and RV basal regions) has been reportedly successful in eliminating the VT.¹⁷

Ablation Technique

Ablation may be performed with a 4-mm-tip catheter (maximal target temperature of 60°C and maximal power of 50 W), an 8-mm-tip catheter (maximal temperature of 65°C and maximal power of 75 W), or an irrigated-tip catheter (maximal temperature of 40°C to 45°C and maximal power of 40 to 50 W). Irrigated RF ablation catheters are preferred because power delivery can otherwise be limited in the trabeculated and annular regions where cooling from circulating blood flow is low (as well as the epicardial surface where there is no passive blood pool cooling). However, careful attention to power titration and monitoring impedance is necessary to reduce the risk of perforation when ablating in the free wall of the RV. Ablation is usually maintained for 60 to 120 seconds at the site where the tachycardia is terminated (while ablating during stable VT) or at each point along the linear ablation. The use of a deflectable sheath can help catheter manipulation in the RV.^{74,82,85}

Endpoints of Ablation

Successful VT ablation is defined as noninducibility of any VT (excluding very fast [TCL <240 milliseconds] nonclinical VTs) using the entire programmed electrical stimulation protocol. When the VT is scarcely inducible at baseline, the endpoint of substrate-based scar dechanneling involves conducting channel entrance conduction block, as described earlier. When linear ablation is performed, conduction block across the ablation line needs to be verified.^{74,82,85}

Outcome

Ablation of VT in ARVC remains a clinical challenge and should be viewed as a potentially palliative, rather than curative, procedure in selected patients. Although VT ablation has been reported to successfully eliminate inducible VT acutely in up to 60% to 80% of patients, the recurrence rates during long-term follow-up of 3 to 5 years are as high as 50% to 70%, even following extensive or repeated ablation attempts. Recurrences usually manifest as nonsustained VT, a slower monomorphic sustained VT, or a new monomorphic VT.²

The discrepancy between the good acute results and the unfavorable long-term outcome may be related to the progressive nature of ARVC, which predisposes to the occurrence of new and malignant arrhythmogenic substrates over time.^{2,89} Furthermore, multiple morphologies, hemodynamic instability, or noninducibility can limit the success of VT ablation. In addition, ARVC can create a large number of potential circuits; an empirical approach may not eliminate all the possible pathways. Achieving adequate energy delivery also can be a problem, especially in regions difficult to access by catheter; in particular, abnormal regions along the tricuspid annulus, which can require the use of 8-mm-tip or irrigation-tip ablation catheters to achieve effective lesions underneath the tricuspid valve. It is necessary to emphasize that caution must be taken when using irrigated-tip ablation in patients with very thin ventricular walls, although thick fibrous tissue is present in many areas. The risk of creating deeper lesions in thin walls of the RV body or apex potentially increases the risk of perforation. Although the magnitude of this risk is not well known, it seems to be infrequent.

Furthermore, recent studies have shown a high prevalence of epicardial isthmuses in ARVC. Epicardial mapping and ablation, and combined endocardial/epicardial substrate-based ablation approaches have yielded a significant improvement in short- and long-term ablation efficacy (VT free survival in up to 71% of patients over a mean follow-up of 56 months). Therefore it is reasonable to begin mapping endocardially, but be prepared to move to epicardial mapping following

eFig. 29.6 Ablation of Ventricular Tachycardia in Arrhythmogenic Right Ventricular Cardiomyopathy (ARVC). Shown is radiofrequency (RF) energy delivery in the basal lateral right ventricle in a patient with ARVC. Note the mid-diastolic potential (red arrow) 130 milliseconds prior to QRS onset and almost immediate cessation of ventricular tachycardia on RF delivery. The blue arrow marks initiation of RF energy delivery. Abl, Ablation; RVA, right ventricular apex; RVOT, right ventricular outflow tract.

pericardial puncture if endocardial mapping and ablation do not quickly yield good results. Combined endocardial-epicardial mapping and ablation strategy also may be considered as an initial strategy, especially in patients with VT recurrences after prior endocardial ablation.^{2,74,82,85}

PATHOPHYSIOLOGY

In general, patients with congenital heart disease (CHD) are prone to two forms of ventricular tachyarrhythmias: (1) macroreentrant monomorphic ventricular tachycardia (VT) related to scar or prosthetic materials used during surgical repair, such as that observed in patients with repaired tetralogy of Fallot, ventricular septal defects repaired through a ventriculotomy incision, and Ebstein anomaly; and (2) polymorphic VT and ventricular fibrillation (VF) (with the risk of sudden cardiac death [SCD]) which occur in the setting of a generalized ventricular myopathic process related to chronic pressure and volume overloads that ultimately result in advanced degrees of hypertrophy, fibrosis, and ventricular dilation. The latter type can be observed in patients with transposition of the great arteries after Mustard or Senning operations, congenital aortic outflow obstruction, tetralogy of Fallot, unrepaired ventricular septal defect (VSD) with Eisenmenger syndrome, and univentricular hearts with Fontan circulation.¹

Most information concerning patients with monomorphic VT and CHD pertains to tetralogy of Fallot, as compared with other forms of CHD. Tetralogy of Fallot is the most common cyanotic congenital cardiac malformation. The core lesion is an underdeveloped subpulmonary infundibulum, which is superiorly and anteriorly displaced, resulting in the well-known tetrad of pulmonic stenosis, ventricular septal defect, aortic override, and right ventricular (RV) hypertrophy. Correction of the anomaly involves patch closure of the ventricular septal defect and relief of right ventricular outflow tract (RVOT) obstruction, which typically requires resection of a large amount of RV muscle. When the procedure was first performed, it was not done through the tricuspid valve but required a ventriculotomy. The pulmonic valve annulus is usually small, and repair with a transannular patch leads to chronic pulmonic insufficiency, which can be severe if associated with downstream obstruction caused by pulmonary arterial stenosis, and can eventually precipitate RV dilatation and dysfunction.²

Macroreentry is the most common mechanism for sustained ventricular arrhythmias in adults with repaired tetralogy of Fallot. The

sites of the diastolic activation and delayed conduction along the reentrant circuit have been shown to have significant abnormalities such as interstitial or replacement fibrosis, adiposis, and degeneration of the myocardium.³ The scattered surviving myocyte islets embedded in the extensive adiposis or fibrosis can form an electrical maze around the ventriculotomy incision and patch repairs, resembling the histological findings in the border zone of infarcted myocardium. Furthermore, RV remodeling induced by pressure overload (caused by inadequate relief of obstruction) and volume overload (secondary to severe pulmonic regurgitation) promotes hypertrophy and fibrosis, which can potentially result in slow conduction, providing the link between impaired hemodynamics and VT.⁴

Using intraoperative mapping, monomorphic VT after surgical correction of tetralogy of Fallot has been classified into two types: (1) VT originating from the RVOT, which is considered to be related to prior right ventriculotomy or reconstruction of the RVOT (Fig. 30.1); and (2) VT originating from the RV inflow tract septum, which is thought to be related to closure of the ventricular septal defect. Reentry circuit isthmuses are located within anatomically defined pathways bordered by unexcitable tissue.^{4,5}

EPIDEMIOLOGY AND NATURAL HISTORY

CHD is the most common form of birth defect, with an estimated 0.5% to 1% of live newborns afflicted by moderate or severe types. Currently, more than 1 million adults are living with CHD in the United States, and this group now outnumbers children with CHD, reflecting the marked improvements in the early diagnosis and surgical and medical management of CHD. Ventricular arrhythmias late after repair of CHD are an increasingly common finding, predominantly in patients with tetralogy of Fallot, and contribute to mortality and morbidity in this population.

The incidence of SCD in the general CHD population is relatively low (less than 0.1% per year), but it accounts for 20% to 25% of all late deaths in adults with CHD.⁶ The risk of SCD is higher in patients

Fig. 30.1 Ventricular Tachycardia (VT) Postsurgical Repair of Tetralogy of Fallot Illustrated is scar-based reentry in surgically repaired tetralogy of Fallot with a right ventriculotomy. The incision heals as a nonconductive scar, leaving a small rim of muscle between the pulmonic valve annulus and scar. This is the diastolic corridor for rotation in either direction as shown, giving rise to VT with left bundle branch block–like QRS morphology and left superior axis or, in the opposite direction of rotation, right bundle branch block–like QRS morphology and right inferior axis. Ao, Aorta; CL, cycle length; LBBB, left bundle branch block; LS, left superior; PA, pulmonary artery; RA, right atrium; RI, right inferior; RV, right ventricle.

with complicated hemodynamic lesions, including tetralogy of Fallot (0.2% to 0.3% per year), D-transposition of the great arteries with Mustard or Senning baffles, congenitally corrected transposition of the great arteries, left-sided obstructive lesions, Eisenmenger syndrome, and Ebstein anomaly.^{6,7}

Although ventricular ectopy and nonsustained VT are relatively common, sustained monomorphic VT is rare in the general adult CHD population, with an annual incidence of 0.1% to 0.2%.⁶ Notably, the incidence of arrhythmias increases as the patient ages. In patients with tetralogy of Fallot, serious ventricular arrhythmias are rare during the first 10 to 15 years following corrective surgery. This quiescent period is followed by a steady increase in the incidence of ventricular arrhythmias, primarily monomorphic VT, which are prevalent in 15% of adult patients late after surgery. By 35 years of follow-up, the incidence of VT is 11.9%, with an 8.3% risk of SCD.^{6,8–11} Since the mid-1990s, surgical repair of the tetralogy of Fallot has usually been performed using a combined approach through the RA and the pulmonary artery. In these cases, there is no incision in the RV free wall around which reentry can occur, although reentry around the ventricular septal defect patch can still take place. In addition, a limited RV incision may still be needed when patch augmentation for the RVOT or pulmonary annulus is necessary.

Tetralogy of Fallot is the most common substrate for sustained VT and is typically cited as the archetypal lesion when VT in the adult CHD patient population is discussed. Nonetheless, serious ventricular arrhythmias can also develop in other types of congenital heart malformations, even in the absence of direct surgical scarring to ventricular muscle, including congenital aortic stenosis, transposition of the great arteries when the RV supports the systemic circulation, severe Ebstein anomaly, certain forms of single ventricle, and ventricular septal defect with pulmonary arterial hypertension. The appearance of ventricular

arrhythmias in these cases commonly coincides with deterioration in overall hemodynamic status.^{6,7}

INITIAL EVALUATION

Patients with CHD presenting with symptoms suggestive of ventricular arrhythmias, such as palpitations, dizziness, and syncope, require careful evaluation to help document cardiac rhythm during clinical symptoms. This is typically achieved by ambulatory cardiac monitoring or implantation of a loop recorder. Electrophysiological (EP) testing can also be considered when the index of suspicion is high.

Importantly, new-onset or worsening ventricular arrhythmias can herald deterioration of the hemodynamic status, which requires a thorough evaluation of ventricular function and residual lesions. In addition, detailed evaluation of cardiac function and anatomy and knowledge of the congenital anomaly and previous surgical procedures are very important. This evaluation can require transthoracic or transesophageal echocardiography, right or left heart catheterization, angiography of the desired cardiac chamber, and cardiac magnetic resonance imaging.

RISK STRATIFICATION

Noninvasive Risk Stratification

Some subgroups of patients with CHD are recognized as being at risk for life-threatening ventricular arrhythmias and SCD, including those with large scars from a prior ventriculotomy (e.g., tetralogy of Fallot repair) and those who develop advanced degrees of ventricular dysfunction from longstanding hemodynamic burdens (e.g., congenital aortic stenosis, single ventricle).

Although controversy still exists, several noninvasive risk factors for VT and SCD have been identified in the CHD patient population. Tetralogy of Fallot is the one condition for which such data are fairly extensive. QRS duration exceeding 180 milliseconds, left ventricular (LV) systolic dysfunction (ejection fraction less than 50 %), and LV diastolic dysfunction (LV end-diastolic pressure ≥ 12 mm Hg) have consistently predicted adverse outcome. In addition, symptomatic nonsustained VT and atrial arrhythmias are associated with increased SCD risk. Asymptomatic nonsustained VT has been associated with inducible sustained VT by programmed ventricular stimulation and with clinical ventricular tachyarrhythmias in implantable cardioverter-defibrillator (ICD) recipients, but its value for SCD risk prediction is limited. Several other clinical characteristics, such as RV pressure overload and RV systolic dysfunction, have been proposed as risk factors for SCD but with inconsistent validation in the literature.^{2,8,9,12} A risk score to predict appropriate ICD shocks in tetralogy patients with ICDs for primary prevention indications was derived from six clinical variables (surgical, hemodynamic, electrocardiographic, and EP factors) identified by multivariate analyses (Table 30.1). Patients with fewer than 3 points (low risk) experienced no appropriate shocks. In patients with 3 to 5 points (intermediate risk) and more than 5 points (high risk), the annual rates of appropriate shocks were 3.8% and 17.5%, respectively. Although these risk-stratification schemes can provide reasonable sensitivity, they have suboptimal specificity for patients at high risk because of the small population size and the relatively low incidence of SCD in CHD patients (approximately 2% per decade of follow-up in patients with repaired tetralogy of Fallot repair).¹³

For congenital malformations other than tetralogy of Fallot, SCD risk predictors have not been clearly defined. Severely impaired systolic function of the systemic ventricle (ejection fraction $\leq 35\%$) has been associated with ventricular arrhythmias and SCD; however, QRS duration has been inconsistently noted to predict SCD. Recurrent unexplained syncope in the presence of ventricular dysfunction may also identify a

TABLE 30.1 Risk Score for Appropriate Defibrillator Shocks in Primary Prevention in Patients With Tetralogy of Fallot

Variable	Exponential Values of Beta Coefficients	Points Attributed
Prior palliative shunt	3.2	2
Inducible sustained ventricular tachycardia	2.6	2
QRS duration ≥ 180 msec	1.4	1
Ventriculotomy incision	3.4	2
Nonsustained ventricular tachycardia	3.7	2
Left ventricular end-diastolic pressure ≥ 12 mm Hg	4.9	3
Total points		0–12

high-risk group. Factors such as nonsustained VT, prior palliative shunt, ventriculotomies, and atrial tachyarrhythmias have been proposed, but uncertainty remains as to their true prognostic significance. Notably, among ICD recipients, adults with non-tetralogy of Fallot congenital lesions are significantly less likely to receive appropriate ICD therapy than those with tetralogy of Fallot (11.5% vs. 27.3%).^{6,14}

Electrophysiological Testing

In patients with repaired tetralogy of Fallot, inducible monomorphic or polymorphic sustained VT by programmed ventricular stimulation is independently associated with a nearly fivefold higher rate of clinical VT or SCD on follow-up. Sustained VT is inducible in approximately 35% of this patient population, which is similar to that reported in patients with prior myocardial infarction (MI) and LV ejection fractions less than 40% and spontaneous nonsustained VT. Independent risk factors for inducible sustained VT include: (1) age older than 18 years at the time of testing, (2) history of palpitations, (3) prior palliative surgery, (4) frequent or complex ventricular ectopy or nonsustained VT, and (5) cardiothoracic ratio of greater than 0.6 on chest radiograph. The diagnostic value of EP testing (sensitivity, 77%; specificity, 80%; diagnostic accuracy, 79%) and prognostic significance (relative ratio, 4.7 for subsequent clinical VT or SCD) compares favorably with programmed ventricular stimulation in post-MI patients. However, the yield of EP testing remains too imperfect and too impractical to be recommended as a general screening tool and the timing and frequency of testing remain to be elucidated. Nonetheless, EP testing may be considered in selected patients with concerning symptoms (e.g., palpitations, dizziness, or unexplained syncope) or Holter findings, when VT is suspected but not yet proven. In addition, the subpopulation of patients deemed at intermediate risk of SCD based on a combination of other parameters may benefit most from risk stratification with an EP study.^{8,10,12}

For congenital malformations other than tetralogy of Fallot, the value of programmed ventricular stimulation in risk stratification remains uncertain. Inducibility of sustained VT at EP study does not appear to predict clinical VT or SCD in patients with transposition of the great arteries and Mustard or Senning baffles.⁶

PRINCIPLES OF MANAGEMENT

Implantable Cardioverter-Defibrillator

ICDs play an important role in the primary and secondary prevention of SCD in patients with CHD. In a prevalence study, ICDs were implanted in 10% of the adult population with repaired tetralogy of Fallot for

either primary (59%) or secondary (41%) prevention indications. Both groups experienced high rates of appropriate therapies.

Secondary Prevention

ICD implantation is recommended in patients who have survived cardiac arrest or an episode of spontaneous sustained VT. The most common anatomical diagnosis among ICD recipients is tetralogy of Fallot, followed by transposition of the great arteries and aortic stenosis. The rate of appropriate therapies for VT or VF events in this patient population averages 9.8% per year, and approximately 35% over a follow-up period of 5 years, with the median time to first shock less than 1 year.^{8,9,13,15}

Primary Prevention

Recent data support the benefit of ICD implantation for primary prevention in patients deemed to be at high risk for SCD. Up to 44% of patients with repaired tetralogy of Fallot repair who received prophylactic ICDs experience sustained ventricular tachyarrhythmias, with an annual rate of appropriate ICD therapies of 7.7%. These annual rates are comparable with those of other high-risk populations, including patients with primary prevention ICDs for ischemic, dilated, or hypertrophic cardiomyopathy.^{8,9}

As noted, multiple risk factors for VT and SCD in CHD patients have been identified in an effort to better define which are most likely to benefit from a primary prevention ICD; however, at present, there is no generally accepted scheme for rhythm surveillance in asymptomatic CHD patients.^{8,10} Box 30.1 lists the current recommendations for ICD therapy in adults with CHD.

Even in patients considered at risk for malignant ventricular arrhythmias, the benefit of ICD implantation should be carefully weighed against the risks of such a procedure in this unique group of patients. Transvenous implantation of the ICD may not be feasible in patients with the more complex varieties of CHD, necessitating epicardial insertion of the ICD leads with the added morbidity of a sternotomy or thoracotomy for epicardial electrodes. Even when transvenous implantation procedures are feasible, they can be very challenging in patients with distorted anatomy, requiring that the implanting physician be well acquainted with the details of congenital heart lesions and the types of surgical repairs. Because of the considerable variation in surgical techniques and individual anatomy, careful review of detailed operative reports is essential in these cases. In addition, the ICD lead failure rate from both insulation breaches and conductor breaks is high in this patient population, exceeding 20% over 5 years (likely due to the young age and high activity level of this patient group), which results in added morbidity of corrective procedures. Moreover, the negative psychological impact of an implanted device and inappropriate shocks (occurring in more than 20%, predominantly caused by supraventricular tachycardias and lead failures) in a relatively young patient should not be underestimated. Programming ICD treatment zones with faster VT detection rates and longer detection times can help to reduce the rate of inappropriate shocks.¹⁶

For all these reasons, ICD decisions in CHD patients should be individualized, taking into account the various risk factors, all of which must then be viewed in the context of the individual patient's history and general hemodynamic status to refine the selection process.^{8,13,15}

Antiarrhythmic Drug Therapy

Similar to patients with post-MI VT, antiarrhythmic agents are generally not a stand-alone therapy in CHD patients with sustained ventricular arrhythmias or cardiac arrest but can be considered in two main settings: (1) as adjunctive therapy in patients with an ICD, and (2) as preventive therapy in patients who do not want or are not candidates for an ICD. ICD patients who experience frequent symptoms or device

BOX 30.1 Recommendations for ICD Therapy in Adults With CHD**Class I**

1. Cardiac arrest due to VF or hemodynamically unstable VT of nonreversible etiology
2. Spontaneous sustained VT
3. Systemic LV ejection fraction $\leq 35\%$, biventricular physiology, and NYHA class II or III symptoms

Class IIa

1. ICD therapy is reasonable in selected adults with tetralogy of Fallot and multiple risk factors for SCD, such as LV systolic or diastolic dysfunction, nonsustained VT, QRS duration ≥ 180 msec, extensive RV scarring, or inducible sustained VT at EP study

Class IIb

1. CHD and a single or systemic RV ejection fraction $<35\%$, particularly in the presence of additional risk factors such as complex ventricular arrhythmias, unexplained syncope, NYHA functional class II or III symptoms, QRS duration ≥ 140 msec, or severe systemic AV valve regurgitation
2. CHD and a systemic ventricular ejection fraction $<35\%$ in the absence of overt symptoms (NYHA class I) or other known risk factors

3. CHD and syncope of unknown origin with hemodynamically significant sustained VT or VF inducible at EP study
4. Nonhospitalized adults with CHD awaiting heart transplantation
5. Syncope and moderate or complex CHD in whom there is a high clinical suspicion of ventricular arrhythmia and in whom thorough invasive and non-invasive investigations have failed to define a cause

Class III

1. Life expectancy with an acceptable functional status <1 year
2. Incessant VT or VF
3. Significant psychiatric illness that may be aggravated by ICD implantation or preclude systematic follow-up
4. Patients with drug-refractory NYHA class IV symptoms who are not candidates for cardiac transplantation or cardiac resynchronization therapy
5. Advanced pulmonary vascular disease (Eisenmenger syndrome)
6. Endocardial leads are generally avoided in adults with CHD and intracardiac shunts. Risk assessment regarding hemodynamic circumstances, concomitant anticoagulation, shunt closure prior to endocardial lead placement, or alternative approaches for lead access should be individualized

Modified from Khairy P, Van Hare GF, Balaji S, et al. PACES/HRS Expert Consensus Statement on the Recognition and Management of Arrhythmias in Adult Congenital Heart Disease: developed in partnership between the Pediatric and Congenital Electrophysiology Society (PACES) and the Heart Rhythm Society (HRS). *Heart Rhythm*. 2014;11:e102–e165.

discharges triggered by ventricular arrhythmias may benefit from adjunctive drug therapy. When antiarrhythmic drug therapy is required, beta-blockers and sotalol are commonly used. Amiodarone can carry a significant long-term risk of adverse events given the young age of the patient population. The efficacy of dofetilide and dronedarone has not been adequately evaluated in this group.¹⁰

Surgical Repair and Ablation

Surgical interventions to improve cardiac status and alleviate residual hemodynamic problems (such as valve replacement, closure of septal defect, or relief of conduit stenosis) can play a role in reducing arrhythmia risk in certain carefully selected CHD patients, especially those with new-onset or worsening arrhythmias. However, the impact of surgery on modifying the risk for SCD remains controversial. In patients with clinical monomorphic VT who require cardiac surgery, mapping and ablation of the arrhythmia can be performed intraoperatively at the time of the surgery.^{1,8,10,12}

In tetralogy of Fallot patients, replacement of the pulmonary valve is frequently required later in life after the initial repair, but it does not appear to reduce the risk of SCD. In these patients, empirical intraoperative ablation the RVOT appears to be safe and may be protective and may be considered in patients with preoperative syncope, nonsustained or sustained VT, or inducible VT during previous EP study. In these patients, ablation lesions are performed to connect the superior aspect of the ventricular septal defect patch to the pulmonary annulus or to connect the ventriculotomy to the pulmonary or tricuspid annulus.

Catheter Ablation

Catheter ablation for VT in repaired tetralogy of Fallot generally is not considered a stand-alone therapy, given the potential risk of recurrences of the same or new ventricular arrhythmias, and is primarily performed in patients with recurrent sustained monomorphic VT that is causing frequent ICD shocks or significant symptoms. Catheter ablation may

also be considered in patients with symptomatic spontaneous sustained monomorphic VT in whom ICD implantation is not recommended or not feasible.

However, catheter ablation can be considered as isolated VT therapy in a selected group of patients presenting with hemodynamically stable monomorphic VT in the absence of residual lesions and with a preserved ventricular function, and in whom ablation successfully eliminated inducibility of all monomorphic VTs. Even then, follow-up EP studies need to be considered to ensure that the same or different circuits cannot be induced before dismissing the need for an ICD.

Furthermore, tetralogy of Fallot patients with a history of syncope and induced monomorphic VT during EP testing may be considered for either ICD placement or an attempt at catheter ablation of the VT with or without back-up ICD implantation.^{5,10}

ELECTROCARDIOGRAPHIC FEATURES

During normal sinus rhythm (NSR), QRS widening after tetralogy of Fallot repair is probably the result of a combined effect of the surgical injury to the myocardium and the right bundle branch and from the RV enlargement. Therefore a prolonged QRS duration cannot be considered the specific expression of delayed intraventricular conduction from an arrhythmogenic substrate but a nonspecific marker of electrical instability.

The VT in CHD patients is most commonly monomorphic and macroreentrant, rotating clockwise or counterclockwise around myotomy scars or surgical patches. QRS morphology during VT is determined by the pattern of ventricular activation around the scar. Most commonly, left or right bundle branch block with right inferior axis morphology is seen during clockwise rotation around the scar. Less commonly, left bundle branch block with left axis morphology is observed (Fig. 30.2). Right bundle branch block–like morphology can be present if the tachycardia exits on the septal aspect of the RV free wall.

Fig. 30.2 Surface Electrocardiogram of Ventricular Tachycardia Postsurgical Repair of Tetralogy of Fallot. Note the left bundle branch block pattern and left superior axis morphology characteristic of clockwise macroreentry around the right ventriculotomy scar.

MAPPING

Detailed knowledge of the congenital and surgical anatomy, including all available operative reports, is essential before ablation. Transthoracic and transesophageal echocardiography, angiography of the chamber of interest, computed tomography, and/or magnetic resonance imaging should be considered to clarify the anatomical landmarks for mapping.⁶

Vascular and Cardiac Access

Feasibility and adequacy of vascular access must be confirmed in advance. In the CHD patient population, several conditions can pose vascular or cardiac chamber access challenges. There is often limited opportunity to place the standard number of diagnostic electrode catheters due to access issues. A superior vena cava (SVC) approach (via the internal jugular or subclavian veins) or, in rare instances, transhepatic approach can be required in some patients. In addition, in some cases, access to the target ventricle can require nonconventional approaches. For example, in patients who have had a Mustard or Senning procedure for D-transposition of the great arteries, access to the RV (the systemic ventricle) is accomplished via the retrograde aortic approach.

Identification of Barriers and Potential Lines of Block

As noted, in patients with repaired tetralogy of Fallot, the mechanism of VT is scar-based macroreentry involving the RV, either at the site of anterior right ventriculotomy or at the site of a ventricular septal patch. Hence three-dimensional (3-D) electroanatomic substrate (voltage) mapping is initially performed before VT induction to identify RV anatomical landmarks and conduction barriers (such as the ventricular septal defect patch, ventriculotomy scar, and RVOT patch).^{1,2,4} These systems also allow for good reconstruction of a 3-D anatomical shell of the often distorted cardiac chamber and integration of the created chamber geometry with preacquired cardiac CT or CMR images or

with intraprocedural intracardiac echocardiography or rotational angiography images.

Most VT circuits use the anatomical isthmus between the RVOT free wall scar or patch and the tricuspid annulus or pulmonic valve, and/or the septal scar or patch and either the tricuspid annulus or the pulmonic valve. Identification of those anatomical isthmuses by substrate mapping helps to guide subsequent mapping and ablation strategies. Confluent of electrically silent areas (defined as having a ventricular potential amplitude less than 0.05 mV and the absence of ventricular capture at 20 mA, provided that catheter contact is verified) can localize scar tissue and patches. Lines of block (manifest as double or split potentials separated by a clearly discernible isoelectric period) are tagged for easy identification because they can serve as boundaries for a subsequent design of ablation strategies.

Identification of the Critical Isthmus

The clinical monomorphic VT can be induced by programmed ventricular stimulation in the majority of patients after repair of CHD. Once sustained and stable monomorphic VT is induced, endocardial activation mapping and entrainment mapping are performed to identify the critical isthmus of the reentry circuit. Initial mapping efforts are focused on potential reentry isthmuses identified by substrate mapping. Activation mapping during VT is used to identify sites with mid-diastolic activity. Electrograms recorded within the critical isthmus can exhibit long, fractionated, low-amplitude potentials, but that is not uniformly observed.

Entrainment mapping is performed in a manner analogous to that used for post-MI VT and is used to characterize the relationship of ventricular sites to the reentrant circuit and to verify that a diastolic electrogram, regardless of where in diastole it occurs and its position and appearance on initiation of VT, is part of the VT circuit. Entrainment with concealed fusion should be sought; this indicates that the

pacing site is in a protected isthmus located within or attached to the reentrant circuit. Whether the protected isthmus is crucial to the reentrant circuit or just a bystander site needs to be verified by comparing the postpacing interval (PPI) with the tachycardia cycle length (TCL) and the stimulus-to-QRS (S-QRS) interval with the electrogram-QRS interval. A difference between the PPI and TCL not exceeding 30 milliseconds and S-QRS interval not exceeding 70% of the TCL helps to identify the critical isthmus of the reentrant circuit to be targeted by catheter ablation.

For VTs that are not mappable because of hemodynamic instability or termination during catheter manipulation or entrainment mapping, pace mapping during sinus rhythm is used to identify exit sites of the reentrant circuit, as guided by voltage mapping. Reentry circuit isthmuses can be approximated by pace mapping at sites where the QRS morphology matches that of the VT with an S-QRS interval of at least 40 milliseconds. If the VT can be briefly tolerated, the catheter is moved to the presumed isthmus site during NSR, and the VT is reinduced to confirm the position within the circuit either by entrainment mapping or by termination during radiofrequency (RF) energy application.⁴

When VT is short-lived, hemodynamically unstable, or cannot be reproducibly initiated, simultaneous multisite data acquisition using a noncontact mapping system (EnSite 3000; St. Jude Medical, St. Paul, MN, United States) can help to localize the VT site of origin. Propaga-

tion of activation within the RV can be traced throughout the whole tachycardia cycle by analyzing color-coded isopotential maps to identify the protected zone of the reentrant circuit between surgical barriers, anatomic barriers, or both. In addition, dynamic substrate mapping allows the creation of voltage maps from a single cardiac cycle and provides the ability to identify low-voltage areas, as well as fixed and functional block, on the virtual endocardium through noncontact methodology.¹⁷

ABLATION

Target of Ablation

The critical isthmus of the VT circuit is the usual target of ablation. A good pace map and entrainment with concealed QRS fusion and a prolonged S-QRS interval indicate more precisely an adequate site for ablation. Linear ablation lesions can also be performed using data obtained from substrate mapping to target anatomical isthmuses between surgical and structural lines of block.

In tetralogy of Fallot patients, four discrete anatomical isthmuses that often support macroreentrant VT have been identified (Fig. 30.3): (1) the isthmus between the superior aspect of the tricuspid annulus and ventriculotomy scar/patch in the free wall of the RVOT, (2) the isthmus between the pulmonic valve annulus and RV free wall scar (in

Fig. 30.3 Anatomical Isthmuses for Ventricular Tachycardia (VT) in Repaired Tetralogy of Fallot (rTOF). Anatomical isthmus 1 is located between the tricuspid annulus (TA) and a right ventricular (RV) incision/ RV outflow tract (RVOT) patch (A and B), and anatomical isthmus 2 is located between a RV incision and pulmonary valve (PV; B). Anatomical isthmus 3, located between the PV and ventricular septal defect (VSD) patch, and anatomical isthmus 4, located between the VSD patch and TA (C), are bordering on the septum. ccw, Counterclockwise; cw, clockwise. (From Kapel GF, Reichlin T, Wijnmaalen AP, et al. Left-sided ablation of ventricular tachycardia in adults with repaired tetralogy of Fallot a case series. *Circ Arrhythm Electrophysiol*. 2014;7:889–897.)

the absence of a transannular patch), (3) the isthmus between pulmonic valve annulus and the ventricular septal patch, and (4) the isthmus between the tricuspid annulus and ventricular septal patch through the region of the ventriculo-infundibular fold. Significant variation exists in the frequency of the presence and involvement of these isthmuses in the VT circuit, as well as variability in the anatomical characteristics of these isthmuses. In general, the isthmus between the superior aspect of the tricuspid annulus and unexcitable scar/patch in the free wall of the RVOT is the most common isthmus incorporated in the VT circuit, and frequently it is the isthmus with the greatest overall dimensions in terms of length and wall thickness.³

Ablation lines transecting these anatomical isthmuses eliminate the VT in most patients, even when conventional mapping is not feasible because of poorly tolerated or noninducible tachycardia. Typically, linear ablation should be continued to span the entire width of the VT isthmus, connecting two anatomical boundaries, even when partial isthmus ablation results in termination or noninducibility of the VT. This ablation approach is comparable to ablation of the cavotricuspid isthmus-dependent for typical atrial flutter.^{3, 4, 5, 17, 18}

Although VT in tetralogy of Fallot patients is primarily RV in origin, a left-sided approach can be required for ablation of some anatomical isthmuses bordering on the infundibular septum. The hypertrophied septal myocardium, the overlying pulmonary homograft, and overlying ventricular septal defect patch can potentially prohibit complete ablation of those isthmuses via the RV.^{18, 19}

When the isthmus between the superior aspect of the tricuspid annulus and unexcitable scar/patch in the free wall of the RVOT is the ablation target, achieving complete isthmus block can be challenging due to its length and thickness. In these situations, ablation of the nearby, smaller isthmus (between the ventriculotomy incision and the ventricular septal defect patch) in combination with ablation of the isthmus between the septal patch and tricuspid annulus can potentially serve as an alternate ablation strategy to create a line of block between the RVOT scar/patch and tricuspid annulus.³

Ablation Technique

RF ablation is usually performed with an irrigated-tip ablation catheter (power limit, 50 W) or an 8-mm-tip catheter (power limit, 70 W). Ablation is performed during VT when possible. Slowing or termination of the VT during RF application should prompt additional lesions being placed to connect the adjoining anatomical boundaries across the VT circuit isthmus, as defined by voltage mapping and pace mapping techniques, and RF lesions being placed during NSR until unipolar pacing fails to capture.⁴ Because manipulating catheters in the often-distorted chambers is challenging, the use of long, preformed or deflectable vascular sheaths can help to augment the reach of the ablation catheter and ensure adequate and stable catheter-tissue contact.

Endpoints of Ablation

Tachycardia Termination

When ablation is performed during sustained VT, termination of VT during RF application suggests that the lesion has affected a critical isthmus, and that site should be targeted for additional lesions. However, VT termination is not an adequate endpoint because VT can terminate spontaneously by partial, rather than complete, ablation of the critical isthmus.¹⁷

Noninducibility of Tachycardia

Noninducibility of the clinical VT is an important endpoint of the procedure. In addition, noninducibility of any sustained monomorphic VT should be verified, especially when ICD implantation is not preferred. It is important to carefully assess VT inducibility at baseline and use

the best method of reproducible induction of the VT for postablation testing. In the setting of easy inducibility prior to ablation, one can consider the lack of inducibility as an indicator of successful ablation. Noninducibility of the arrhythmia is not applicable if the original arrhythmia either is noninducible at baseline or was inadvertently terminated mechanically.¹⁷

Documentation of a Line of Block

Termination and noninducibility of VT can be the result of conduction delay in the critical isthmus and not stable block and hence may not represent adequate procedural endpoints. Achievement of complete and stable conduction block across the anatomical isthmus of the VT circuit is the most objective endpoint for successful ablation. The demonstration of a continuous corridor of widely split double potentials recorded during sinus rhythm along the entire length of the ablation line confirms the presence of block. In addition, differential ventricular pacing can help to verify conduction block across the ablation line. Ventricular pacing is performed at two separate sites on the same side of the ablation line, one site very close to the ablation line and the second site 10 to 20 mm farther away. Local activation time is recorded on the contralateral side of the ablation line. In the presence of conduction block across the ablation line, moving the pacing site away from the ablation line shortens the conduction time to the contralateral side and shortens the distance between the double potentials straddling the ablation line. Withdrawal of the pacing site farther away from the ablation line results in a delay of the first component of the double potentials (which represents activation on the side of the ablation line ipsilateral to the pacing site). In contrast, the second component of the double potentials (which represent activation on the contralateral side of the ablation line) becomes activated earlier because the length of the detour the wavefront has to travel around the line of block is shortened by the new site of pacing. Consequently, the separation of double potentials decreases. On the other hand, in the setting of incomplete block, both components of the double potentials are the result of sequential activation by the same paced wavefront propagating across the ablation line. Therefore withdrawal of the pacing site farther away from the ablation line causes a similar degree of delay of the timing of both components of the electrogram (relative to the pacing stimulus), so that the interval between the double potentials remains constant.¹⁷

Outcome

The experience with catheter ablation of VT in CHD is limited. Several reports have described single-center experiences spanning several eras of technological advances. The limited acute and long-term success rates are related to the complexity of the underlying congenital defect and surgical repair and the complexity of the reentry circuits. In a report of 20 patients with VT and CHD, 50% of patients were unable to undergo ablation because of VT noninducibility, hemodynamic instability, access or anatomical problems, or proximity of the ablation target to the His bundle. The acute success rate for mappable VTs was 83%, with a long-term recurrence rate of 40%. Other studies reported procedural success rates ranging from 74% to 94%.^{4, 17, 18}

Sudden cardiac death (SCD) is a major contributor to population mortality, with an overall incidence in the United States estimated to be between 0.1% and 0.2%, resulting in approximately 300,000 to 350,000 deaths annually. Ventricular fibrillation (VF) or pulseless ventricular tachycardia (VT) is the initial rhythm recorded in 25% to 36% of witnessed cardiac arrests occurring at home, but in a much higher proportion (38% to 79%) of witnessed cardiac arrests occurring in a public setting. The majority of SCD events are associated with structural heart disease, with coronary artery disease and its complications being involved in up to 60% to 80% of cases, followed by other cardiomyopathies. However, in 10% to 20% of SCDs, no cardiac structural abnormalities are detectable. The lack of an apparent cause in many of those cases initially led to the classification as “sudden unexplained death syndrome” (SUDS) or “sudden infant death syndrome” (SIDS). Many of these are caused by primary electrical disorders, including long QT syndrome

(LQTS), catecholaminergic polymorphic VT (CPVT), Brugada syndrome, and short QT syndrome (SQTS), as well as cases identified as “idiopathic VF” when the underlying cause often remains unknown.¹

LONG QT SYNDROME

The LQTS is an uncommon inherited cardiac channelopathy that is associated with an abnormally prolonged QT interval and an increased propensity for life-threatening ventricular arrhythmias in the presence of a structurally normal heart.

In 1957, Anton Jervell and Fred Lange-Nielsen published the first report on a familial (autosomal recessive) disorder (“Jervell and Lange-Nielsen syndrome”) characterized by the presence of a striking prolongation of the QT interval, congenital deafness, and a high incidence of SCD at a young age. Subsequently, Romano and Ward independently

identified an almost identical, but autosomal dominant, disorder that is not associated with deafness (“Romano-Ward syndrome”). A genetic relationship between the two was then proposed and the two syndromes were considered variants of one disease under the unifying name of “LQTS.” In the contemporary literature, Romano-Ward syndrome is used interchangeably with LQTS, but is now less commonly used in favor of the LQT1 to LQT17 scheme according to the underlying genetic mutation (see later).

The initial molecular studies suggested that all genes linked to the LQTS phenotype encode for various subunits of cardiac ion channels. Subsequent findings, however, revealed that LQTS could also be caused by mutations of gene coding for channel-associated cellular structural proteins as well. Nonetheless, the concept that LQTS genes ultimately affect cardiac ion currents, either directly (ion channel mutations) or indirectly (modulators), still holds true.

Genetics of the Long QT Syndrome

To date, more than 600 mutations of 17 different genes responsible for a hereditary form of LQTS have been identified (LQT1–17) (Table 31.1; Fig. 31.1), with the majority (more than 90%) of the known mutations located in the first three genes: LQT1 (*KCNQ1*) mutations account for 40% to 55% of genetically positive LQTS, LQT2 (*KCNH2*) for 30% to 45%, and LQT3 (*SCN5A*) for 5% to 10%.

Overall, nine of these genes encode ion channel subunits that are specifically involved in cardiac action potential generation. LQT4, LQT9, LQT11, LQT12, and LQT14–LQT17 are caused by mutations in a family of versatile membrane adapters other than ion channel subunits.

The majority of LQTS cases are inherited in an autosomal dominant fashion. Conversely, Jervell and Lange-Nielsen syndrome, which is inherited in an autosomal recessive fashion, is very rare, affecting less than 1% of LQTS cases.

Genetic analysis reveals two or more mutations in 8% to 11% of LQTS patients with clinical phenotypes of autosomal dominant Romano-Ward syndrome. These compound mutations (so-called “double hits”)

appear to be associated with a more severe phenotype than that associated with a single hit.

Most reported LQTS genetic mutations occur in coding regions, although noncoding mutations (resulting in the loss of allele expression) have also been described. Most LQTS families have their own mutations, which are often termed “private” mutations.

Several genetic mechanisms have been implicated in the development of LQTS including abnormalities in protein synthesis (transcription, translation), posttranslational protein processing resulting in abnormal transport to the cell surface membrane (protein trafficking, folding, assembly of subunits, glycosylation), ion channel gating (biophysical and kinetic properties), or permeation (ion selectivity, unitary conductance).

The majority of LQTS cases are caused by heterozygous disease; thus mutations causing abnormalities in channel coassembly or trafficking result in up to 50% maximal reduction in the number of functional channels (haplotype insufficiency), because the gene product from the healthy allele remains intact. On the other hand, mutations that abolish channel function while preserving subunit assembly can result in dominant-negative suppression of the healthy allele as well, causing a more severe reduction (up to 94%) of the total amount of functional protein (dominant-negative effect) and favoring a more severe clinical course and a higher frequency of arrhythmia-related cardiac events.

Mutations Related to the Potassium Current

Mutations related to the slowly activating delayed rectifier potassium current. Slowly activating delayed rectifier potassium current (I_{Ks}) contributes to human atrial and ventricular repolarization, particularly during action potentials of long duration, and plays an important role in determining the rate-dependent shortening of the cardiac action potential. Mutations in LQT1, LQT5, and LQT11 result in attenuation of I_{Ks} and, as a consequence, prolongation of repolarization, action potential duration and QT interval. LQT1 is caused by loss-of-function mutations of

TABLE 31.1 Molecular Basis of the Congenital Long QT Syndrome

Disease	Gene	Protein	Functional Effect	Frequency
LQT1	<i>KCNQ1 (KvLQT1)</i>	K _v 7.1	↓ I_{Ks}	40%–55%
LQT2	<i>KCNH2 (HERG)</i>	K _v 11.1	↓ I_{Kr}	30%–45%
LQT3	<i>SCN5A</i>	Na _v 1.5	↑ I_{Na}	5%–10%
LQT4 (Ankyrin-B syndrome)	<i>ANKB</i>	Ankyrin-B	Aberrant ion channel/transporter localization	<1%
LQT5	<i>KCNE1</i>	MinK	↓ I_{Ks}	<1%
LQT6	<i>KCNE2</i>	MiRP1	↓ I_{Kr}	<1%
LQT7 (Andersen-Tawil syndrome)	<i>KCNJ2</i>	Kir2.1	↓ I_{K1}	<1%
LQT8 (Timothy syndrome)	<i>CACNA1C</i>	Ca _v 1.2	↑ I_{CaL}	<1%
LQT9	<i>CAV3</i>	Caveolin 3	↑ I_{Na}	<1%
LQT10	<i>SCN4B</i>	Na _v β4	↑ I_{Na}	<1%
LQT11	<i>AKAP9</i>	Yotiao	↓ I_{Ks}	<1%
LQT12	<i>SNTA1</i>	Syntrophin-α1	↑ I_{Na}	<1%
LQT13	<i>KCNJ5</i>	Kir3.4 (GIRK4)	↓ I_{KACH}	<1%
LQT14	<i>CALM1</i>	Calmodulin 1	↑ I_{CaL}	1%–2%
LQT15	<i>CALM2</i>	Calmodulin 2	↑ I_{CaL}	<1%
LQT16	<i>CALM3</i>	Calmodulin 3	↑ I_{CaL}	<1%
LQT17 (Triadin knockout syndrome)	<i>TRDN</i>	Triadin	↑ I_{CaL}	2%
JLN1	<i>KCNQ1 (KvLQT1)</i>	K _v 7.1	↓ I_{Ks}	Very rare
JLN2	<i>KCNE1</i>	MinK	↓ I_{Ks}	Very rare

I_{CaL} , L-type Ca^{2+} current; I_{K1} , inward rectifier K^{+} current; I_{KACH} , acetylcholine-activated inward rectifier K^{+} current; I_{Kr} , rapidly activating delayed rectifier K^{+} current; I_{Ks} , slowly activating delayed rectifier K^{+} current; I_{Na} , Na^{+} current; JLN1 and JLN2, Jervell and Lange-Nielsen syndrome types 1 and 2, respectively; LQT1 to LQT17, long QT syndrome types 1 to 17, respectively.

Fig. 31.1 Current-Centric Classification of Long QT Syndrome (LQTS) Genotypes. The clinical phenotypes resulting from the abnormal ventricular cardiac action potential depolarization (purple) or repolarization (orange) are grouped according to the specific current perturbed by an underlying genetic defect. Blue circles represent mutations that confer a loss of function to the specified current, whereas green circles confer a gain of function. Solid lines indicate those disorders that are autosomal dominant, whereas dashed lines indicate those disorders that are autosomal recessive. Solid black outlines indicate nonsyndromic genotypes and solid orange outlines represent multisystem genotypes. ABS, Ankyrin-B syndrome; COTS, cardiac-only Timothy syndrome; JLN1, Jervell and Lange-Nielsen syndrome; $I_{Ca,L}$, L-type calcium current; I_{K1} , inwardly rectifying potassium current; I_{KACh} , G-protein-coupled inwardly rectifying potassium current; I_{Kr} , rapid component of the delayed rectifier potassium current; I_{Ks} , slow-component of the delayed rectifier potassium current; I_{Na} , cardiac sodium current; TKO, triadin knockout syndrome. (From Giudicessi JR, Ackerman MJ. Calcium revisited. *Circ Arrhythmia Electrophysiol.* 2016;9:e002480.)

the *KCNQ1* (*KvLQT1*) gene, which encodes the α subunit ($K_v7.1$) of the inward I_{Ks} . More than 170 mutations of this gene have been reported, comprising many Romano-Ward (autosomal dominant) syndromes and accounting for approximately 40% to 55% of all genotyped LQT families. Of note, mutations involving the transmembrane domain of *KCNQ1* result in more severe disease compared with C-terminal mutations. LQT5 is caused by loss-of-function mutations of the *KCNE1* gene, which encodes the β -subunit (MinK) that modulates I_{Ks} .

Homozygous or compound heterozygous loss-of-function mutations of either the *KCNQ1* or *KCNE1* genes cause the autosomal recessive form of LQTS (the Jervell and Lange-Nielsen syndrome). Patients with *KCNQ1* mutations (type 1 Jervell and Lange-Nielsen syndrome) have an almost sixfold greater risk of arrhythmic events, whereas patients with *KCNE1* mutations (type 2 Jervell and Lange-Nielsen syndrome)

appear to be at lower risk. Although the Jervell and Lange-Nielsen syndrome is the most severe among the major variants of LQTS, the parents of Jervell and Lange-Nielsen syndrome patients are generally less symptomatic than other LQT1 patients, despite the fact that they all are heterozygous for the same gene. This is likely related to the observation that most of the LQT1 genetic variants are missense mutations exerting a dominant-negative effect, whereas most (74%) Jervell and Lange-Nielsen mutations of *KCNQ1* are frame-shift/truncating mutations that are unable to cause dominant-negative suppression but are likely to interfere with subunit assembly. Jervell and Lange-Nielsen syndrome accompanies complete loss of I_{Ks} in hair cells and endolymph of the inner ear, which results in congenital deafness.

LQT11 is caused by loss-of-function mutations of the *AKAP9* gene, which encodes an A-kinase anchoring protein (Yotiao), shown to be

an integral part of the I_{Ks} macromolecular complex. The presence of Yotiao is necessary for the physiological response of the I_{Ks} to beta-adrenergic stimulation. LQT11 mutations reduce the interaction between Yotiao and the I_{Ks} channel ($K_{0.7.1}$), preventing the functional response of I_{Ks} to cyclic adenosine monophosphate (cAMP) and adrenergic stimulation and causing an attenuation of I_{Ks} .

Mutations related to the rapidly activating delayed rectifier potassium current. Rapidly activating delayed rectifier potassium current (I_{Kr}) presents the principal repolarizing current at the end of the plateau phase in most cardiac cells and plays an important role in governing the cardiac action potential duration and refractoriness. Mutations in LQT2 and LQT6 result in attenuation of I_{Kr} and cause a decrease in the K^+ outward current and prolongation of repolarization, action potential duration, and QT interval.

LQT2 is caused by loss-of-function mutations of the *KCNH2* (*HERG*) gene, which encodes the α -subunit ($K_{0.11.1}$) of the inward I_{Kr} . LQT2 syndrome accounts for almost 30% to 45% of all genotyped congenital LQTS cases. Approximately 200 mutations in this gene have been identified, which result in rapid closure of the hERG channels and decrease the normal rise in I_{Kr} , leading to delayed ventricular repolarization and QT prolongation. Mutations involving the pore region of the hERG channel are associated with a significantly more severe clinical course than nonpore mutations; most pore mutations are missense mutations with a dominant-negative effect.

LQT6 is caused by loss-of-function mutations of the *KCNE2* gene, which encodes the accessory β -subunit (MiRP1) of the hERG channel. LQT6 displays clinical resemblance to LQT2.

Mutations related to the inward rectifier potassium current. Inward rectifier potassium current (I_{K1}) contributes to the terminal portion of phase 3 repolarization. Andersen-Tawil syndrome (LQT7) is caused by loss-of-function mutations of the *KCNJ2* gene, which encodes the voltage-dependent K^+ channel (Kir2.1) that contributes to the inward I_{K1} . Kir2.1 channels are expressed primarily in skeletal muscle, heart, and brain. The majority of mutations exert a dominant-negative effect on channel current.

Disruption of the I_{K1} function can potentially lead to prolongation of the terminal repolarization phase and QT interval, which can predispose to the generation of early afterdepolarizations (EADs) and delayed afterdepolarizations (DADs) causing ventricular arrhythmias. However, unlike other types of LQTS, where the afterdepolarizations arise from reactivation of L-type Ca^{2+} channels, the EADs/DADs generated in LQT7 are likely secondary to Na^+ - Ca^{2+} exchanger-driven depolarization. It is believed that the differential origin of the triggering beat is responsible for the observed discrepancy in arrhythmogenesis and the clinical features compared with other types of LQTS. In addition, it is likely that prolongation of the action potential duration in LQT7 is somewhat homogeneous across the ventricular wall (i.e., transmural dispersion of repolarization is less prominent than in other types of LQTS), which can potentially explain the low frequency of torsades de pointes. Flaccid paralysis results from failure to propagate action potentials in the skeletal muscle membrane as a result of sustained membrane depolarization.

Mutations related to the acetylcholine-activated potassium current. LQT13 is caused by loss-of-function mutations of the *KCNJ5* gene, which encodes the α subunit (Kir3.4, GIRK4) of the inward acetylcholine-activated potassium current (I_{KACH}). Kir3.4 mutations exert dominant-negative effects on Kir3.1/Kir3.4 channel complexes by disrupting membrane targeting and stability of Kir3.4.

Mutations Related to the Sodium Current

LQT3 is caused by gain-of-function mutations of the *SCN5A* gene, which encodes the α subunit ($Na_v1.5$) of the cardiac voltage-gated Na^+

channel that is responsible for the sodium content (I_{Na}). LQT3 accounts for approximately 5% to 10% of genotype-positive LQTS cases. More than 200 mutations have been identified in the *SCN5A* gene, with the majority being missense mutations mainly clustered in $Na_v1.5$ regions that are involved in fast inactivation, or in regions that stabilize fast inactivation.

Several mechanisms have been identified to underlie ionic effects of *SCN5A* mutations in LQT3. Most of the *SCN5A* mutations cause a gain of function through disruption of fast inactivation of the Na^+ channel, allowing repeated reopening during sustained depolarization and resulting in an abnormal, small but functionally important sustained (or persistent) noninactivating Na^+ current (I_{sus}) during the action potential plateau that acts to slow repolarization and prolong the action potential duration (eFig. 31.1). Other, less common mechanisms (eFig. 31.2) include increased window current, which results from delayed inactivation of mutant Na^+ channels, occurring at more positive potentials and widening the voltage range during which the Na^+ channel may reactivate without inactivation. In addition, some mutations cause slower inactivation, which allows longer channel openings, and causes a slowly inactivating Na^+ current (the late Na^+ current, I_{NaL}).

Regardless of the mechanism, increased Na^+ current (I_{sus} , window current, I_{NaL} , or peak I_{Na}) upsets the balance between depolarizing and repolarizing currents in favor of depolarization. Gain-of-function LQT3 mutations often increase I_{NaL} two- to fourfold. Because the general membrane conductance is small during the action potential plateau, the presence of a persistent inward Na^+ current, even of small amplitude, can potentially have a major impact on the plateau duration and can be sufficient to prolong repolarization and QT interval. The resulting delay in the repolarization process triggers EADs (i.e., reactivation of the L-type Ca^{2+} channel during phase 2 or 3 of the action potential), especially in Purkinje fiber myocytes where action potential durations are intrinsically longer. Also, increased influx of Na^+ (via the enhanced I_{NaL}) can stimulate the Na^+ - Ca^{2+} exchanger in the reverse mode (3 Na^+ ions out, one Ca^{2+} ion in), with consequent intracellular Ca^{2+} overload and DADs. QT prolongation and the risk of developing arrhythmia is more pronounced at slow heart rates, when the action potential duration is longer, allowing more Na^+ current to enter the cell.²

LQT9 is caused by gain-of-function mutations of the *CAV3* gene, which encodes caveolin-3, a plasma membrane scaffolding protein that interacts with $Na_v1.5$ and plays a role in compartmentalization and regulation of channel function. Mutations in caveolin-3 induce kinetic alterations of the Na^+ channel that result in persistent late Na^+ current (I_{sus}) and have been reported in cases of SIDS.

LQT10 is caused by gain-of-function mutations of the *SCN4B* gene, which encodes the β -subunit ($Na_v\beta_4$) of the $Na_v1.5$ ion channel. To date, only a single mutation in one patient has been described, which resulted in a shift in the inactivation of the Na^+ current toward more positive potentials, but did not change the activation. This resulted in increased window currents at membrane potentials corresponding to phase 3 of the action potential.

LQT12 is caused by mutations of the *SNTA1* gene, which encodes $\alpha 1$ -syntrophin, a cytoplasmic adaptor protein that enables the interaction between $Na_v1.5$, nitric oxide synthase, and sarcolemmal Ca^{2+} adenosine triphosphatase (ATPase) complex that appears to regulate ion channel function. By disrupting the interaction between $Na_v1.5$ and sarcolemmal calcium ATPase complex, *SNTA1* mutations cause increased $Na_v1.5$ nitrosylation with consequent reduction of channel inactivation and increased I_{sus} densities.

Mutations Related to the Calcium Current

Mutations related to the L-type calcium current. Timothy syndrome (LQT8) is caused by gain-of-function mutations of the *CACNA1C*

A

B

A

C

eFig. 31.1 Mechanism of Long QT Syndrome Type 3 (LQT3). (A) QT interval prolongation results from delayed repolarization of ventricular action potentials. (B) Delayed repolarization in LQT3 is often due to the presence of abnormal sustained non-inactivating sodium current (green area). (C) Sustained current results from incomplete inactivation of the sodium channels (green circles). (From Amin AS, Asghari-Roodsari A, Tan HL. Cardiac sodium channelopathies. *Pflügers Arch Eur J Physiol.* 2010;460:223–237.)

B

C

eFig. 31.2 Alternative Mechanisms of Sodium Channel Gain-of-Function in Long QT Syndrome Type 3. (A) Increased window current due to delayed inactivation of cardiac sodium channels (green circles). Increased window current is carried at potentials corresponding to phases 2 and 3 of the ventricular action potential (green area), remote from the peak sodium current during phase 0 (blue area). (B) Slower inactivation creates a late sodium current (green area). (C) Increased peak sodium current. (From Amin AS, Asghari-Roodsari A, Tan HL. Cardiac sodium channelopathies. *Pflügers Arch Eur J Physiol.* 2010;460:223–237.)

gene, which encodes the α subunit ($\text{Ca}_v1.2$) of the voltage-dependent L-type Ca^{2+} channel that contributes to L-type calcium current (I_{CaL}).

Recently, multiple nonsyndromic LQTS-causative mutations in *CACNA1C* were described in LQTS patients with isolated QT prolongation and propensity to ventricular arrhythmias in the absence of congenital heart defects and extracardiac manifestations that define Timothy syndrome clinically (nonsyndromic LQT8).³ Other *CACNA1C* mutations were found to cause cardiac-only Timothy syndrome (COTS), characterized by the concomitant but variably expressed phenotypes of LQTS (QT prolongation), hypertrophic cardiomyopathy, congenital heart defects, and SCD in the absence of any extracardiac symptoms.^{3,4}

The inward I_{CaL} sustains depolarization and gives rise to the plateau phase essential for excitation-contraction coupling. Gain-of-function mutations of *CACNA1C* result in near complete elimination of voltage-dependent inactivation of $\text{Ca}_v1.2$ channels, leading to inappropriate continuation of the depolarizing I_{CaL} and lengthening of the plateau phase, predisposing to the generation of EADs. In addition, augmentation of I_{CaL} leads to intracellular Ca^{2+} overload, which promotes spontaneous ectopic Ca^{2+} release from sarcoplasmic reticulum and the generation of potentially arrhythmogenic DADs.³

The exact pathophysiology of hypertrophic cardiomyopathy, congenital heart defects, and extracardiac manifestations of Timothy syndrome and their relation to *CACNA1C* mutations remain unclear.

Mutations related to calmodulin (calmodulinopathy). Calmodulin is a small cytoplasmic Ca^{2+} -binding protein with ubiquitous expression. Calmodulin is involved, directly and indirectly, in modulation of several ion channels, including Na^+ , K^+ , L-type Ca^{2+} , and RYR2 channels. The main binding partner of calmodulin in cardiac cells is RyR2, which regulates Ca^{2+} release from the sarcoplasmic reticulum. Acting as an intracellular Ca^{2+} sensor, Ca^{2+} -saturated calmodulin binds RYR2 to inhibit Ca^{2+} release by stabilizing the RyR2 channel closed state.

Three different genes (*CALM1–3*) in the human genome encode exactly the same calmodulin protein. Recent genetic studies have identified several calmodulin mutations associated with CPVT, LQTS, and idiopathic VF. Defective calmodulin–RyR2 binding results in impaired calmodulin inhibition of RyR2 function with consequent dysregulation of sarcoplasmic reticulum Ca^{2+} release. Further, de novo mutations in *CALM1*, *CALM2*, or *CALM3* genes were found to disrupt Ca^{2+} -dependent inactivation of the cardiac L-type Ca^{2+} channel ($\text{Ca}_v1.2$), which leads to augmentation of I_{CaL} , prolongation of the plateau phase of action potential, and LQTS phenotype (LQT14–16).^{5,6}

Mutations related to triadin: triadin knockout syndrome. *TRDN* encodes triadin, a sarcoplasmic reticulum protein functionally and physically related to the RYR2. Homozygous or compound heterozygous loss-of-function mutations in *TRDN* likely reduce triadin-mediated negative feedback on the L-type Ca^{2+} channel, resulting in augmentation of I_{CaL} , prolonged action potential duration, and the recessively inherited LQTS phenotype (LQT17). Intracellular Ca^{2+} overload and increases in spontaneous sarcoplasmic reticulum Ca^{2+} release, particularly in the setting of beta-adrenergic stimulation, result in ventricular arrhythmias.

LQT17 is characterized by extensive T wave inversions in the precordial leads V_1 through V_4 , with either persistent or transient QT prolongation, exercise-induced cardiac arrest in early childhood (2 to 6 years of age), and mild-to-moderate proximal skeletal muscle weakness. Because all *TRDN*-null patients display a strikingly similar phenotype, it has been proposed that either triadin knockout syndrome or *TRDN*-mediated autosomal-recessive LQTS should be used rather than LQT17.^{3,7}

Mutations in the Ankyrin-B Gene: Ankyrin-B Syndrome

LQT4 is caused by loss-of-function mutations of the *ANK2* gene, which encodes ankyrin-B, a structural membrane adapter protein that anchors

ion channels to specific domains in the plasma membrane. Functionally, ankyrins bind to several ion channel proteins, targeting these proteins to specialized membrane domains, such as the anion exchanger (chloride-bicarbonate exchanger), Na^+ - K^+ ATPase, I_{Na} , the Na^+ - Ca^{2+} exchanger ($I_{\text{Na-Ca}}$), and Ca^{2+} release channels (including those mediated by the receptors for inositol triphosphate [IP_3] or RyR2). Hence, *ANK2* mutations can potentially result in improper localization and activity of ion-conducting proteins.

Mutations of the *ANK2* gene have been reported to lead to increased intracellular concentration of Ca^{2+} and, sometimes, fatal arrhythmia. However, QT interval prolongation is not a consistent feature in patients with ankyrin-B dysfunction, and the clinical phenotypes often extend beyond the typical LQTS, including sinus node dysfunction (SND), atrioventricular (AV) block, and atrial fibrillation (AF), in addition to idiopathic VF, exercise-induced, polymorphic VT, and SCD. Therefore ankyrin-B dysfunction is now regarded as a clinical entity distinct from classic LQTS (referred to as the “ankyrin-B syndrome”).

Pathophysiology of the Long QT Syndrome

Mechanism of QT Interval Prolongation

Any factor that evokes lengthening of the action potential duration holds the potential of causing an LQTS phenotype, especially if it does it heterogeneously. Electrophysiologically, prolongation of the action potential duration and QT interval can arise from either a decrease in the outward repolarizing current (K^+ currents: I_{Kr} , I_{Ks} , I_{K1} , I_{KACh}) or an increase in inward depolarizing membrane current (I_{Na} , I_{CaL}) during phases 2 and 3 of the action potentials (Fig. 31.2).

Most commonly, QTc prolongation is produced by delayed repolarization due to attenuation of I_{Ks} (LQT1, LQT5, LQT11), I_{Kr} (LQT2, LQT6), I_{K1} (LQT7), or I_{KACh} (LQT13). Less commonly, QT prolongation results from prolonged depolarization due to an increase in I_{Na} (LQT3, LQT4, LQT9, LQT10, LQT12) or I_{CaL} (LQT8, LQT14–17).

Mechanism of Dispersion of Repolarization

LQTS is caused by an excessive and heterogeneous prolongation of the repolarization phase of the ventricular action potential. In the normal ventricle, there are heterogeneous cell types with different action potential morphologies and durations, mainly attributed to cell-specific and regional variability in the functional expression of different populations of ion channels (transient outward K^+ channels [I_{to}], I_{Ks}) and the Na^+ window current (I_{Na}), and their accessory proteins. Some experimental studies proposed the presence of three irregular cell layers in the ventricular wall with distinct electrical properties: endocardial, midmyocardial (putative M cells), and epicardial cells. Overall, the midmyocardial cells (which have a smaller I_{Ks} , a larger late I_{Na} , and a larger Na^+ - Ca^{2+} exchange current [$I_{\text{Na-Ca}}$]) appear to generate longer action potential durations that are more susceptible to modification compared with the endocardium and epicardium. The epicardial cells have the shortest action potential durations because of a prominent I_{to} . Repolarization of endocardial cells usually occurs between repolarization of the epicardial and midmyocardial cells. Notably, factors that prolong the action potential appear to elicit a disproportionate prolongation of the action potential duration in midmyocardial cells. As a result, dispersion of the action potential duration becomes irregularly exaggerated across the ventricular wall, yielding an increase in the action potential duration heterogeneity.

Conditions leading to a reduction in I_{Kr} (e.g., LQT2) or augmentation of late I_{Na} (e.g., LQT3) produce a preferential prolongation of the midmyocardial cell action potential. Consequently, QT interval prolongation is accompanied by a dramatic increase in transmural dispersion of repolarization. In contrast, conditions leading to a reduction in I_{Ks} alone (e.g., LQT1) result in a homogeneous prolongation of action

Fig. 31.2 Pathophysiology of Long QT Syndrome. Transmembrane action potentials and transmural electrocardiogram (ECG) traces in control and after I_{Ks} block (A), I_{Kr} block (B), and increase in late I_{Na} (C), in arterially perfused canine left ventricular wedge preparations. (A) to (C) depict action potentials simultaneously recorded from endocardial (Endo), M cell, and epicardial (Epi) sites, together with a transmural ECG trace. Basic cycle length, 2000 milliseconds. In all cases, the peak of the T wave in the ECG is coincident with the repolarization of the epicardial action potential, whereas the end of the T wave is coincident with the repolarization of the M cell action potential. Repolarization of the endocardial cell is intermediate between that of the M cell and epicardial cell. Transmural dispersion of repolarization across the ventricular wall, defined as the difference in the repolarization time between M and epicardial cells, is denoted below the ECG traces. ATX-II, Sea anemone toxin; I_{Na} , sodium current; I_{Kr} , rapidly activating delayed rectifier K⁺ current; I_{Ks} , slowly activating delayed rectifier potassium current. (From Antzelevitch C. Drug-induced channelopathies. In: Zipes DP, Jalife J, eds. *Cardiac Electrophysiology: From Cell to Bedside*. 5th ed. Philadelphia: WB Saunders; 2009:195–203.)

potential duration across the ventricular wall with little increase in transmural dispersion of repolarization. However, concurrent beta-adrenergic stimulation (e.g., exercise, isoproterenol) results in abbreviation of epicardial and endocardial action potential duration with little or no change in the midmyocardial cell action potential, resulting in marked augmentation of transmural dispersion of repolarization and arrhythmogenesis (see Fig. 31.2).

Mechanism of Torsades de Pointes

The excessive increase in the spatial and/or temporal heterogeneity of the duration of the action potential favors the generation of EADs caused by reactivation of L-type Ca^{2+} channels, and on some occasions the late I_{Na} or Na^{+} - Ca^{2+} exchanger. EADs can cause premature ventricular complexes (PVCs) (predominantly arising from the Purkinje network) that can potentially infringe on the underlying substrate of heterogeneous repolarization to initiate polymorphic reentrant VT. Excessive transmural heterogeneity of the action potential duration provides the substrate for unidirectional block and functional reentry circuits to perpetuate torsades de pointes. Although controversy still exists, it is likely that the propagation of torsades de pointes is facilitated by intramural reentrant mechanisms giving rise to one or more intramural rotors that impose a rapid ectopic ventricular rhythm (typically 150 to 300 beats/min) while migrating inside the ventricular wall. Hence, with each new cycle the principal depolarization focus migrates accordingly, resulting in a progressive change of the electrical axis, typically rotating 180 degrees in approximately 10 to 12 cycles. This results in a polymorphic VT with the characteristic sinusoidal “twisting of the points” pattern on the 12-lead electrocardiogram (ECG).⁸

Notably, although the atrium seems to be resistant to generating EADs in response to agents that prolong repolarization, atrial EADs

and “atrial torsades de pointes” have been reported in some LQTS patients as well as cesium-treated dogs.

Mechanism of Exercise-Induced QT Interval Changes

Arrhythmic events in LQTS are strongly associated with triggers linked to inappropriate QT adaptation to changes in heart rate. Patients with LQT1 and LQT2 genotypes have differing patterns of QT adaptation during beta-adrenergic stimulation (e.g., during stress, exercise, or epinephrine infusion). LQT1 patients appear to have less repolarization reserve during exercise as evidenced by a progressive or persistent pattern of QTc prolongation at faster heart rates, compared with patients with LQT2, in whom maximal QTc prolongation occurs at submaximal heart rates in the early phase of sympathetic stimulation with subsequent fall toward baseline values at faster heart rates.

I_{Ks} is an important determinant of rate-dependent shortening of the cardiac action potential and QT interval. As heart rate increases, I_{Ks} increases because channel deactivation is slow and incomplete during the shortened diastole. This allows I_{Ks} channels to accumulate in the open state during rapid heart rates and contribute to the faster rate of repolarization. Furthermore, I_{Ks} is markedly enhanced by beta-adrenergic stimulation through G-protein/cAMP-mediated channel phosphorylation by protein kinase A (PKA) (requiring AKAP9 [Yotiao]) and PKC (requiring MinK). Importantly, I_{Ks} is functionally upregulated when other repolarizing currents (such as I_{Kr}) are reduced, potentially serving as a “repolarization reserve” and a safeguard against loss of repolarizing power, especially when beta-adrenergic stimulation is present. LQT1 subjects have compromised I_{Ks} channels that are not as responsive to sympathetic stimulation, and phase 3 repolarization in these individuals is retarded. Consequently, during beta-adrenergic stimulation, there are relatively more unopposed depolarizing forces via the L-type Ca^{2+}

channel and the $\text{Na}^+\text{-Ca}^{2+}$ exchanger that prolong the action potential duration and the QT interval.

In contrast, subjects with LQT2 have dysfunctional I_{Kr} channels, which represent a smaller fraction of the K^+ channels responsible for phase 3 repolarization and are not as sympathetically responsive as I_{Ks} channels. Therefore, in LQT2 patients, the QT fails to shorten at the intermediate heart rates in the early phase of exercise or epinephrine infusion because of attenuation of I_{Kr} . This is followed by recruitment of I_{Ks} (“repolarization reserve”) at faster heart rates during continuing exercise or epinephrine infusion, with concomitant appropriate abbreviation of the action potential duration and QT shortening, which persists into the recovery phase. This consequently leads to an exaggerated QT difference between the exercise and recovery QT/R-R curves that is manifested as increased QT hysteresis, which appears to be a characteristic feature of the LQT2 phenotype.

The LQT3 phenotype is characterized by a constant reduction of the action potential duration with epinephrine because of stimulation of the intact I_{Ks} channel and augmentation of the late inward I_{Na} . In fact, LQT3 patients may have supernormal QT adaptation in response to exercise compared with control subjects. *SCN5A* mutations in LQT3 cause a gain of function through disruption of fast channel inactivation, allowing repeated reopening during sustained depolarization and resulting in a small but functionally important enhancement of the I_{Na} during action potential plateau. As a consequence, the risk of developing arrhythmia will be expected to be particularly high at slow heart rates, when the action potential duration is longer, allowing more Na^+ current to enter the cell.

The differences in the dynamic response of ventricular repolarization to sympathetic stimulation may explain the epidemiological observation that patients with LQT1 are more likely to have life-threatening events during sympathetic activation compared with patients with other genotypes and also may underlie the responsiveness of LQT1 patients to beta-blocker therapy.⁹

Mechanism of Genotype-Phenotype Variability

The LQTS is a complex and multifactorial disorder characterized by significant phenotypic heterogeneity. The clinical phenotype (QTc values, arrhythmia-related symptoms, and outcomes) is highly variable, with a broad continuous spectrum of clinical or subclinical phenotypes, not only between families carrying different pathogenic mutations, but also among family members carrying an identical mutation. One end of this spectrum is concealed LQTS (silent carriers of disease-causing mutations), whereby no QT prolongation or related symptoms are observed. At the other end of the spectrum are the severe symptomatic LQTS patients, who often represent the index cases easily identified in families. In between are patients with different degrees of QT prolongation and different levels of severity of arrhythmias.

A multitude of genetic and acquired interacting factors (some defined but many still unknown) influence the pathophysiology and clinical course of each LQTS subject and ultimately determine a spectrum of phenotypes. Among these factors is the fact that action potential generation is a polygenic process; different LQTS genes affect different ion current mechanisms. Even mutations in the same gene can affect gene expression levels and ionic current activity to different extents and via different mechanisms. As noted above, mutations located in the transmembrane segment (for LQT1) or pore region (for LQT2) of the ion channel generally result in more malignant disease compared with mutations in other locations. Similarly, mutations causing a dominant-negative effect (e.g., missense mutations involving the pore region of the channel) result in more profound channel dysfunction and more severe clinical disease than those associated with haplotype insufficiency (e.g., mutations causing coassembly or trafficking abnormalities).

The “repolarization reserve” concept can underlie, at least in part, the phenotypic heterogeneity in LQTS. Cardiac muscle repolarization has built-in redundancy, or reserve, such that perturbation of one ion current does not necessarily result in excessive repolarization changes because other currents can compensate. Hence, there exists an inherent variability of arrhythmic response to QT interval prolongation with the relationship between perturbations of one ion channel in relation to the sum total of repolarizing currents. This concept implies that often multiple “hits” to repolarization are required to compromise repolarization and surpass the threshold for developing clinical QT prolongation and torsades de pointes. In this setting, a mutation in one of the LQT-linked genes causing an attenuation of a cardiac ionic current may result in only a limited disruption of the repolarization process, which can be clinically concealed and become unmasked (manifesting as QT prolongation and arrhythmias) only when accompanied by another insult to the same or a different ionic current (e.g., drugs or electrolyte abnormalities). In fact, it has been suggested that some cases of acquired LQTS represent inadvertent “unmasking” of subclinical congenital LQTS.^{10,11}

Adding to the complexity is the “double-hit” phenomenon, secondary to either two mutations in the same gene (compound heterozygosity) or mutations in two different LQT genes (digenic heterozygosity). Double hits occur in 5% to 10% of LQTS patients and the resulting phenotype is more severe than with a single hit.

Genetic factors are also involved in the control of cardiac repolarization at the population level. The heritability of the QTc interval has been estimated as being between 25% and 52%. Ventricular action potential is under the joint control of multiple ionic currents, and the activity and expression levels of the channels underlying each of these currents establish a subtle equilibrium between depolarizing and repolarizing currents determining the action potential duration in each individual. Common genetic variants differing from the ancestor sequence by one nucleotide (i.e., single nucleotide polymorphism) in genes coding for proteins that are known or suggested to affect ion channel function appear to influence this equilibrium even via weak effects on activity and/or expression level of channel subunits and can potentially play a role in determining cardiac repolarization duration and QTc length in healthy individuals. Therefore apart from the known LQT-linked genetic mutations, allelic variation elsewhere in the genome, most often single nucleotide polymorphisms, in the same disease-causing gene or in other genes, can amplify otherwise subclinical disturbances of the repolarization into overt LQTS and potentially contribute to the variable penetrance and clinical phenotype heterogeneity.

Furthermore, the resultant intrinsic risk for arrhythmias can be modulated by a variety of intrinsic or extrinsic environmental factors, including age, gender, heart rate, sympathetic tone, electrolyte balance, presence of QT-prolonging drugs, as well as inherited and acquired pathological conditions such as LV hypertrophy, and heart failure.

In summary, the interaction of the underlying LQTS genetic mutation with other genetic factors in the same gene or elsewhere in the host genome (“modifier genes”), as well as with multiple superimposed acquired risk determinants (“disease modifiers”), has a substantial impact on the expressivity of the phenotype of the LQT genotype.¹²

Mechanism of Gender Effects

In the healthy population, QTc intervals are longer in women than in men, a difference that becomes apparent only after puberty. This is associated with a higher susceptibility to drug-induced LQTS and torsades de pointes; women account for 70% of cases of drug-induced QT prolongation and torsades de pointes. In healthy volunteers, drug-induced QT interval prolongation is greatest during the menses and ovulation phases and least during the luteal phase. Age-dependent

gender-related differences also exist among patients with congenital LQTS. Although the risk of cardiac events is higher in boys with LQTS as compared with girls during childhood and early adolescence, a gender risk reversal occurs after the onset of puberty. LQT1 and LQT2 women of childbearing age have longer QT intervals and higher risk for polymorphic VT and SCD than men. The extent of QT prolongation and the risk of cardiac events appear to be more pronounced during periods with high estradiol and low progesterone levels (e.g., during the follicular phase of the menstrual cycle) and mildly reduced during periods with higher progesterone/estradiol ratio (e.g., during the luteal phase of the menstrual cycle, and during pregnancy). The arrhythmogenic risk markedly increases immediately postpartum (especially among women with the LQT2 genotype), when serum progesterone concentrations abruptly decline.^{13–15}

The mechanisms underlying these gender-related differences are poorly understood. Environmental (increased physical activity), hormonal, and genetic factors (modifier genes not shared by boys and girls) have been proposed. Current evidence supports the role of sex hormones as a significant contributor to the action potential duration. Recent studies suggest that the duration of ventricular repolarization and QTc interval are influenced by complex interactions between sex steroid hormones and gonadotropins depending on gender, rather than on one single hormone. In general, testosterone in men and an increased progesterone/estradiol ratio in women shorten repolarization, whereas follicle-stimulating hormone prolongs repolarization in both genders.^{15,16}

The effect of sex hormones on the QT interval and arrhythmogenesis in LQTS can partly be explained by direct and indirect interaction with the ion channel. Experimental studies suggest that estrogen suppresses I_{Kr} and increases I_{CaL} , Na^+-Ca^{2+} exchanger activity, RyR2 leakiness, and α_1 - and β_2 -adrenoceptor responsiveness. Estradiol also enhances the sensitivity of I_{Kr} channels to their specific antagonist and predisposes to greater drug-induced QT prolongation. Conversely, testosterone enhances the outward currents (I_{Kr} , I_{Ks} , I_{K1}) and reduces the inward current (I_{CaL}). Progesterone, a testosterone precursor, enhances I_{Ks} and reduces I_{CaL} . Thus estradiol can potentially exert a proarrhythmic effect

in LQTS patients, whereas testosterone and progesterone shorten QT duration and exert an antiarrhythmic effect with a reduced susceptibility to sympathetic stimuli.^{14,15,17} In fact, a recent study demonstrated potential benefit of oral progesterone for the prevention of drug-induced QT interval prolongation.¹⁸

Epidemiology

There are no systematic studies on LQTS prevalence in the general population. A recent estimate of the prevalence of LQTS is 1:2000 live births, based on the results of genetic screening in families and the incidence of compound heterozygotes (i.e., persons with two mutations). However, the clinical disease is less common (approximately 1 in 5000) because most mutation carriers remain asymptomatic. The usual mode of inheritance is autosomal dominant, with the exception of the autosomal recessive Jervell and Lange-Nielsen type and triadin knockout syndrome (LQT17).

LQT1, LQT2, and LQT3 comprise more than 90% of all genotyped LQTS cases. LQT1 is the most frequent genetic form of LQTS, accounting for 40% to 55% of genotyped LQTS cases. LQT2 and LQT3 account for 30% to 45% and 5% to 10% of genotyped LQTS cases, respectively (Table 31.2). The remaining 14 types (LQT4 to LQT17) make up less than 5% of the genotype-identified LQTS. Although LQT3 is infrequent among adolescents and adults with LQTS, it constitutes the most common genetic form associated with LQTS-related perinatal and early-infancy mortality.

LQTS exhibits incomplete penetrance (i.e., not all carriers of the pathogenic mutation will develop a phenotypic expression) and variable expressivity (i.e., the level of phenotypic expression varies among affected patients).

Clinical Presentation and Natural Course

Romano-Ward Syndrome

Most information regarding the clinical features of LQTS have been derived from analysis of data from large series of LQTS patients, the largest of which is the International LQTS Registry. LQTS probands

TABLE 31.2 Common Types of the Long QT Syndrome

	LQT1	LQT2	LQT3
Pathophysiology			
Gene	<i>KCNQ1 (Kv LQT1)</i>	<i>KCNH2 (HERG)</i>	<i>SCN5A</i>
Protein	Kv7.1	Kv11.1	Na _v 1.5
Ionic current	Decreased I_{Ks}	Decreased I_{Kr}	Increased late I_{Na}
Clinical Presentation			
Incidence of cardiac events	63%	46%	18%
Incidence of SCD	4%	4%	4%
Arrhythmia triggers	Emotional/physical stress (swimming, diving)	Emotional stress, arousal (alarm clock, telephone), rest	Sleep/rest
Electrocardiogram	Broad-based T wave	Low-amplitude, bifid T wave	Long isoelectric ST segment
QT response to exercise	Attenuated QTc shortening and an exaggerated QTc prolongation during early and peak exercise	Normal QT during exercise but with exaggerated QT hysteresis	Supernormal QT shortening
Management			
Exercise restriction	+++	++	?
Response to beta-blockers	+++	+++	?
Potassium supplement	+	++	+
Left cervicothoracic sympathectomy	++	++	++
Response to mexiletine	+	+	++

I_{Kr} , Rapidly activating delayed rectifier K⁺ current; I_{Ks} , slowly activating delayed rectifier potassium current; I_{Na} , sodium current; QTc, corrected QT interval; SCD, sudden cardiac death.

are diagnosed at an average age of 21 years. The clinical course of patients with LQTS is variable, and is influenced by age, gender, genotype, environmental factors, therapy, and possibly other modifier genes. At least 37% of individuals with the LQT1 phenotype, 54% with the LQT2 phenotype, and 82% with the LQT3 phenotype remain asymptomatic and many are referred for evaluation because of the diagnosis of LQTS of a family member or the identification of a long QT interval on a surface ECG obtained for unrelated reasons.

Symptomatic patients can present with palpitations, presyncope, syncope, or cardiac arrest. Syncope is the most frequent symptom, occurring in 50% of symptomatic probands by the age of 12 years, and in 90% by the age of 40 years. The incidence of syncope in LQTS patients is approximately 5% per year, but can vary depending on the LQTS genotype. Syncope in patients with LQTS is generally attributed to polymorphic VT (torsades de pointes), but can also be precipitated by severe bradycardia in some patients with LQT3. Cardiac arrest and SCD are usually due to VF. Recurrent syncope can mimic primary seizure disorders.

The incidence of SCD is much lower, approximately 1.9% per year. Nonfatal events (syncope and aborted cardiac arrest) in LQTS patients remain the strongest predictors of subsequent LQTS-related fatal events. The overall risk of subsequent SCD in an LQTS patient who has experienced a previous episode of syncope is approximately 5% per year. Of individuals who die of complications of LQTS, SCD is the first sign of the disorder in an estimated 10% to 15%. The risk for SCD from birth to age 40 years has been reported as approximately 4% in each of the phenotypes.

Risk and lethality of cardiac events among untreated individuals are strongly influenced by the genotype. The frequency of cardiac events is significantly higher among LQT1 (63%) and LQT2 (46%) patients than among patients with the LQT3 genotype (18%). However, the likelihood of dying during a cardiac event is significantly higher among LQT3 patients (20%) than among those with the LQT1 (4%) or the LQT2 (4%) genotype. Overall, LQT3 is to be considered a severe LQTS variant; the first cardiac event is more likely to be lethal and seems to occur later in childhood, during or after puberty.¹⁹

Cardiac events (syncope, cardiac arrest, SCD) in LQTS patients do not occur at random; the factors precipitating cardiac events seem to

be specific for each genetic variant. LQT1 patients present an increased risk during physical or emotional stress (90%), and only 3% of the arrhythmic episodes occur during rest or sleep. Swimming and diving appear as highly specific triggers in LQT1 patients. LQT2 patients are at higher risk for lethal events during arousal (44%), but are also at risk during sleep and at rest (43%). Only 13% of cardiac events occur during exercise. Cardiac events in LQT2 patients are characteristically associated with arousal and auditory stimulation. In fact, the triggering of events by startling, sudden awakening, or sudden loud noises (such as a telephone or alarm clock ring) is virtually diagnostic of LQT2. Notably, individual factors such as gender, location and type of mutation, and QTc prolongation appear to be associated with trigger-specific events; female adolescents with LQT2 appear to experience a greater than ninefold increase in the risk for arousal-triggered cardiac events compared with male adolescents in the same age group. In contrast, gender does not seem to be a significant risk factor for exercise-triggered events among carriers of the same genotype (Fig. 31.3).

On the other hand, LQT3 patients experience cardiac events largely while asleep or at rest (65%) without emotional arousal, and only occasionally during exercise (4%). Notably, the majority of patients continue to experience their cardiac events under conditions similar to their first classified event.²⁰

The effect of gender on outcome is age dependent, with boys being at higher risk than girls during childhood and early adolescence, but no significant difference in gender-related risk being observed between 13 and 20 years. The gender-related risk reverses afterward, and female patients maintain higher risk than male patients throughout adulthood.

The genotype can potentially affect the clinical course of the LQTS and modulate the effects of age and gender on clinical manifestations. Although the three major LQTS genotypes (LQT1, LQT2, or LQT3) are associated with similar risks for life-threatening cardiac events in children and adolescents after adjustment for clinical risk factors (including gender, QTc duration, and time-dependent syncope), the risk for cardiac events is augmented in LQT2 women aged 21 to 40 years and in LQT3 patients greater than 40 years of age. The risk of syncope and SCD decreases during pregnancy but increases in the postpartum period, especially among LQT2 women.

Fig. 31.3 Trigger-Specific Risk Factors and Response to Therapy in Long QT Syndrome Type 2 (LQT2). Trigger-specific risk factors and response to therapy in long QT syndrome type 2. *Heart Rhythm*. 2010;7:1797–1805.)

Jervell and Lange-Nielsen Syndrome

The Jervell and Lange-Nielsen syndrome is the recessive variant of the LQTS, characterized by congenital deafness and cardiac phenotype (QT prolongation, ventricular arrhythmias, and SCD). The Jervell and Lange-Nielsen syndrome is caused by two homozygous or compound heterozygous mutations of one of the two genes (*KCNQ1* and *KCNE1*) that encode components of the I_{Ks} channel.

Patients with Jervell and Lange-Nielsen syndrome have a more severe cardiac phenotype than those with Romano-Ward syndrome. Patients begin to experience cardiac events very early in life; 15% suffer a cardiac event during the first year of life, 50% by age 3 years, and 90% by age 18 years. In untreated patients, approximately 50% die of ventricular arrhythmias by the age of 15 years. Furthermore, SCD occurs in more than 25% of patients despite medical therapy. In addition, complete loss of I_{Ks} in hair cells and endolymph of the inner ear results in congenital bilateral sensorineural deafness.

The conditions that trigger the cardiac events are, overall, very similar to those described for LQT1. Up to 95% of events occur during sympathetic activation (exercise and emotions), and only 5% of the events occur at rest or during sleep.

Andersen-Tawil Syndrome

Andersen-Tawil syndrome (LQT7) is a rare autosomal dominant disorder caused by mutations of the gene *KCNJ2*, which encodes the inward rectifier potassium channel, Kir2.1. This syndrome is characterized by a triad of a cardiac phenotype, a skeletal muscle phenotype (periodic paralysis caused by abnormal muscle relaxation), and distinctive craniofacial and skeletal dysmorphic features (low-set ears, ocular hypertelorism, small mandible, fifth-digit clinodactyly, syndactyly, short stature, scoliosis, and a broad forehead).

Although Andersen-Tawil syndrome is classified as LQTS (LQT7), QT prolongation is more related to a prominent U wave (i.e., prolonged “QTUc interval”) rather than a QTc prolongation. Further, unlike other types of LQTS, cardiac arrhythmias in Andersen-Tawil syndrome are characterized by high burden of asymptomatic PVCs, ventricular bigeminy, or nonsustained VT, with a predominantly benign course and very rare degeneration into hemodynamically compromising rhythms like torsades de pointes. In addition, a specific type of polymorphic VT, bidirectional VT, is observed in Andersen-Tawil syndrome, similar to that observed in CPVT patients. Beta-blockers, Ca^{2+} channel blockers, and flecainide have been utilized for suppression of ventricular arrhythmias in these patients, but the efficacy of these drugs is yet to be proven.²¹

Patients with Andersen-Tawil syndrome present initially with periodic paralysis or cardiac symptoms (palpitations, syncope, or both) in the first or second decade of life. Intermittent weakness occurs spontaneously, or can be triggered by prolonged rest or rest following exertion; however, the frequency, duration, and severity of symptoms are variable between and within affected individuals, and are often linked to fluctuations in plasma K^+ levels. Mild permanent weakness is common.

There is a high degree of variability in penetrance and phenotypic expression. Approximately 60% of affected individuals manifest the complete triad and up to 80% express two of the three cardinal features.

Timothy Syndrome

Timothy syndrome (LQT8) is an extremely rare multisystem disorder caused by mutations of the *CACNA1C* gene, which encodes the L-type Ca^{2+} channel ($Ca_v1.2$), and is characterized by syndactyly, QT prolongation, congenital heart disease, cognitive and behavioral problems, musculoskeletal diseases, immune dysfunction, and more sporadically, autism.

Timothy syndrome is a severe form of LQTS, characterized by a remarkable prolongation of the QTc interval (QTc often exceeding 550 to 600 milliseconds), functional 2:1 AV block (observed in up to 85% of patients, and likely caused by the extremely prolonged ventricular repolarization and refractory periods), and macroscopic T wave alternans (positive and negative T waves alternating on a beat-to-beat basis). In addition, congenital heart defects are observed in approximately 60% of patients and include patent ductus arteriosus, patent foramen ovale, ventricular septal defect, tetralogy of Fallot, and hypertrophic cardiomyopathy. Timothy syndrome is highly malignant; the majority of patients seldom survive beyond 3 years of age. Polymorphic VT and VF occur in 80% of patients (commonly triggered by an increase in sympathetic tone) and are the leading cause of death, followed by infection and complications of intractable hypoglycemia.³

Extracardiac features include cutaneous syndactyly (variably involving the fingers and toes), which is observed in almost all patients. Facial findings (observed in approximately 85% of individuals) include low-set ears, flat nasal bridge, thin upper lip, small upper jaw, small, misplaced teeth, and round face. Neuropsychiatric involvement occurs in approximately 80% of individuals and includes global developmental delays and autism spectrum disorders.

In general, the diagnosis of Timothy syndrome is made within the first few days of life based on the markedly prolonged QT interval and 2:1 AV block. Occasionally, the diagnosis is suspected prenatally because of fetal distress secondary to AV block or bradycardia.

Although LQT8 (Timothy syndrome) is associated with gain-of-function in I_{CaL} , reduction of I_{CaL} influx by Ca^{2+} channel blockade (such as verapamil) failed to shorten QTc or prevent ventricular arrhythmias. A recent report suggested a potential antiarrhythmic benefit of ranolazine (an antianginal agent with inhibitory effects on multiple ion channels) in patients with Timothy syndrome.

Electrocardiographic Features

Abnormal prolongation of the QT interval on the surface ECG, reflecting delayed ventricular repolarization, is the hallmark of LQTS. In addition, T wave abnormalities are encountered in the majority of patients.

QT Interval Measurement

The QT interval is the body surface representation of the duration of ventricular depolarization and subsequent repolarization. Any deviation or dispersion of depolarization (e.g., bundle branch block) or repolarization (e.g., prolongation or dispersion of the action potential duration) results in prolongation of the QT interval.

An accurate measurement of the QT interval is important for the diagnosis of LQTS. A 12-lead ECG tracing at a paper speed of 25 mm/s at 10 mm/mV is usually adequate to make accurate measurements of the QT interval. The QT interval is measured as the interval from the onset of the QRS complex, that is, the earliest indication of ventricular depolarization, to the end of the T wave, that is, the latest indication of ventricular repolarization. The QT interval is measured in all ECG leads where the end of the T wave can be clearly defined (preferably leads II and V_5 or V_6), with the longest value being used. The end of the T wave is the point at which the descending limb of the T wave intersects the isoelectric line. Three to five consecutive cardiac cycles are taken to derive average values for R-R, QRS, and QT intervals.²²

When the end of the T wave is indistinct, or if a U wave is superimposed or inseparable from the T wave, it is recommended that the QT be measured in the leads not showing U waves (often leads aVR and aVL) or that the downslope of the T wave be extended by drawing a tangent to the steepest proportion of the downward limb of the T wave until it crosses the baseline (i.e., the T-P segment) (Fig. 31.4).

Fig. 31.4 Schematic illustration of the use of the tangent method to define the end of the T wave in normal and abnormal TU-wave morphologies. CPVT, Catecholaminergic polymorphic ventricular tachycardia; IVF, idiopathic ventricular fibrillation. (From Postema PG, Wilde AAM. The measurement of the QT interval. *Curr Cardiol Rev.* 2014;10:287–294.)

However, it should be recognized that defining the end of the T wave in these ways can potentially underestimate the QT interval. Some investigators advocate measurement of both the QT interval and the QTU interval (with the latter measurement taken to the end of the U wave as it intersects the isoelectric line) because the QTU interval probably reflects the total duration of ventricular depolarization.

The highest diagnostic and prognostic value in LQTS families has been observed for QTc in leads II and V₅ of the 12-lead ECG. Thus QTc should be obtained in one of these leads if measured in only a single ECG lead. However, other leads were found to offer similar diagnostic (aVR) or prognostic (V₂/V₃) value alone, and, in general, the lead with the longest QT interval is used for measurement.

The QT interval should ideally be measured at a heart rate closest to 60 beats/min and definitely less than 100 beats/min. The use of beta-blockers or long-term ECG monitoring need to be considered to obtain optimal measurements.

QT Interval Correction for Gender

The QT interval shortens after puberty in males but not in females, resulting in a longer QT in women than in men. The reported gender difference in various studies varies from 6 to 10 milliseconds in older age groups and from 12 to 15 milliseconds in younger adults. Overall, the gender difference in the QTc interval becomes small after 40 years of age and practically disappears in older men and women. Separate gender- and age-specific QT adjustment formulas have been proposed to accommodate these differences.

TABLE 31.3 Formulas for Heart Rate Correction of the QT Interval	
Bazett	QTcB = QT/(R-R interval) ^{1/2} (all intervals in seconds)
Framingham-Sagie	QTcFa = QT + 154(1 – 60/HR)
Fridericia	QTcFi = QT/(R-R interval) ^{1/3}
Hodges	QTcH = QT + 1.75(HR – 60)
Nomogram-Karjalainen	QTcN = QT + nomogram correction factor
Rautaharju	QTcRa = QT – 155 × (60/HR – 1) – 0.93 × (QRS – 139) + k (k = –22 msec for men, and –34 msec for women)

HR, Heart rate.

QT Interval Correction for Heart Rate

Because the heart rate (R-R cycle length) is the primary modifier of ventricular action potential, QT interval measurements must be corrected (QTc) for the baseline R-R interval to allow for comparisons. Various correction formulas have been developed (Table 31.3), the most widely used being the formula derived by Bazett in 1920 from a graphic plot of measured QT intervals in 39 young subjects. The Bazett correction, however, performs less well at high and low heart rates (under-corrects at fast heart rates and overcorrects at slow heart rates).

In addition to the Bazett formula, many other correction formulas, such as the Framingham-Sagie, Fridericia, Hodges, and Nomogram-Karjalainen formulas, have been proposed. In a study comparing the accuracy of those five different QT correction formulas for determining drug-induced QT interval prolongation, the Bazett correction formula provided the most marked QTc variations at heart rates distant from 60 beats/min. The Fridericia formula was found to overestimate QTc at faster heart rates, being more reliable at slower heart rates. Conversely, the Hodges, Nomogram, and Framingham formulas demonstrated less QTc variability over the whole range of the investigated heart rates and seemed to be similarly satisfactory at heart rates of up to 100 beats/min. Among them, the Hodges method, followed by the Nomogram-Karjalainen method, appeared to be the most accurate in determining the correct QTc and subsequently in guiding clinical decisions.²²

Nonetheless, the Bazett formula remains the one most commonly used to measure the QT interval for the diagnosis of LQTS. However, when a prolonged QTc is observed during faster heart rates (greater than 90 beats/min), it is important to repeat the ECG once the heart rate slows down, to minimize the error that can potentially be introduced by heart rate correction formulas.

Importantly, there exists a substantial interindividual variability of the relationship between QT duration and heart rate (the QT/R-R relationship). In contrast, a high intraindividual stability of the QT/R-R pattern has been demonstrated, suggesting that a genetic component might partly determine individual QT length. Therefore population-based and averaged QT correction cannot accurately predict a normal QT interval at a given R-R interval in a *given* patient. Individual-specific QT/R-R hysteresis correction in combination with individualized heart rate correction can potentially reduce intraindividual QTc variability.

QT Interval Correction to QRS Duration

The QT interval prolongs in ventricular conduction defects, mainly due to a delay in depolarization (i.e., prolongation of the QRS duration) and not in repolarization. Most QT correction formulae do not take bundle branch block into consideration. Only a few formulae (such as the Rautaharju formula, the Bogossian formula, and the JT index) are designed to include bundle branch blocks in their calculations, but none of them have been widely adopted in clinical practice.

A widely used approach is to apply the Bazett formula to the uncorrected QT interval and accept a longer QTc as the upper limit of acceptable (550 milliseconds rather than 500 milliseconds). Another method to adjust the QT measurement after the development of a bundle branch block is to subtract the difference in QRS widths before and after the block (when such information is available). A third method is to measure the JT interval from the end of the QRS complex to the end of the T wave. Unlike the QTc interval which describes both cardiac depolarization and repolarization, the JTc interval is independent of the QRS duration and thus represents only repolarization ($JTc = QTc - QRS$). If the JT interval is chosen, normal standards established specifically for the JT interval should be used. QT and JT adjustment formulas have recently been introduced for use in the setting of prolonged ventricular conduction. With confirmation, they may be incorporated into automated algorithms to provide appropriate correction factors.^{23,24} However, because of delay in depolarization in left bundle branch block (LBBB), repolarization begins before the end of the QRS complex (i.e., before the J point); hence, the JT interval likely underestimates the duration of repolarization, particularly when QRS duration was very prolonged (greater than 175 milliseconds).²⁵

A recent study in a series of patients with intermittent LBBB found that the net increase in QRS duration contributes to 92% of the extra time in measured QT in LBBB, and a new formula (the Wang formula) was developed to calculate the true QT: True QT interval = measured

QT in LBBB – $(0.86 * QRS \text{ in LBBB} - 71)$. The QT so derived can then be corrected using the Bazett or other standard formulation.²⁵

QT Interval Measurement During Right Ventricular Pacing

Reliable estimation of the QT interval in ventricular paced rhythm is challenging. It has been demonstrated that the Rautaharju formula (see Table 31.3) yields QTc values during ventricular pacing that are closest with the non-paced QTc interval values; however, this formula is complex to apply and exhibits significant interaction with heart rate changes.

The Framingham and Nomogram correction methods were found to offer the most optimal balance for assessing the QTc interval, including minimal interaction between pacing mode and heart rate. The use of the Bazett formula significantly exaggerates the QTc rate dependency during ventricular pacing and, therefore, is less reliable.²⁶

A recent study suggested the use of the Framingham and Nomogram methods to calculate the corresponding nonpaced intrinsic QTc interval from the measured ventricular paced QTc interval (regardless of heart rate) by subtracting 43 milliseconds in normal-QTc patients, and 37 milliseconds (for the Framingham method) or 36 milliseconds (for the Nomogram method), in prolonged-QT patients.²⁶

Another study found that RV pacing causes prolongation of the QT due to a paced LBBB without prolongation of the JT interval, and that QT prolongation caused by ventricular pacing constitutes about 50% of the QRS width. The Bogossian formula subtracts this value from the measured ventricular paced QT interval ($QT \text{ in LBBB} = \text{measured QT interval} - 50\% * QRS \text{ duration}$).²³ Although this formula can provide a simple method for estimating the nonpaced intrinsic QT interval, it tends to overcorrect the QT interval, that is, making the QT shorter than it should be.

The paced JTc interval was found to more accurately represent ventricular repolarization (as compared to the paced QTc interval) and mirror repolarization changes observed during nonpaced rhythm. However, as noted previously, the sensitivity of the JT interval in identifying patients with delayed ventricular repolarization decreases with increasing QRS duration, and that can artificially shorten the calculated QT interval. Therefore the JT interval appears ineffective in predicting delayed repolarization in patients with a very wide QRS.^{24,25}

QT Interval Prolongation

The diagnosis of QT interval prolongation can be challenging because of the difficulty in defining the “end” of the T wave and the need for correction for heart rate, age, and gender. This is further complicated by the lack of linear behavior of the Bazett formula at slower and faster heart rates as well as the arbitrary definition of the gender-based diagnostic cutoff values that define an abnormally prolonged QTc (QTc of 450 milliseconds for men and QTc of 460 milliseconds for women; Table 31.4).

TABLE 31.4 Suggested Bazett-Corrected QT Interval Values for Diagnosis of QT Prolongation

Rating	1–15 Years	Adult Man	Adult Woman
Normal	<440	<430	<450
Borderline	440–460	430–450	450–470
Prolonged	>460	>450	>470

Values given in milliseconds.

From Goldenberg I, Moss AJ. Long QT syndrome. *J Am Coll Cardiol*. 2008;51:2291–2300.

Fig. 31.5 Electrocardiogram Recordings From Leads II, V₃, and V₅ in Three Patients From Families With Long QT Syndrome (LQTS). The typical morphology of LQT3 with straight ST segment and small T wave is shown in the right panel. (From Ruan Y, Liu N, Bai R, Priori SG, Napolitano C. Congenital long QT syndrome type 3. *Card Electrophysiol Clin*. 2014;6:705–713.)

Furthermore, no single QTc value separates all LQTS patients from healthy controls. In fact, LQTS cannot be excluded merely by the presence of a normal QTc interval. The QT interval is subject to large variations even in healthy individuals, and substantial overlap exists with QTc values obtained from LQTS mutation carriers in the range between 410 and 470 milliseconds. In up to 40% of LQTS patients, QTc intervals fall in the normal range. On the other hand, QTc values greater than 470 milliseconds in men and greater than 480 milliseconds in women are practically not observed among healthy individuals (especially when their heart rate is 60 to 70 beats/min). Therefore unless excessive QTc prolongation (greater than 500 milliseconds, corresponding to the upper quartile among affected genotyped individuals) is present, the QTc interval should always be evaluated in conjunction with the other diagnostic criteria.

Of note, a considerable variability in QTc interval duration can be observed in patients with LQTS when serial ECGs are recorded during follow-up. This time-dependent change in QTc duration is an important determinant of the phenotypic expression of the disease. Up to 40% of patients with LQTS will have QTc greater than 500 milliseconds at least once during long-term follow-up, but only 25% will have that degree of QT prolongation during their initial evaluation. The maximal QTc duration measured at any time before age 10 years was shown to be the most powerful predictor of cardiac events during adolescence, regardless of baseline, mean, or most recent QTc values. In addition, the QT interval may normally exhibit individual variations during the day. Therefore in the case of borderline QTc prolongation, serial ECG and 24-hour Holter recordings can potentially assist in establishing QT prolongation.

T Wave Morphology

ST-T wave abnormalities are common among LQTS patients, and some of the ST-T changes are characteristic for a certain genotype. Specifically, “broad,” “notched,” and “late” T waves are associated with LQT1,

LQT2, and LQT3, respectively, although these features are often subtle and inconsistently observed (Fig. 31.5).²⁷

Patients with LQT1 commonly exhibit a smooth, broad-based T wave that is present in most leads, and particularly evident in the precordial leads. The T wave generally has a normal to relatively high amplitude and often no distinct onset. LQT2 patients generally present with low-amplitude T waves, which are notched or bifid in approximately 60% of carriers. The bifid T wave can be confused with a T-U complex; however, unlike the U waves, the bifid T waves are usually present in most of the 12 ECG leads. LQT3 patients often show late-onset, narrow, peaked, and/or biphasic T waves with a prolonged isoelectric ST segment. Occasionally, the T wave is peaked and asymmetrical with a steep downslope. These ST-T wave patterns can be seen in 88% of LQT1 and LQT2 carriers and in 65% of LQT3 carriers.

No specific T wave pattern has been suggested in the LQT5 and LQT6 syndromes. T-U wave abnormalities such as biphasic T waves following long pauses like those found in the LQT2 syndrome are commonly observed in the LQT4 syndrome. Enlarged U waves separated from the T wave are reported to be characteristic ECG features in the LQT7 syndrome. Severe QT interval prolongation and macroscopic T wave alternans can be observed in LQT8.

Despite the initial enthusiasm in achieving a genotype-phenotype correlation for specific LQT-associated genes, this approach failed to provide a high diagnostic yield because of the frequent exceptions in T wave morphology presentation. Furthermore, the T wave pattern can vary with time, even in the same patient with a specific mutation. Therefore other T wave parameters, such as duration, amplitude, asymmetry, and flatness, as well as the interval from the peak of the T wave to the end of the T wave (Tp-e), have been used as highly specific quantitative descriptors (see later).

Of note, quantitative analysis of T wave morphology in lead V₆ was found in a recent report to be capable of distinguishing patients with genetically proven LQTS from matched controls and even permits

identification of over 80% of patients with LQTS, despite having a normal resting QTc. The potential implications of this tool for universal screening for LQTS warrant further investigation.²⁸

Torsades de Pointes

Torsades de pointes is a polymorphic VT occurring in the setting of QT interval prolongation (acquired or congenital LQTS) and is characterized by a progressive change of the electrical axis, typically rotating 180 degrees in approximately 10 to 12 cycles. This results in the characteristic sinusoidal twisting of the peaks of the QRS complexes around the isoelectric line of the recording; hence, the name *torsades de pointes* or “twisting of the points.” However, this characteristic pattern may not be evident in all ECG leads. Also, during a very fast VT, periodic decrease in the amplitude of the entire QRS-T complex can be observed with less distinct shifts in the QRS axis. Occasionally, a polymorphic QRS configuration is observed without displaying those characteristics. Of note, different patterns can be seen in different VT episodes from the same patient.²⁹

The VT is frequently preceded by a variable period of bigeminal rhythm caused by one or two PVCs coupled to the prolonged QT interval of the preceding basic beat. The tachycardia rate is typically in the range of 150 to 300 beats/min. In many cases, torsades de pointes is a self-limiting arrhythmia that spontaneously dies out after a few tens of cycles; however, most patients experience multiple episodes of the VT occurring in rapid succession. Only in a minority of cases does torsades de pointes degenerate into VF, which almost without exception leads to SCD if immediate rescue intervention, including defibrillation, is not performed.

Dispersion of Repolarization

Prolongation of the action potential duration (and QT interval) per se is not pathogenic, as evidenced by the fact that a homogeneous action potential duration prolongation (such as occurs following amiodarone therapy) fails to generate reentry. As demonstrated in experimental models of the LQTS, prolonged repolarization, transmural dispersion of repolarization, and EADs are the three electrophysiological (EP) components linked to the genesis of torsades de pointes. Transmural dispersion of repolarization arises from repolarization heterogeneity that exists between the epicardial and putative midmyocardial (M) cells that lie toward the endocardium of the LV wall. These midmyocardial cells are especially sensitive to a repolarization challenge and exhibit significant prolongation of the action potential duration compared with other transmural cell types. Several ECG indices have been proposed in recent years as noninvasive surrogates for transmural dispersion of repolarization, including the T wave peak to T wave end (Tp-e) interval, QT interval dispersion, and ratio of the amplitudes of the U and T waves.

Tp-e interval. Although controversy exists, some experimental models suggest that the peak of the T wave coincides with the end of epicardial repolarization (the shortest action potentials), whereas the end of the T wave coincides with the end of repolarization of the M cells (the longest action potentials). Hence, the Tp-e interval in each surface ECG lead has been proposed as an index of transmural repolarization. However, subsequent investigations using intact hearts have challenged this concept and suggested that, in vivo, the Tp-e interval is a measure of “global” dispersion of repolarization of the whole ventricle rather than “transmural” dispersion.

Because increased dispersion of repolarization promotes reentry and enhances arrhythmogenesis, prolongation of the Tp-e interval has been proposed as a more sensitive predictor of risk for arrhythmic events than the QT interval; the latter represents the total duration of electrical ventricular activation and not necessarily the dispersion of

transmural repolarization. In fact, a prolonged Tp-e interval has been shown to be a marker of increased arrhythmogenic risk in patients with Brugada syndrome, hypertrophic cardiomyopathy, and structural heart disease, as well as in certain populations.

Although changes in the Tp-e interval can potentially show the dynamicity of the dispersion of repolarization in clinical settings in LQTS patients, the role of measuring the Tp-e interval in these patients has yet to be clearly defined. In fact, the normal value of the Tp-e interval on the ECG has not been established. Nonetheless, an interval of more than 100 milliseconds is uncommon in normal subjects compared with that in patients with LQTS (9% vs. 55%).

On ambulatory monitoring, LQT2 exhibits a larger-degree of dispersion of repolarization, as measured by the Tp-e interval, compared with LQT1 and normal hearts. In fact, the Tp-e interval has been proposed as a diagnostic criterion in differentiation between LQT2 and LQT1 patients. Also, LQT1 patients exhibit abrupt increases in Tp-e intervals at elevated heart rates, whereas LQT2 patients exhibit increases in dispersion of repolarization at a much wider range of rates. In addition, beta-adrenergic stimulation (exercise or epinephrine infusion) increases dispersion of repolarization in both LQTS models, transiently in LQT2 and persistently in LQT1.

QT interval dispersion. An alternate approach to determine repolarization heterogeneity is provided by the dispersion of the QT interval. The QT dispersion index is obtained by the difference between the maximal and minimal QT intervals (QT_{max} – QT_{min}) measured on a 12-lead ECG. The QT dispersion index reflects the spatial heterogeneity of myocardial refractoriness more accurately than single QT values. Visualization of the differences in QT interval in the different ECG leads can be facilitated by the display of temporally aligned simultaneous ECG leads with a slight separation on the amplitude scale.

Importantly, QT interval dispersion measurements are subject to similar shortcomings encountered with the QT interval assessment, as a large overlap between affected and healthy individuals is observed. Further, accurate measurement on the scalar ECG at a paper speed of 25 mm/s is difficult. The same caveat applies to measuring the Tp-e interval.

U wave-to-T wave amplitude ratio. The ratio of the amplitudes of the U and T waves has been suggested as the clinical counterpart of EADs, and a progressive increase in this ratio was found to precede the onset of torsades de pointes in an experimental model of LQTS. In addition, the increment in U wave amplitude after a PVC has been suggested as a marker for arrhythmia risk in “pause-dependent” LQTS.

In patients with bifid T waves, some investigators used the late component of the T wave, rather than the U wave. The diurnal maximal ratio between late and early T wave peak amplitude was found to correlate with a history of LQTS-related symptoms better than the baseline QTc interval in both LQT1 and LQT2 patients, and the diurnal distributions of maximal T2-to-T1 wave amplitude ratios were similar to those of cardiac events.

Diagnosis of the Long QT Syndrome

According to the most recent consensus statement, LQTS can be diagnosed in individuals testing positive for an unequivocally pathogenic mutation in one of the LQTS genes. In the absence of a pathogenic mutation, and in the absence of a secondary cause for QT prolongation, the diagnosis of LQTS requires the presence of one of the following: (1) QTc interval of at least 500 milliseconds (using the Bazett formula) on repeated 12-lead ECGs; (2) QTc interval between 480 and 499 milliseconds on repeated 12-lead ECGs in conjunction with unexplained syncope; or (3) Schwartz score of at least 3.5 points (see later).

In addition, LQTS can be suspected in individuals with QTc values exceeding 450 milliseconds for men and exceeding 460 milliseconds

for women; the probability for LQTS increases if these subjects also have a history of syncope and familial SCD. On the other hand, LQTS is very unlikely among men with QTc less than 390 milliseconds and among women with QTc less than 400 milliseconds.

It is important to note that the LQTS is largely a clinical diagnosis, primarily based on the clinical presentation, personal and family history, and ECG findings. A detailed family history of syncope and SCD is essential, not only in first-degree relatives (mother, father, siblings, children), but also in more distant relatives. Also, the family history should also be investigated for other potential manifestations of malignant arrhythmias that might not have been classified as cardiac in origin, such as drowning, death while driving, epileptic seizures, and SIDS. Data on comorbidities in evaluated individuals or family members (such as congenital deafness) should also be acquired. Clinical features such as triggers of syncope and specific QT morphological attributes in patients in whom the clinical diagnosis has been made can suggest the affected gene in 70% to 90% of patients.

Importantly, a significant proportion (20% to 40%) of patients with genetically proven LQTS have normal or borderline QTc measurements at rest ("concealed" LQTS). It has been reported that these silent mutation carriers account for 36% of LQT1 patients, 19% of LQT2 patients, and 10% of LQT3 patients. Therefore the diagnosis of LQTS should not be excluded based solely on a QTc interval in the normal range (400 to 450 milliseconds), and additional testing is indicated whenever the clinical history requires exclusion of LQTS. In this setting, obtaining a resting ECG periodically and ambulatory ECG monitoring can sometimes uncover abnormal prolongation of the QTc interval, given the considerable day-to-day variability in QTc of patients with LQTS. In addition, reviewing the ECGs of all family members can be valuable because some family members can have obvious QT prolongation. The probability of LQTS in an index subject can be augmented if one of those family members has QTc prolongation.

Several provocative tests have been used to unmask LQTS patients with normal QTc on resting ECG. These include QT measurement upon abrupt standing, in the recovery phase of exercise testing, or during infusion of epinephrine. Also, genetic testing is recommended in patients with a strong clinical index of suspicion for LQTS. Although these diagnostic tools can all contribute to identifying patients with LQTS, a gold standard diagnostic tool is still lacking. Invasive EP testing is generally not useful in the diagnosis of LQTS.¹

Clinical Scoring Systems

When the diagnosis of LQTS is suspected but uncertain, a clinical scoring system (Schwartz score) has been developed to enhance the diagnostic reliability of clinical parameters and to estimate the probability of LQTS. The most recent (2011) update of the Schwartz score incorporates ECG features in combination with personal clinical history and family history. Scores were arbitrarily divided into three probability categories, providing a quantitative estimate of the risk for LQTS (Table 31.5). A score of 3.5 or higher makes the diagnosis of LQTS very likely and should compel further investigation, including genetic testing when available. Among patients with suspected LQTS (based on QTc interval prolongation or clinical history), "high probability" of LQTS (score greater than or equal to 3.5) using the Schwartz criteria identified LQTS mutation carriers with a sensitivity of 89% and a specificity of 82%. Further testing is required in the group with "intermediate probability" of LQTS to confirm or exclude the diagnosis, including serial ECGs, Holter recordings, and provocative testing.^{30,31}

Ambulatory Cardiac Monitoring

Holter monitoring is not sufficiently well standardized to serve in the primary assessment for ventricular repolarization analysis, and only

TABLE 31.5 Diagnostic Criteria for the Long QT Syndrome

			Points
Electrocardiographic Findings^a			
A	QTc ^b	≥480 msec	3
		460–479 msec	2
		450–459 (male) msec	1
B	QTc ^b fourth minute of recovery from exercise stress test	≥480 msec	1
C	Torsade de pointes ^c		2
D	T wave alternans		1
E	Notched T wave in three leads		1
F	Low heart rate for age ^d		0.5
Clinical History			
A	Syncope ^e	With stress	2
		Without stress	1
B	Congenital deafness		0.5
Family History			
A	Family members with definite LQTS ^e		1
B	Unexplained sudden cardiac death younger than age 30 among immediate family members ^e		0.5

Score: ≤1 point: low probability of LQTS. 1.5–3 points: intermediate probability of LQTS. ≥3.5 points high probability.

^aIn the absence of medications or disorders known to affect these electrocardiographic features.

^bQTc calculated by the Bazett formula where QTc = QT/√RR.

^cMutually exclusive.

^dResting heart rate below the second percentile for age.

^eThe same family member cannot be counted in A and B. (From Di Fusco SA, Palazzo S, Colivicchi F, Santini M. The influence of gender on heart rhythm disease. *Pacing Clin Electrophysiol.* 2014;37:650–657.)

From Schwartz PJ, Crotti L. QTc behavior during exercise and genetic testing for the long-QT syndrome. *Circulation.* 2011;124:2181–2184.

rarely will show spontaneous arrhythmias in LQTS patients. However, this method can sometimes be used for the detection of extreme QT interval events that occur infrequently during the day. An important value of Holter recordings lies in showing T wave changes characteristic of LQTS, which can become evident especially during sleep or following post-extrasystolic pauses.³²

A recent study described a novel computer algorithm that measures QTc in a beat-to-beat manner during 24-hour Holter monitoring. The QTc measurements for a population or for an individual patient are displayed on a plot ("QTc clock" plot) to illustrate QT dynamics and characterize the extent and duration of QT prolongation. Using this technology, unique patterns of QT prolongation were observed in patients with LQT1 and LQT2. LQT1 patients were more likely to have diagnostic QTc prolongation during the daytime hours than during the night, likely correlating with the level of sympathetic activity (eFig. 31.3). Conversely, LQT2 patients showed more QT prolongation during the night. Whether these observations can be used to distinguish between the different LQTS genotypes or to predict arrhythmogenic risk requires further investigation.³³

QT Interval Response to Abrupt Standing

The brief tachycardia associated with abrupt standing can potentially uncover patients with insufficient QT adaptation abilities and poor

eFig. 31.3 QTc Clock. QTc clock plots for long QT syndrome type 1 (*LQ1*) males and females (top left and right panels, respectively), *LQ2* males and females (middle left and right panels, respectively), and *LQ3* males and females cohorts (bottom left and right panels, respectively). Each area is defined by the middle 68th percentile of QTc values, that is, same percentage as ± 1 SD, measured across all Holter recordings, for each 1-minute slice. The dark green area represents the expected range of QTc variations in our healthy cohort. The figure highlights the changes in QT prolongation in *LQ2* and *LQ3* cohorts during the night. This phenomenon is expressed as graph asymmetry in which the area corresponding to *LQ2*/*LQ3* cohort stretches away from the normal value during the night (22:00–08:00). Arrows indicate median QTc between two periods of the day: 3:00–4:00 a.m. and 3:00–4:00 p.m. Note that the *LQ3* ranges are computed from only six female and eight male patients. (From Page A, Aktas MK, Soyata T, Zareba W, Couderc J-P. “QT clock” to improve detection of QT prolongation in long QT syndrome patients. *Heart Rhythm*. 2016;13:190–198.)

repolarization reserve, which characterize LQTS. Initially, an ECG is obtained in the supine position; then, the patient is asked to stand up briskly and a second ECG is obtained.

In one report, postural-induced QTc prolongation was more than 30 milliseconds in 68% of patients with “concealed” LQTS. Also, a QTc cutoff value of 490 milliseconds yielded a sensitivity of 89% and a specificity of 87% for the diagnosis of LQTS in patients with no excessive prolongation of the supine QT intervals (i.e., less than 480 milliseconds for females, less than 470 milliseconds for males).²² Postural QTc prolongation can be attenuated with beta-blockade.

Furthermore, T wave morphology changes exposed by quick standing are useful for diagnosing LQTS. The diagnosis of LQTS can be made with a higher degree of confidence when QT prolongation is accompanied by abnormal T wave morphology. The value of postural changes of T wave morphology for determining the specific LQTS genotype is modest, being most useful for LQT2, less useful for LQT1, and least useful for LQT3.³⁴

QT Interval Response to Exercise

Exercise testing can be useful to assess QT adaptation to heart rate, a measure of the integrity of the I_{Ks} channels. Changes in QTc duration and prolonged QT hysteresis during exercise testing can be helpful in identifying patients with LQTS and even in predicting the genotype. Gradual supine bicycle testing can help minimize signal artifact from upper body motion observed during treadmill exercise.

In particular, the QTc at 4 minutes of recovery after maximal exercise discriminates between patients with LQTS and healthy subjects. In one study of patients with normal or borderline QTc intervals at baseline (i.e., less than 480 milliseconds for females, less than 470 milliseconds for males), a QTc greater than or equal to 480 milliseconds during the fourth minute of recovery identified LQTS patients with a sensitivity of 94% and a specificity of 90%. However, these diagnostic strategies have not been meticulously studied in an unselected population suspected of LQTS.²²

In addition, a gene-specific QTc interval behavior during exercise has been reported. Genetic mutations in LQT1 result in reduction of the amplitude of I_{Ks} , one of the dominant K^+ currents responsible for repolarization especially at rapid heart rates. Attenuation of I_{Ks} results in failure of the QT to adapt (i.e., failure to shorten) in response to increasing heart rate. A maladaptive, paradoxical prolongation of the QTc interval during the recovery phase (QTc greater than 470 milliseconds or a Δ QTc [QTc at 3 minutes of recovery minus the baseline supine QTc] greater than 30 milliseconds) was found to distinguish patients with manifest or concealed LQT1 from normal subjects and those with LQT2 and LQT3 genotypes.

In contrast, patients with LQT2 mutations have normal QT shortening or minimal QTc prolongation during exercise, but they characteristically demonstrate an exaggerated QT hysteresis compared with LQT1 patients and normal subjects. QT hysteresis is normally measured by comparing the QT intervals during exercise versus the recovery period at comparable heart rates (e.g., when the heart rate accelerates to approximately 100 beats/min during early exercise, and when the heart rate decelerates to approximately 100 beats/min during the recovery phase). In LQT2 patients, the QT fails to shorten at these intermediate heart rates in early exercise because of attenuated I_{Kr} (a so-called I_{Kr} zone). This is followed by recruitment of the unimpaired, sympathetically responsive I_{Ks} , resulting in appropriate QT shortening at faster heart rates through to peak exercise, which persists into the recovery phase. This leads to increased QT hysteresis, that is, the QT interval is significantly longer during exercise than during recovery at comparable heart rates.

The LQT3 phenotype is characterized by a constant shortening of the QT interval with exercise because of stimulation of the intact I_{Ks}

channel and augmentation of a late inward Na^+ current. In fact, the QT interval in LQT3 patients shortens during exercise much more in LQT1 and LQT2 patients and even more than in healthy controls.

In addition, exercise treadmill testing can reveal the characteristic T wave morphology in patients with LQT1 and LQT2 syndromes.

Exercise-induced QTc prolongation and QT hysteresis can be attenuated with beta-blockade; therefore beta-blocker therapy should be discontinued before exercise testing.

Importantly, induction of arrhythmias during exercise is very rare in LQTS patients. Exercise-induced ventricular ectopy exceeding isolated PVCs is observed in less than 10% of patients. The presence of exercise-induced ventricular ectopy beyond single, isolated PVCs must prompt intense evaluation because it was found to have a positive predictive value exceeding 90% for the presence of significant cardiac pathology. However, CPVT, rather than LQTS, is the far more likely diagnosis.³²

Epinephrine QT Stress Test

Catecholamine provocation testing can help diagnose patients with concealed LQT1, with a positive predictive value approaching 75% and a negative predictive value of 96%. Furthermore, epinephrine provocation testing was found to be a powerful test to predict the genotype of LQT1, LQT2, and LQT3 syndromes.

Two major protocols have been developed for epinephrine infusion. Using the “escalating-dose infusion protocol,” epinephrine infusion is initiated at 0.025 μ g/kg per minute and then increased sequentially every 10 minutes to 0.05, 0.1, and 0.2 μ g/kg per minute. The 12-lead ECG is continuously recorded during sinus rhythm under baseline conditions and during epinephrine infusion. The QT interval is measured 5 minutes after each dose increase. Epinephrine infusion should be stopped for systolic blood pressure greater than 200 mm Hg, sustained or nonsustained VT, frequent PVCs (greater than 10 per minute), T wave alternans, or patient intolerance. A paradoxical QT interval response (prolongation of the absolute QT interval of greater than or equal to 30 milliseconds) during low-dose epinephrine infusion provides a presumptive clinical diagnosis of LQT1, with a positive predictive value of 75%. The diagnostic accuracy can be reduced in patients receiving beta-blockers.

Using the “bolus and infusion protocol,” an epinephrine bolus (0.1 μ g/kg) is administered and immediately followed by continuous infusion (0.1 μ g/kg per minute) for 5 minutes. The QT interval is measured 1 to 2 minutes after the start of epinephrine infusion when the R-R interval is the shortest (which represents the peak epinephrine effect) and 3 to 5 minutes after the start of epinephrine infusion (which represents the steady-state epinephrine effect). During the epinephrine test, patients with LQT1 manifest prolongation of the QTc at the peak of the epinephrine effect, which is maintained under steady-state conditions of epinephrine. In contrast, epinephrine prolongs the QTc more dramatically at the peak of epinephrine infusion in LQT2 patients, but the QTc returns to baseline levels under steady-state conditions. A much milder prolongation of QTc at the peak of epinephrine has been described in LQT3 patients and in healthy subjects, and it returns to the baseline levels under steady-state conditions. A subject is considered to have an LQT1 response if the QTc increase in the peak phase is greater than 35 milliseconds and is maintained throughout the steady-state phase (Fig. 31.6). LQT2 response is likely if the peak QTc increase of greater than 80 milliseconds is not maintained in the steady-state phase. In one report, the sensitivity and specificity of the epinephrine test to differentiate LQT1 from LQT2 were 97% and 96%, those from LQT3 were 97% and 100%, and those from healthy subjects were 97% and 100%, respectively, when Δ QTc greater than 35 milliseconds at steady state was used. The sensitivity and specificity to differentiate LQT2 from

Fig. 31.6 Epinephrine Provocative Testing for the Diagnosis of Long QT Syndrome (LQTS). Control, Normal subjects; LQT, long QT syndrome genotype; QTc, corrected QT interval.

LQT3 or healthy subjects were 100% and 100%, respectively, when Δ QTc greater than 80 milliseconds at peak was used.

The escalating-dose infusion protocol is generally better tolerated by the patient and carries a lower incidence of false-positive responses. On the other hand, the bolus and infusion protocol offers the ability to monitor the temporal course of the epinephrine response at peak dose (during the bolus) and during steady state (during the infusion), which is particularly important in individuals with LQT2 in whom transient prolongation of the uncorrected QT interval can occur, followed by subsequent shortening.

Genetic Testing

Although the diagnosis of LQTS can frequently be certain based on clinical diagnostic measures, genetic testing can still be of value; identification of the specific disease-causing mutation can potentially guide therapeutic choice, enhance risk stratification, and facilitate the identification of affected family members and implementation of lifestyle adjustment and presymptomatic treatment. Furthermore, genetic testing may be important in the identification of concealed LQTS, because a significant proportion (25% to 50%) of individuals with genetically proven LQTS can have a nondiagnostic QTc.

However, genetic testing remains expensive. Depending on the stringency of clinical phenotype assessment, the yield for positive genetic results in LQTS ranges from 50% to 78%, and is highest among tested individuals with the highest clinical probability (i.e., those with longer QTc intervals and more severe symptoms). The remaining probands with a strong clinical probability of LQTS will have a negative genetic test result, probably because of technical difficulties with genotyping, noncoding variants, or as yet unidentified disease-associated genes. Therefore a negative genetic test in a subject with clinical LQTS (i.e., genotype-negative/phenotype-positive LQTS) does not provide a basis to exclude the diagnosis. Nonetheless, a negative genetic test renders the diagnosis of LQTS very unlikely in those patients with low to moderate pretest probability based on clinical findings.³²

There is also the potential for false-positive results; genetic testing may identify novel mutations of unclear significance, which could represent normal variants, and require validation and further analysis (e.g., linkage within a family or in vitro studies).

Currently, comprehensive or targeted (LQT1, LQT2, and LQT3) genetic testing is recommended for symptomatic patients with a strong

clinical index of suspicion for LQTS (Schwartz score greater than or equal to 3.5 points) and for asymptomatic patients with QT prolongation (QTc greater than or equal to 480 milliseconds [prepuberty] or greater than or equal to 500 milliseconds [adults]) in the absence of other clinical conditions that might prolong the QT interval. In addition, LQTS genetic testing may be considered for the asymptomatic subject with a QTc greater than or equal to 470 milliseconds on serial ECGs but with negative family history.³²

Differential Diagnosis: Acquired Long QT Syndrome

It is important to distinguish acquired factors that result in QT interval prolongation from the inherited form of LQTS. Acquired LQTS is far more prevalent than the congenital form. However, the occurrence of torsade de pointes is far less common than that of QT prolongation. Nonetheless, there is an increased risk for torsade de pointes whenever the QTc interval exceeds 500 milliseconds and whenever the QTc interval increases by more than 60 milliseconds from baseline, especially when the increase occurs rapidly.

In contrast to the most common types of congenital LQTS (LQT1 and LQT2), a short-long-short pattern of R-R cycles constitutes the typical pattern of initiation of torsades de pointes in acquired LQTS. The long pause exaggerates the QT interval prolongation, and the short-long-short sequence is thought to promote torsades de pointes by increasing transmural dispersion of repolarization. The short-long R-R interval is usually caused by a short-coupled PVC followed by a compensatory pause and then another PVC occurring during the T wave. However, because of the underlying QT interval prolongation, this R-on-T PVC does not have the short coupling interval that is characteristic of idiopathic VF. Torsades de pointes can also occur in association with bradycardia or frequent pauses (sometimes referred to as “pause-dependent LQTS”).³⁵

Etiology

Acquired causes of abnormal prolongation of the QT interval include myocardial ischemia, cardiomyopathies, electrolyte abnormalities (hypokalemia, hypomagnesemia, and hypocalcemia), autonomic influences, drugs, hypothyroidism, hypothermia, pheochromocytoma, intracranial bleeding, and bradycardia.

Hypokalemia causes prolongation of the action potential duration because of reductions in multiple K^+ currents including I_{Kr} , I_{K1} , and I_{to} . Low extracellular K^+ levels accelerate fast inactivation of the hERG channel and further decrease I_{Kr} .^{36,37}

Acquired LQTS is also observed in the setting of extreme bradycardia, in particular, bradycardia complicating acquired AV block (spontaneous or iatrogenic). In fact, the original description of torsade de pointes, the hallmark arrhythmia of the LQTS, was entirely based on patients with LQTS complicating atrioventricular block. It is important to note that QT prolongation in patients with complete AV block is more pronounced than that in response to similar degrees of sinus bradycardia, and it is the magnitude of this QT prolongation in response to bradycardia, rather than the bradycardia per se, that determines the risk of torsade de pointes. It has been proposed that a change in QRS morphology, commonly observed in the setting of complete AV block but not during SND, leads to T wave changes associated with cardiac memory, which contributes to excessive QT prolongation. In one report, patients who developed a change in QRS morphology at the time of AV block had a sevenfold higher incidence of torsades de pointes and a change in the QRS axis seemed to be associated with an even greater incidence. These observations suggest that repolarization changes influenced by cardiac memory play a role in arrhythmia risk during AV block. Also, premature beats that lead to short-long-short cycles can foster the development of torsade de pointes.^{10,38}

By far, the most common environmental stressor resulting in acquired LQTS is drug therapy, including antiarrhythmic drugs, some antihistamines, antipsychotics, and antibiotics (www.qtdrugs.org). Noncardiovascular drugs that can potentially precipitate QT interval prolongation and arrhythmias comprise approximately 2% to 3% of total prescribed medications. Indeed, the risk of acquired LQTS is the most common cause of withdrawal or restriction of drugs that have already been marketed. For specific drugs, the incidence of torsade de pointes is difficult to quantify, and ranges from extremely low for many of the macrolide antibiotics, to 0.5% to 1% for drugs such as sotalol and azimilide, to 1.5% to 9% for quinidine.^{36,39}

The vast majority of drugs associated with the acquired form of LQTS are known to interact with the hERG channel (which mediates I_{Kr}), likely because of unique structural properties rendering this channel unusually susceptible to blockade by a wide range of different drugs. Compared with other cardiac K^+ channels, the hERG channel has a large, funnel-like vestibule that allows many small-sized molecules to enter and block the channel (see Chapter 2). The more spacious inner cavity is due to the lack of the Pro-X-Pro sequence motif in the S6 segment (which is present in most other voltage-gated K^+ channels and is believed to induce a sharp bend in the inner S6 helices of voltage-gated K^+ channels, reducing the inner vestibule), presumably facilitates access of drugs to the pore region from the intracellular side of the channel to block the channel current. In addition, the hERG channel contains two aromatic sites inside its pore (not present in most other K^+ channels), which provide high-affinity binding sites for aromatic moieties of a wide range of structurally diverse compounds. Interaction of these compounds with the channel's pore causes functional alteration of its biophysical properties, occlusion of the permeation pathway, or both.

Other mechanisms underlying drug-induced LQTS have been recently described, including disruption of hERG channel protein trafficking, with consequent reduction of surface membrane expression of otherwise functional channels (e.g., pentamidine), or folding and assembly of channel subunits. The accessory β -subunit (MiRP1, *KCNE2*) of the hERG channel also determines the drug sensitivity.

Risk Factors of Drug-Induced Long QT Syndrome

Several factors can potentially increase the susceptibility to drug-induced LQTS, including female gender (70% of patients with drug-induced torsades de pointes are women), advanced age, hypokalemia, hypomagnesemia, hypocalcemia, bradycardia, congestive heart failure, LV hypertrophy, recent conversion from AF, and the presence of QT interval prolongation on baseline ECG. Other risk factors include high drug doses (with the exception of quinidine), rapid IV infusion, and concurrent use of other drugs that prolong the QT interval or promote other QT-prolonging factors (such as bradycardia or electrolyte abnormalities). Also, conditions leading to accumulation of QT-prolonging drugs in plasma, such as from drug-drug interactions, are in general risk factors for torsades de pointes. These include the presence of renal or hepatic failure and the concomitant use of drugs that slow drug metabolism or impair drug excretion.¹⁰ In addition, genetically determined variability in pharmacodynamics (e.g., polymorphisms and mutations of the cytochrome system) can be responsible for significant variations in drug response. Most patients with drug-induced torsades de pointes have one or more risk factors.^{10,37,40}

Hospitalized patients appear to be at greater risk of drug-induced QT interval prolongation and torsades de pointes than outpatients, likely due to a greater preponderance of risk factors, including structural heart disease, advanced age, electrolyte abnormalities, bradycardia, or renal or hepatic disease.⁴¹ A risk score was developed for predicting the risk of developing acquired LQTS in hospitalized patients in cardiac care units (Table 31.6). The risk score effectively distinguished hospital-

TABLE 31.6 Calculation of Risk Score for QTc Interval Prolongation

Risk Factor Points	
Age ≥ 68 years	1
Female sex	1
Loop diuretic	1

ized patients at moderate or high risk for QTc interval prolongation from those at low risk. The occurrence of drug-induced torsades de pointes is an extremely rare event in patients without any risk factors. Over 90% of patients who develop torsades de pointes have at least one, and 71% of patients have at least two risk factors.^{42,43}

Genetics

Evidence suggests that drug-induced LQTS can represent a “forme fruste” of congenital LQTS in a significant proportion of patients, whereby drug challenge merely exposes the presence of the congenital form of the syndrome. This is likely related to a redundancy in repolarizing currents; normal repolarization is accomplished by multiple ion channels, providing a safety reserve for repolarization (the concept of “repolarization reserve”), which is genetically determined and compensates for any factor (e.g., drugs or genetic mutation) that might either decrease repolarizing or increase depolarizing currents during the action potential. As a result, a mutation or polymorphism in one of the LQTS genes can be clinically inapparent until another insult to repolarization, such as a drug, hypokalemia, or hypomagnesemia, is superimposed.³⁶

Mutations of ion channel genes responsible for LQTS have been implicated as a risk factor. In fact, previously unrecognized congenital LQTS, of any subtype, can be identified in as many as 36% to 40% of drug-induced LQTS patients. In addition, polymorphisms (i.e., common genetic variations present in greater than 1% of the population) in cardiac ion channels can potentially increase the risk for the development of drug-induced torsades de pointes. In a recent study, drug-induced LQTS patients had a greater burden of amino acid coding variants (missense, nonsynonymous, or frameshift), than the control subjects, suggesting that multiple rare variants, notably across congenital LQTS genes, predispose to drug-induced LQTS.⁴⁴

In a large cohort of acquired LQTS subjects, the QTc interval remained prolonged (although to a milder degree than that observed in congenital LQTS carriers) in a significant proportion of patients even after the QT-prolonging factors are removed (withdrawal of culprit drugs or correction of serum electrolytes), suggesting that acquired LQTS could represent at least in part a latent genetic predisposition. Further, 28% of acquired LQTS subjects were found to harbor mutations in one of the major LQTS-related genes (most commonly in the *KCNH2* gene). Even among the “true” acquired LQTS, i.e., those with normal QT interval outside the triggering episode, 23% had congenital LQTS-causing

mutations. Predictors for carrying a pathogenic mutation in acquired LQTS included (1) age less than 40 years, (2) baseline QTc interval exceeding 440 milliseconds, and (3) history of symptoms at the time of acquired LQTS diagnosis (Table 31.7). Of the acquired LQTS patients carrying a mutation, 88% had two or more of those predictors, while only 3% of patients with one or none of those risk factors had a mutation. Therefore some investigators have proposed genetic screening in acquired LQTS subjects with two or more of the risk factors to enable “cascade screening” in their family members and thereby prevent avoidable risks of life-threatening arrhythmias.⁴⁵

Management

First-line treatment approaches to torsades de pointes include removal of the offending causes, the use of IV magnesium, maintenance of high-normal serum K⁺ level, and avoidance of QT-prolonging agents. In some refractory cases, isoproterenol infusion or temporary transvenous overdrive pacing may be required to increase heart rate, which can shorten the QT interval and suppress torsades de pointes.

Magnesium suppresses torsades de pointes without shortening the QT interval, presumably by suppressing the EADs that trigger torsades de pointes. EAD suppression by magnesium has been attributed to its Ca²⁺ channel-blocking effects but may also be mediated by a reduction of the late component of the sodium current (I_{NaL}). The value of acute K⁺ repletion is less well documented than that of IV magnesium for the acute treatment of drug-induced torsades de pointes. Normal levels of both potassium and magnesium should be maintained aggressively in hospitalized patients at risk.⁴⁶

Recent studies suggested that mexiletine (a strong I_{NaL} blocker) may be an effective treatment for acute termination of torsades de pointes in several acquired causes of QT interval prolongation. Although torsades de pointes often responds to a lidocaine bolus, arrhythmias tend to recur despite continuous infusions. In contrast, ranolazine (an I_{NaL} blocker), flecainide (a strong I_{Na} blocker), and verapamil (a strong I_{CaL} blocker) also block I_{Kr}, thus limiting their use in patients with drug-induced LQTS.³⁵ Of note, a recent report demonstrated potential benefit of oral progesterone for the prevention of drug-induced QT interval prolongation.¹⁸

Risk Stratification

The clinical course in LQTS patients is not uniform and is influenced by many factors, including age, gender, genotype, environmental factors, therapy, and possibly other modifier genes.

Clinical Markers of Risk

Syncope. Nonfatal events (syncope and aborted cardiac arrest) in LQTS patients remain the strongest predictor of subsequent LQTS-

related fatal events, and the overall risk of subsequent SCD in an LQTS patient who has experienced a previous episode of syncope is approximately 5% per year.

The risk of subsequent syncope episodes can be reduced with beta-blocker therapy; however, patients experiencing syncope while receiving beta-blockers are at high risk of subsequent cardiac events, a risk similar to that observed in patients who are not treated with beta-blockers.

Both the timing and frequency of syncopal events are related to the subsequent risk of cardiac events. Patients with recent (within the past 2 years) syncope and a higher number of syncopal events during this period carry a higher risk of subsequent cardiac events.

However, it is important to distinguish between suspected arrhythmogenic and nonarrhythmogenic causes of syncope, especially given the fact that neurocardiogenic syncope is not uncommon in this patient population and its occurrence does not impact the prognosis negatively. A detailed clinical history in LQTS patients presenting with syncope is imperative, since clinical features (in particular, the occurrence of prodromes and the presence of specific triggers) can allow distinction between suspected arrhythmogenic and nonarrhythmogenic etiologies in a large proportion of cases.

Family history. The incomplete penetrance and variable expressivity in LQTS preclude predicting severity of symptoms in relatives of a symptomatic LQTS patient. In fact, SCD of a sibling (at any age) does not seem to contribute to increased personal risk of LQTS-related life-threatening cardiac events. Instead, the risk of adverse events in relatives appears to be determined more by the individual's own risk factors (QTc duration, personal history of syncope, and gender).

Gender. The effect of gender on outcome is age dependent, with boys exhibiting a significant (71% to 85%) increase in risk for syncope, aborted cardiac arrest, or SCD as compared with girls during childhood and early adolescence. However, a gender risk reversal occurs after age 14 years, in which girls exhibit an 87% increase in the risk of cardiac events compared with boys among probands and a 3.3-fold increase in the risk among affected family members. When only life-threatening cardiac events (aborted cardiac arrest or SCD) are considered, the onset of gender risk reversal occurs at a later age. The cumulative probability of a first life-threatening cardiac event from age 1 to 12 years is 5% in boys compared with only 1% among girls, whereas in the age range of 12 to 20 years, there is no significant gender difference in risk. Risk reversal for the endpoint of aborted cardiac arrest or SCD occurs after the age of 20 years, and women maintain higher risk than men throughout adulthood.

Importantly, the effect of gender on outcome appears to be genotype dependent. Among those younger than 15 years, male LQT1 patients exhibit the highest risk of cardiac events; female LQT1 patients had intermediate risk; and both male and female LQT2 patients had the lowest risk. No significant gender-related difference in risk was shown among LQT2 and LQT3 children. In contrast, in the 15- through 40-year-old age group, the risk is highest among LQT2 women, intermediate among LQT1 women, and lowest among LQT1 and LQT2 men.¹⁹

Age. Risk factors in LQTS are time dependent and age specific (Table 31.8). LQTS patients who experience an aborted cardiac arrest during the first year of life are at a very high risk for subsequent life-threatening cardiac events during the first decade of life. The risk factors for a cardiac event in LQTS infants also include a QTc of at least 500 milliseconds, a heart rate not exceeding 100 beats/min, and female gender.

In LQTS children, risk factors for life-threatening cardiac events include male gender, a history of syncope at any time during childhood, and a QTc duration greater than 500 milliseconds.

Among adolescent patients with suspected LQTS, recent episodes of syncope (in particular within the past 2 years) and QTc greater than

TABLE 31.8 Age-Specific Risk Factors for Life-Threatening Cardiac Events in Long QT Syndrome Patients^a

Age Group	Risk Factor	Hazard Ratio (P Value)	Beta-Blocker Efficacy, % Reduction (P Value)

^aFindings are from separate multivariable Cox models in each age group for the endpoint of aborted cardiac arrest or sudden cardiac death.

^bBecause long QT syndrome (LQTS)-related events are more difficult to delineate in the older age group, the endpoint in the 41- to 60-year-old age group comprised aborted cardiac arrest or death from any cause.

^cLack of a statistically significant beta-blocker effect in this age group may relate to the broad endpoint of death from any cause.

QTc, Corrected QT interval.

From Goldenberg I, Moss AJ. Long QT syndrome. *J Am Coll Cardiol*. 2008;51:2291–2300.

530 milliseconds predict increased risk of LQTS-related cardiac events. Although LQT1 genotype predicts higher risk in patients not more than 14 years of age (especially boys), the risk is higher for LQT2 in patients 15 years of age or older (especially women).

In adult patients, predictors of worse outcome include a QTc greater than 500 milliseconds, female gender, and history of syncope before age 18 years. In addition, patients with LQT2 mutations appear to be at a greater risk for a cardiac event than patients with LQT1 or LQT3 genotypes.

Beyond 40 years of age, recent syncope (within the past 2 years) appears to be the predominant risk factor in affected subjects, and those with a positive mutation had a significantly higher mortality, particularly those with an LQT3 mutation. Furthermore, women with a QTc greater than 470 milliseconds are at a higher risk of LQTS-related cardiac events, whereas in men, event rates are similar in the various QTc categories. After the age of 60 years, the risk of death due to LQTS competes with other disease entities that may lead to death.

Electrocardiographic Markers of Risk

QT interval prolongation. The QTc interval is the best prognostic ECG parameter in LQTS families. A QTc interval of at least 470 milliseconds is a predictor for increased risk for symptoms, whereas a QTc of at least 500 milliseconds predicts an increased risk of life-threatening cardiac events. Although there is no threshold of QTc prolongation at which torsades de pointes is certain to occur, a gradual increase in risk for torsades de pointes is observed as the QTc interval increases. Each 10-millisecond increase in QTc contributes approximately a 5% to 7% additional increase in risk for torsades de pointes. Therefore a patient with a QTc of 540 milliseconds has a 63% to 97% higher risk of

developing torsades de pointes than a patient with a QTc of 440 milliseconds.

Importantly, considerable time-dependent variability and instability of ventricular repolarization exist in LQTS. Thus risk stratification should take into account the risk associated with variability in the duration of the QTc interval in the individual LQTS patient during follow-up. In fact, it has been shown that the maximum QTc duration measured at any time before age 10 was the most powerful predictor of cardiac events during adolescence, regardless of baseline, mean, or most recent QTc values.

Furthermore, a considerable variability in the duration of the QTc interval exists among LQTS patients with identical mutations. Evidence suggests that mutation-specific QTc variability (defined as QTc standard deviation [QTcSD] among all carriers of a specific mutation) provide incremental prognostic information for risk stratification that is independent of those related to the individual's own QTc. A greater degree of repolarization instability associated with specific LQTS mutations (manifesting as a high mutation-specific QTcSD) was identified as an independent risk predictor even in high-risk patients with long QTc durations. It has been reported that every 20-millisecond increment in mutation-specific QTcSD resulted in a 33% increased risk for cardiac events after adjustment for the patient-specific QTc, and patients who had mutations with QTcSD of 45 milliseconds or more experienced a significant 48% increase in the risk of cardiac events compared with patients who had mutations with QTcSD less than 45 milliseconds. These findings emphasize the importance of checking mutation-specific effects in various genetic backgrounds to identify mutations that are more susceptible to intrinsic or extrinsic modifying factors. It is important to note that the prognostic implications of QTcSD appear to be

genotype specific; the risk associated with a higher QTcSD was pronounced among patients with LQT1, whereas in patients with LQT2, no significant association of QTcSD with cardiac events was found.⁴⁷

T-U wave morphology. The ratio of the amplitude of the U wave to that of the T wave has been suggested as the clinical counterpart of EADs; a progressive increase in the ratio of the U wave to the T wave preceded the onset of torsades de pointes in an experimental model of LQTS. In addition, the increment in U wave amplitude after a PVC has been suggested as a marker for arrhythmia risk in “pause-dependent” LQTS.

In patients with bifid T waves, the diurnal maximal ratio between late and early T wave peak amplitude was found to correlate with a history of LQTS-related symptoms better than the baseline QTc interval in both LQT1 and LQT2 patients, and can potentially be used to assess the risk of symptoms in asymptomatic patients with known type 1 or 2 LQTS genotype. In LQT1 patients, a ratio of at least three suggests a high probability of being symptomatic whereas a ratio not exceeding two suggests a low probability. Among LQT2 patients, ratios suggestive of being symptomatic or asymptomatic are, respectively, at least 2.4 and not more than 1.5.

Of note, the presence of macroscopic T wave alternans (bidirectional beat-to-beat changes in T wave polarity) indicates electrical instability and high acute risk of ventricular arrhythmias.

Genetic Markers of Risk

The genotype is an important predictor of LQTS-related cardiac events. The risk of cardiac events has been shown to be significantly higher in LQT1 and LQT2 when compared with LQT3, with events occurring at a younger age. The cumulative mortality, however, appears to be similar regardless of the genotype, since patients with LQT3 develop arrhythmias less often, but these are more likely to be lethal when they ultimately occur.

LQT1 patients exhibit a 49% increase in the risk of cardiac events as compared with LQT2 patients. However, in the 15- through 40-year-old age group, the risk of a first cardiac event is significantly higher among LQT2 patients (67% increase in the risk as compared with LQT1 patients). Among LQTS patients receiving beta-blocker therapy, the LQT2 and LQT3 genotypes are associated with increased risk of arrhythmic events as compared with LQT1.

In addition to identifying the LQT genotype, knowing the specific mutation and its biophysical function can help improve risk stratification. For LQT1, patients with mutations in the transmembrane domain of the KCNQ1 channel had more frequent cardiac events (syncope, aborted cardiac arrest, or SCD) and a greater risk of the first cardiac event occurring at a younger age than did patients with C-terminal mutations. For LQT2, pore mutations have a more severe clinical course and a higher frequency of arrhythmic events occurring at a younger age when compared with nonpore mutations. In particular, missense mutations in the transmembrane pore (S5-loop-S6) region appear to be associated with the highest risk of clinical arrhythmia.

Preliminary data for LQT3 patients also suggest that the location and biophysical function of the mutation can play a role in determining the severity of the clinical phenotype. Mutations with a dominant-negative effect on ion channel function (greater than 50% reduction in function) have a more severe phenotype compared with mutations exhibiting haploinsufficiency (less than or equal to 50% reduction in function).

Jervell and Lange-Nielsen syndrome and the Timothy syndromes (LQT8) have a highly malignant course with poor prognosis, and are less likely to respond to beta-blocker therapy alone. In contrast, the Andersen-Tawil syndrome has a generally more benign clinical course in terms of arrhythmic death.

The presence of multiple mutations (the so-called “double hits,” observed in 8% to 11% of patients with LQTS) is associated with a significantly higher risk for life-threatening cardiac events as compared with patients with a single mutation. Also, among patients with multiple mutations, a double hit in a single gene (compound heterozygosity) was associated with a greater risk for life-threatening cardiac events than a double hit in different genes (digenic heterozygosity).^{48,49}

Principles of Management

The main therapeutic modalities for the prevention of life-threatening cardiac events include beta-blockers, left (sometimes bilateral) cervicothoracic sympathetic denervation, and implantable cardioverter-defibrillator (ICD) implantation. In nongenotyped patients, beta-blockers comprise the mainstay therapy, whereas cervicothoracic sympathetic denervation and ICD implantation are therapeutic options in high-risk LQTS patients who experience recurrent cardiac events despite beta-blocker therapy (Table 31.9). Renal sympathetic denervation may play a future role.

Pharmacological Therapy

Treatment with beta-blockers is associated with a significant (53% to 64%) reduction in risk of LQTS-related life-threatening events (syncope, cardiac arrest, and SCD), regardless of age (see Table 31.8). The benefit appears to be most substantial in patients at highest risk for cardiac events. On the other hand, very low-risk patients (no history of syncope, QTc less than 500 milliseconds, girls younger than 14 years, LQT2 men of any age, and LQT1 women older than 14 years) have such a small frequency of events that beta-blockers may not provide a substantial benefit.⁵⁰

Genetic data can be used to guide the therapeutic management plan. Given the critical role of catecholamines in precipitating arrhythmias in LQT1, beta-blocker therapy is particularly effective for this group of patients; approximately 90% of LQT1 patients treated with beta-blockers remained free from syncope and cardiac arrest after a mean follow-up time of 5.4 years and showed a total mortality rate of 1%. Although beta-blockers were generally considered to have lower efficacy in LQT2 patients as compared with LQT1 patients, recent data argue for a similar magnitude of risk reduction in LQT2 patients (beta-blocker therapy decreased cardiac events from 58% to 23% after an average follow-up of 4.9 years on therapy). The higher residual event rate in LQT2 patients while receiving beta-blocker therapy is likely due to a higher overall event rate in patients with this genotype, rather than to an attenuated efficacy of medical therapy in this high-risk population. Of note, a trigger-specific response to beta-blocker therapy exists within the LQT2 population; beta-blockers appear to be more protective against exercise-triggered cardiac events than arousal- or non-exercise-related events (see Fig. 31.3).

On the other hand, the value of beta-blocker therapy in LQT3 patients is debated. These patients continue to experience high rates of cardiac events despite beta-blocker therapy. Among LQT3 patients receiving beta-blocker therapy, the adjusted risk for a cardiac event is fourfold higher than among LQT1 patients. However, when excluding LQT3 patients with the most severe phenotype (i.e., patients who had suffered a cardiac event during infancy and those with QTc greater than 600 milliseconds), beta-blocker therapy appears to be beneficial in LQT3. It is important to note, however, that prolongation of the QT intervals is aggravated at slow heart rates; thus a reduction in heart rate with beta-blockers can potentially pose a therapeutic problem in these patients.¹⁹

Currently, beta-blockers are considered the mainstay therapy for the prevention of life-threatening cardiac events and, given the approximately 12% risk of SCD as the first manifestation of LQTS, they should

TABLE 31.9 Expert Consensus Recommendations on Long QT Syndrome (LQTS) Therapeutic Interventions

Class I	<ol style="list-style-type: none"> The following lifestyle changes are recommended in all patients with a diagnosis of LQTS: <ol style="list-style-type: none"> Avoidance of QT-prolonging drugs (www.qtdrugs.org) Identification and correction of electrolyte abnormalities that may occur during diarrhea, vomiting, metabolic conditions, or imbalanced diets for weight loss. Beta-blockers are recommended for patients with a diagnosis of LQTS who are: <ol style="list-style-type: none"> Asymptomatic with QTc ≥ 470 msec <i>and/or</i> Symptomatic for syncope or documented ventricular tachycardia/ventricular fibrillation (VT/VF). Left cardiac sympathetic denervation (LCSD) is recommended for high-risk patients with a diagnosis of LQTS in whom: <ol style="list-style-type: none"> Implantable cardioverter-defibrillator (ICD) therapy is contraindicated or refused <i>and/or</i> Beta-blockers are not effective in preventing syncope/arrhythmias, not tolerated, not accepted, or contraindicated. ICD implantation is recommended for patients with a diagnosis of LQTS who are survivors of a cardiac arrest. All LQTS patients who wish to engage in competitive sports should be referred to a clinical expert for evaluation of risk.
Class IIa	<ol style="list-style-type: none"> Beta-blockers can be useful in patients with a diagnosis of LQTS who are asymptomatic with QTc ≤ 470 msec. ICD implantation can be useful in patients with a diagnosis of LQTS who experience recurrent syncope events while on beta-blocker therapy. LCSD can be useful in patients with a diagnosis of LQTS who experience breakthrough events while on therapy with beta-blockers/ICD. Sodium channel blockers can be useful, as add-on therapy, for LQT3 patients with a QTc > 500 msec who shorten their QTc by > 40 msec following an acute oral drug test with one of these compounds.
Class III	<ol style="list-style-type: none"> Except under special circumstances, ICD implantation is not indicated in asymptomatic LQTS patients who have not been tried on beta-blocker therapy.

From Priori SG, Wilde AA, Horie M, et al. HRS/EHRA/APHRS expert consensus statement on the diagnosis and management of patients with inherited primary arrhythmia syndromes. *Heart Rhythm*. 2013;10:1932–1963.

be considered the first-line measure in all nongenotyped patients and in patients with LQT1 or LQT2 genotypes, regardless of their symptomatic or risk status (Fig. 31.7). Possible exceptions could include very low-risk LQTS patients (based on clinical and ECG parameters) in whom beta-blocker therapy may be considered on an individual basis. That said, it is important to understand that all these recommendations are based on observational studies and not randomized clinical trials.

Propranolol and nadolol are the beta-blockers most widely used. Limited data exist regarding the effectiveness of other beta-blockers in preventing cardiac events in patients with LQTS, although some evidence suggests the superiority of nadolol and propranolol as compared to metoprolol in LQT1 and LQT2 patients. Long-acting medications are preferred to improve compliance and avoid wide fluctuations in blood levels. The nonselective beta-blocker nadolol (which has strong negative chronotropic effect and long half-life [20 to 24 hours]) is the most preferred first-choice therapy in patients with LQTS. Propranolol is probably the preferred beta-blocker in LQT3 patients, given its direct late Na⁺ current blocking properties.^{32,51}

The protective effect of beta-blockers is related to their adrenergic blockade, which diminishes the risk of cardiac arrhythmias; hence, the goal of beta-blocker therapy is to blunt the maximal heart rate during exercise, and the adequacy of beta-blockade should be assessed by exercise testing or ambulatory monitoring. It is recommended to start at a low dose and slowly up-titrate the dose (over several weeks, especially in asymptomatic patients) to help improve patient tolerance and compliance, which can potentially lead to otherwise unnecessary ICD implantation. Of note, beta-blockers do not substantially shorten the QT interval.^{1,52,53}

Despite the beneficial effects of beta-blockers, a high rate of residual cardiac events has been reported in patients receiving beta-blocker therapy, occurring in 10%, 23%, and 32% of LQT1, LQT2, and LQT3 patients, respectively, after a mean follow-up time of 5.4 years. Therefore

patients who remain symptomatic despite treatment with beta-blockers should be considered for other therapeutic modalities. Interestingly, it has been reported that noncompliance is an important cause of events occurring during beta-blocker treatment in LQT1 patients.

Implantable Cardioverter-Defibrillator

ICD therapy is highly effective to prevent SCD in high-risk LQTS patients (mortality of 1.3% in high-risk ICD patients compared with 16% in non-ICD patients during a mean follow-up time of 8 years). Therefore ICD implantation should be considered for secondary prevention in patients with prior cardiac arrest and for primary prevention in those who experience unexplained syncope or ventricular tachyarrhythmias while receiving beta-blocker therapy (Fig. 31.8).⁵³

Although prophylactic ICD therapy used to be considered for LQTS patients with risk factors for SCD (see Table 31.8) regardless of medical therapy, recent data suggest that high-risk LQT1 and LQT2 patients should be considered for prophylactic ICD implantation only if they develop recurrent cardiac events (e.g., syncope or torsades de pointes) despite beta-blocker therapy or when compliance with or intolerance to medical therapy is a concern. Using this approach, most patients with LQTS do not need an ICD. Clear understanding by the patient and family of the relative merits of each strategy is essential. Although beta-blocker therapy significantly reduces the risk of SCD in this population, it is not completely protective, and residual cardiac events still occur. On the other hand, data suggest that syncopal episodes almost always precede cardiac arrest in patients receiving beta-blockers, allowing for institution of other therapeutic modalities, such as ICD implantation. In addition, ICD therapy is not without complications; infection, lead malfunction, inappropriate shocks, psychological sequelae, as well as the need for periodic device or lead revisions, have to be taken into consideration. This is especially important in children and young adults in whom the initial decision to implant an ICD carries decades-long implications, such as multiple procedures for generator replacements

Fig. 31.7 An Algorithm for Acute Pharmacological Treatment of Arrhythmias in Suspected Channelopathies. ^aExcept under special circumstances, ICD implantation is not indicated in asymptomatic patients who have not been tried on beta-blocker therapy.

Fig. 31.8 Consensus Recommendations for Implantable Cardioverter-Defibrillators (ICDs) in Patients Diagnosed With Long QT Syndrome. (From Priori SG, Wilde AA, Horie M, et al. HRS/EHRA/APHS expert consensus statement on the diagnosis and management of patients with inherited primary arrhythmia syndromes. *Heart Rhythm.* 2013;10:1932–1963.)

and lead extractions, increasing the lifetime risks of morbidity and mortality.⁵³

Because ICD therapy does not prevent the occurrence of arrhythmias, concurrent treatment with beta-blockers is recommended for symptomatic and high-risk patients. Furthermore, careful programming of the ICD arrhythmia detection settings is recommended to reduce the risk of inappropriate shocks. This usually involves programming a single VF zone of more than 220 beats/min with or without a monitoring zone of more than 180 beats/min.¹

The European registry of 233 LQTS patients with ICDs showed that 28% received appropriate ICD therapies, and that future appropriate ICD therapies could be predicted by four variables: (1) age younger than 20 years at implantation; (2) QTc greater than 500 milliseconds; (3) prior cardiac arrest; and (4) cardiac events despite therapy. The M-FACT scoring system (Table 31.10), based on those clinical variables, was developed to identify in advance those patients with the highest and lowest probability of receiving appropriate shocks, which might represent the justification for the ICD implantation. Within 7 years, appropriate ICD therapies did not occur in any patients who had none of these factors and did occur in 70% of patients with all four clinical factors. Patients with an M-FACT score of 0 are unlikely to benefit from ICD implantation.^{32,54}

In addition, prophylactic ICD therapy should be considered in very-high-risk patients, including symptomatic patients with two or more gene mutations, including those with the Jervell and Lange-Nielsen syndrome variant with congenital deafness.¹

TABLE 31.10 M-FACT Risk Score

	Points
Event-free on therapy for >10 years	−1
QTc

>550 msec	2
Age at implantation ≤20 years	1
Prior aborted cardiac arrest	1
Events on therapy	1

*Acronym derived from M (minus 1 point for being free of cardiac events while on therapy for >10 years), F (500- and 550-msec QTc), A (age ≤20 years at implantation), C (cardiac arrest), and T (events on therapy).

Left Cervicothoracic Sympathectomy

Left cervicothoracic sympathectomy, which involves resection of the lower half of the left stellate ganglion and the first two to four thoracic ganglia (T1–T4), is another antiadrenergic therapeutic option for patients with LQTS. Care must be taken to not damage the top half of the ganglia to avoid Horner syndrome.

Currently, left cervicothoracic sympathectomy is recommended for the management of high-risk LQTS patients in whom drug therapy may not be sufficiently protective when ICD therapy is refused or not feasible (e.g., small infants) and when beta-blockers are not effective, not tolerated, or contraindicated.^{1,32}

Although cardiac sympathetic denervation provides a significant long-term reduction in the frequency of aborted cardiac arrest and syncope (more effective in patients with LQT1 than in those with other types of LQTS), it is not completely protective against SCD. Studies of LQTS patients who have undergone left cervicothoracic sympathectomy demonstrated a residual mortality rate of 5% at 5 years. Furthermore, about 50% of high-risk LQTS patients have experienced one or more cardiac events, and patients with extremely malignant LQTS might not be responsive to cardiac sympathetic denervation. Hence, left cervicothoracic sympathectomy must not be viewed as curative or as an ICD alternative for high-risk patients.⁵⁵

Importantly, postoperative morbidity is common in patients undergoing left cervicothoracic sympathectomy. A large proportion of patients experience left-sided dryness, unilateral facial flush with exercise, contralateral hyperhidrosis, differential hand temperatures, transient and permanent ptosis, and left arm paresthesia. Nonetheless, postoperative satisfaction is generally high and patients feel safer following the procedure, despite the side effects.^{56,57}

Permanent Pacemaker

Cardiac pacing, in conjunction with beta-blocker therapy, can potentially reduce the risk of bradycardia-dependent QT prolongation, decrease heart-rate irregularities (eliminating short-long-short sequences), and reduce repolarization heterogeneity. Permanent pacemakers can be of value, especially in patients who continue to be symptomatic despite beta-blocker therapy or those in whom bradycardia or AV block limits the use of such therapy. In particular, patients with documented pause- or bradycardia-induced torsades de pointes and those with the LQT3 genotype may derive significant benefit from cardiac pacing.⁵⁸

Nevertheless, the high mortality in patients with recurrent symptoms (syncope or torsades de pointes) while receiving beta-blocker therapy is not adequately attenuated by the addition of cardiac pacing. Therefore

if cardiac pacing is being considered, the use of an ICD is more logical because it provides protection from SCD as well as the benefit of cardiac pacing. However, when ICD implantation is associated with an extremely high rate of adverse events (such as in small infants), an atrial pacemaker in combination with beta-blocker therapy can potentially serve as a bridge to ICD placement.⁵⁸

When cardiac pacing is employed, atrial pacing is preferred, at a rate that shortens the QTc to less than 440 milliseconds. It is recommended to minimize ventricular pacing as possible because it can potentially increase the heterogeneity of ventricular repolarization. However, in patients with AV block, ventricular pacing is important to maintain AV synchrony and elimination of ventricular pauses and long-short cycles.

Catheter Ablation

In LQTS patients, frequent episodes of torsades de pointes are occasionally triggered by focal, monomorphic PVCs. In this setting, catheter ablation of the focus of the PVCs can be valuable in reducing the burden of arrhythmias and the frequency of ICD therapies.

Lifestyle Modifications

Education and lifestyle changes for the prevention of arrhythmias are critical in patients with LQTS. Patients should avoid drugs that prolong the QT interval (www.qtdrugs.org) or reduce their serum potassium or magnesium levels, and they should consult with their physician before taking any medications or over-the-counter supplements. Furthermore, patients need to be educated on conditions that can lead to potentially dangerous electrolyte abnormalities (e.g., dehydration, diarrhea, vomiting, imbalanced diets for weight loss).¹

In addition, the importance of compliance with medical therapy should be emphasized. Beta-blocker noncompliance and use of QT-prolonging drugs account for the vast majority of life-threatening events in LQT1 patients. Preventive measures in LQTS patients in general and LQT2 patients in particular include avoidance of unexpected auditory stimuli (such as alarm clocks, doorbells, and telephones), especially during rest or sleep. Families with LQTS may also consider basic life support training and operation of an automated external defibrillator.

Participation in Sports

Physical activity and stress-related emotions frequently trigger cardiac events in patients with LQTS, especially patients with LQT1 or LQT2. Therefore all competitive sports (except those in the class IA category, such as billiards, bowling, cricket, and golf) should be restricted in symptomatic LQTS patients (regardless of the QTc duration or underlying genotype) as well as asymptomatic patients with baseline QT prolongation (QTc greater than or equal to 470 milliseconds in men, greater than or equal to 480 milliseconds in women). Swimming is particularly hazardous in LQT1 patients and should therefore be limited or performed under appropriate supervision, even in subjects with genotype-positive/phenotype-negative LQT1.

Because many first cardiac events occur before the age of 15 years in male patients, particularly those with the LQT1 genotype, whereas female patients may experience first cardiac events after the age of 20 years, LQT1 male patients require stricter exercise restriction before the age of 15.

Recent data suggests that sports participation is safer than previously recognized, and the restriction limiting participation to class IA activities may be liberalized for the asymptomatic patient with genetically proven LQT3 genotype and those with genotype-positive/phenotype-negative LQTS (especially patients genotyped as non-LQT1 and no family history of multiple SCDs), assuming that appropriate disease-specific

treatments are in place. In addition, automated external defibrillators and personnel trained in basic life support should be readily available. Furthermore, precautionary measures should be undertaken to avoid exercise-related dehydration, heat exhaustion, and electrolyte abnormalities.^{1,59}

Sports participation may also be carefully considered in LQTS patients with QT prolongation and those rendered asymptomatic after institution of treatment. These decisions, however, should be deliberated carefully by an LQTS expert to ensure that the athletes and their family members have been well informed, well risk stratified, and well treated.⁶⁰

Other considerations include the acquisition of a personal automatic external defibrillator as part of the athlete's personal sports safety gear, and establishment of an emergency action plan with the appropriate training facility and team officials.

Gene-Specific Therapy

The standard therapeutic options for LQTS (including beta-blockers, cardiac sympathetic denervation, ICD) rely on genotype to only a minor degree, yet are quite effective. Nevertheless, beta-blockers and left cervicothoracic sympathectomy have some degree of genotype specificity, being quite effective in LQT1 and LQT2 and less effective in LQT3. Similarly, lifestyle modification and exercise restriction are most helpful in LQT1 and LQT2. For practical purposes, however, this apparent genotype specificity influences therapy decisions in only a very small number of patients.

Several gene-specific LQTS therapies are being evaluated, including Na⁺ channel blockers, K⁺ channel activators, alpha-adrenergic receptor blockers, protein-kinase inhibitors, and atropine. However, current experience with these drugs is limited.

LQT3. Currently, LQT3 is the only LQTS variant for which a gene-specific therapy is recommended by current guidelines (see Table 31.9). Given the fact that augmentation of the late Na⁺ inward current (I_{NaL}) underlies the prolongation of the QT interval in patients with the LQT3 genotype, Na⁺ channel blockers have been successfully used in these patients. Mexiletine, a class IB Na⁺ channel blocker, was shown to shorten the QT interval and reduce the occurrence of arrhythmic events in LQT3 patients.⁶¹

Until prospective clinical trials confirm the effectiveness of mexiletine, it should be used in LQT3 patients with a QTc exceeding 500 milliseconds only in conjunction with beta-blockers or with the backup of an ICD. In addition, some investigators recommend testing the effectiveness of mexiletine by the administration of half the daily dose during continuous ECG monitoring. Only if the QTc is shortened by more than 40 milliseconds within 90 minutes of drug administration (when the peak plasma concentration is reached) should mexiletine be added to beta-blocker therapy.

Flecainide, a class IC Na⁺ channel blocker, was shown to shorten the QT interval in LQT3 patients with a specific mutation (D1790G) in the *SCN5A* gene. However, flecainide is reported to elicit a Brugada phenotype in some LQT3 patients; therefore this drug should not be used in LQT3 patients except for those with this specific *SCN5A* mutation.

The antianginal agent ranolazine has unique EP properties. Unlike other Na⁺ channel blockers, which reduce both the early (peak) and late components of the Na⁺ current (I_{Na} and I_{NaL} , respectively), ranolazine preferentially reduces I_{NaL} . Moreover, ranolazine reduces Ca²⁺ overload of myocardial cells and suppresses EAD-triggered arrhythmias in animal models of LQT3. Ranolazine was shown to shorten the QT interval without widening the QRS complex in LQT3 patients, and can potentially offer a therapeutic benefit in these patients.⁶²

LQT2. Potassium supplements can be of value, especially in LQT2 patients, who are particularly sensitive to low K⁺ levels because the

conductance of KCNH2 channels is directly related to extracellular K⁺ concentrations. Therefore efforts should be made to maintain a serum K⁺ level greater than 4 mEq/L in patients with this genotype. Acute treatment with IV potassium can be effective in suppressing torsades de pointes. Furthermore, long-term oral potassium supplements, even in patients with normal K⁺ levels at baseline, can potentially reduce repolarization abnormalities in LQT2. Increasing extracellular K⁺ concentrations enhances IKr, at least partially compensates for the loss of IKr in LQT2, and can potentially limit the development of an arrhythmogenic substrate under long QT conditions. Whether these effects translate into clinical benefit in reduction of the risk of cardiac events remains to be proven.

Family Screening

Timely (often presymptomatic) identification of disease carriers is important because preventive measures and therapies can effectively avert SCD. Therefore when a patient is diagnosed with LQTS, ECGs should be obtained on all first-degree family members (i.e., parents, siblings, offspring) to determine whether others are affected. Unexplained sudden death in a young individual should trigger a similar evaluation to determine if LQTS is present in the family.

When the causal mutation has been identified in the proband, first-degree relatives should be offered genetic screening, even those with a negative clinical and ECG phenotype. Genotyping of family members can help exclude the diagnosis in some persons, and identify silent mutation carriers and allow prophylactic treatment. However, detailed genetic counseling is warranted before proceeding to this testing, particularly for asymptomatic persons for whom the option of not testing must also be recognized.

BRUGADA SYNDROME

The Brugada syndrome is an autosomal dominant inherited channelopathy characterized by typical ECG changes (ST segment elevation or J waves) in the right precordial leads. Described in 1992, the syndrome is associated with a high incidence of SCD secondary to polymorphic VT or VF in the absence of structural heart disease.⁶³

Genetics of the Brugada Syndrome

The Brugada syndrome is a channelopathy that causes current dysfunction in multiple channels participating in the generation of the cardiac action potential. To date, mutations in 19 genes have been identified as associated with the Brugada phenotype (Table 31.11) with an autosomal dominant mode of transmission. These include genes related to the Na⁺ current (I_{Na}) and genes that affect L-type Ca²⁺ channels (I_{CaL}) or transient outward K⁺ channels (I_{to}). These channelopathies cause Brugada syndrome phenotype by attenuating I_{Na} , attenuating I_{CaL} , or enhancing I_{to} , resulting in an outward shift in the balance of current active during the early phases of the action potential in the right ventricular outflow tract (RVOT). The relationships between genotype and phenotype are not always predictive. Mutations in different genes can express similar Brugada syndrome phenotypes. Conversely, mutations in the same gene can lead to different syndromes.^{64,65}

More than 65% of Brugada syndrome probands remain genetically undetermined, which suggests that unknown mutations or pathophysiological cellular regulations (such as posttranslational modulations, phosphorylation, glycosylation) may also cause similar ion current defects and clinical manifestations.⁶⁶

Mutations Related to the Sodium Current

Most cases of the Brugada syndrome are attributable to loss-of-function mutations in the cardiac Na⁺ channel resulting in a reduction of the

inward Na⁺ current (I_{Na}). I_{Na} initiates the ventricular action potential, thereby controlling cardiac excitability and electric conduction velocity.

SCN5A is the first gene to be linked to Brugada syndrome. Loss-of-function mutations in the *SCN5A* gene (encoding the α subunit of the cardiac voltage-gated Na⁺ channel [Na_v1.5]) account for the vast majority (greater than 75%) of genotype-positive Brugada syndrome cases (but only 11% to 28% of total Brugada syndrome probands). A higher incidence of *SCN5A* mutations has been reported in familial than in sporadic cases.^{66,67}

So far, more than 300 Brugada syndrome-associated mutations have been described in the *SCN5A* gene. Some of these mutations result in loss of function due to impaired channel trafficking to the cell membrane, disrupted ion conductance, or altered gating function. Most of the mutations are missense mutations, whereby a single amino acid is replaced by a different amino acid. Missense mutations commonly alter the gating properties of mutant channels. Because virtually all reported *SCN5A* mutation carriers are heterozygous, mutant channels with altered gating can result in an up to 50% reduction of I_{Na}. Different *SCN5A* mutations can cause different degrees of I_{Na} reduction and, hence, different levels of severity of the clinical phenotype of the Brugada syndrome.⁶⁶

SCN5A loss-of-function mutations have also been linked to patients with progressive cardiac conduction system disease (Lev-Lenègre disease). Mutated *SCN5A* can also impede the closure (gain of function) of the Na⁺ channel, leading to type 3 LQTS (LQT3). It was reported that all three syndromes (Brugada syndrome, LQT3, and Lev-Lenègre disease)

occurred within a single family because of a single mutated *SCN5A* gene. Approximately 65% of mutations identified in the *SCN5A* gene are associated with the Brugada syndrome phenotype.

Compared with Brugada patients without an *SCN5A* mutation, those with *SCN5A* mutations generally exhibit longer and progressive conduction delays (PQ, QRS, and HV intervals), frequent occurrences of fragmented QRS complex, and ventricular arrhythmias of extra-RVOT origin.

In addition to *SCN5A* mutations, reduction in I_{Na} can be caused by mutations in *SCN1B* (encoding the β1- and β1b-subunits of the Na⁺ channel [Na_v1.5]), *SCN2B* (encoding the β2-subunit of the Na⁺ channel), and *SCN3B* (encoding the β3-subunit of Na_v1.5), resulting in the clinical phenotype of the Brugada syndrome.⁶⁶ Recently, *SCN10A* (which encodes Na_v1.8, a neuronal Na⁺ channel, which appears to play a role in the heart) was identified as a major susceptibility gene for Brugada syndrome (identified in 16.7% of probands). Loss of function mutations in *SCN10A* lead to significant reduction in I_{Na}. The majority of patients with *SCN10A* Brugada syndrome present with mixed phenotypes, the most common of which is progressive cardiac conduction system disease.⁶⁴

Furthermore, mutations in *GPD1L* (which encodes the protein glycerol-3-phosphate dehydrogenase 1-like [G3PD1L] protein) affect the trafficking of the cardiac Na⁺ channel to the cell surface, resulting in reduction of I_{Na} and Brugada syndrome. The Brugada phenotype associated with *GPD1L* mutations is characterized by progressive conduction disease, low sensitivity to procainamide, and a relatively good prognosis.⁶⁴

Mutations in several other genes have been reported to cause reduction in I_{Na} and lead to the Brugada phenotype, including *HEY2* (encoding the transcriptional factor HEY2), *FGF12* (encoding for a fibroblast growth factor homologous factor-1, which exerts modulatory effects on cardiac Na⁺ and Ca²⁺ channels), *PKP2* (encoding the desmosomal protein plakophilin-2, a known susceptibility gene for arrhythmogenic right ventricular cardiomyopathy [ARVC]), *RANGRF* (encoding MOG1, a protein known to modulate the Na⁺ channel), and *SLMAP* (encoding the sarcolemmal membrane-associated protein, SLMAP, a component of T-tubules and sarcoplasmic reticulum).⁶⁴

Mutations Related to the Calcium Current

Approximately 13% of cases of the Brugada syndrome are attributable to loss-of-function mutations in the cardiac Ca²⁺ channel resulting in a reduction of the depolarizing I_{CaL}. These include *CACNA1C* (which encodes the pore-forming α1C-subunit [Ca_v1.2] of the L-type voltage-gated Ca²⁺ channel), *CACNB2* (which encodes for the regulatory β2-subunit [Ca_vβ2] of Ca_v1.2, which modifies gating of I_{CaL}), and *CACNA2D1* (which encodes the regulatory α2δ-subunit of Ca_v1.2). In this setting, the mechanism of Brugada syndrome involves a reduction of the depolarizing I_{CaL}. Loss of function mutations in these genes are also reported to contribute to SQTs, idiopathic VF, and early repolarization syndrome.⁶⁵

Mutations Related to the Potassium Current

Gain-of-function mutations in *KCNE3* (which encodes the auxiliary β-subunit [MiRP2] of the transient outward K⁺ channel [K_v4.3]) and *KCND3* (which encodes the α-subunit of K_v4.3) result in an increase in I_{to} density and causes Brugada syndrome.

Furthermore, gain-of-function mutations in *SCN1B* (which encodes the auxiliary β1-subunit of the Na⁺ channel), in addition to reducing I_{Na}, can also increase I_{to}. In addition, mutations in *KCNJ8* (which encodes Kir6.1) can augment I_{KATP}, resulting in accentuation of the action potential notch as well as depression of the plateau, leading to Brugada syndrome phenotype. These mutations can also result in shortening of action potential duration and SQTs phenotype. Recently, mutations in *ABCC9*

(which encodes SUR2A, the adenosine triphosphate [ATP]-binding cassette transporter of the I_{KATP} channel) has been reported to cause Brugada phenotype by augmenting I_{KATP} , likely due to reduced channel sensitivity to the inhibitory effects of ATP.⁶⁴

Other Candidate Genes

New susceptibility genes recently proposed and awaiting confirmation include the transient receptor potential melastatin protein-4 gene (*TRPM4*, which encodes a calcium-activated nonselective cation channel) and the *KCND2* gene (which encodes the voltage-gated potassium channel subfamily D, $K_{4.2}$).⁶⁵

Other genetic variants were found to be capable of modulating, but not necessarily causing, the expression of Brugada syndrome by increasing I_{to} (*KCNE5*, which encodes one of the regulatory β -subunits of the I_{to} and I_{Ks} channels), or by increasing I_{Kr} (*KCNH2*, which encodes the α -subunit of the rapid delayed rectifier potassium channel [hERG]). Further, loss-of-function mutations in *HCN4* (encoding the hyperpolarization-activated cyclic nucleotide-gated channel 4 protein of the human cardiac pacemaker channel) can lead to reduction in the pacemaker current (I_f) and bradycardia, which can accentuate or unmask the Brugada syndrome phenotype.⁶⁴

Pathophysiology of the Brugada Syndrome

The mechanisms underlying the ECG changes and arrhythmogenesis in Brugada syndrome patients remain incompletely understood. Two hypotheses have been proposed: (1) the repolarization disorder hypothesis, based on transmural dispersion in repolarization of the RVOT; and (2) the depolarization disorder hypothesis, based on activation delay in the RVOT subepicardium. It is likely that a combination of the two mechanisms plays a role in the genesis of the ECG pattern and arrhythmogenicity and that both may coexist. Also, both hypotheses recognize a central role for the RVOT as a critical arrhythmogenic substrate in Brugada syndrome.⁶⁴

Repolarization Hypothesis

The ST-T wave changes in Brugada syndrome likely reflect a profound change in the process of ventricular repolarization, particularly in the relationship between the endocardial and epicardial repolarization processes. The cellular basis for this phenomenon is thought to be the result of loss of function of Na^+ channels (reduced I_{Na}) that differentially alters the action potential morphology in epicardial versus endocardial cells.

I_{to} is a prominent repolarizing current; it partially repolarizes the membrane, shaping rapid (phase 1) repolarization of the action potential, setting the height of the initial plateau (phase 2), and resulting in a pronounced action potential notch and, in combination with depolarizing Ca^{2+} currents, in a “spike-and-dome” action potential morphology. I_{to} channel densities are heterogeneously distributed across the myocardial wall and in different regions of the heart, being much higher in the right ventricle (RV) than in the left ventricle (LV), in the epicardium than in the endocardium, and nearer the base than the apex of the ventricles. These regional differences are responsible for the shorter duration, the prominent phase 1 notch, and the “spike and dome” morphology of RV epicardial and midmyocardial action potentials compared with endocardium and LV. A prominent I_{to} -mediated action potential notch in ventricular epicardium but not endocardium produces a transmural voltage gradient during early ventricular repolarization that registers as a J wave or J point elevation on the ECG (Fig. 31.9).^{68,69}

Na^+ channel malfunction and reduction of I_{Na} associated with the Brugada syndrome accentuate the notch produced by I_{to} , leading to partial or complete loss of the action potential dome, premature repolarization, and significant action potential shortening, presumably by

deactivation or voltage modulation that reduces I_{CaL} . These changes occur predominantly in regions where I_{to} is abundant (such as RVOT epicardium). In contrast, endocardial cells display a much smaller I_{to} and, consequently, I_{Na} reduction would not significantly affect action potential morphology and duration. This is likely to manifest on the ECG as an early repolarization pattern consisting of a J point elevation, slurring of the terminal part of the QRS, and mild ST segment elevation. A further increase in net repolarizing current can result in complete loss of the action potential dome in the RVOT epicardium, leading to more pronounced dispersion of repolarization (epicardial repolarization precedes repolarization in endocardial regions) and a transmural voltage gradient that manifests as greater ST segment elevation.^{68,69}

Depolarization Hypothesis

A growing body of evidence suggests that depolarization abnormalities related to ionic channelopathy and structural abnormalities in the RVOT contribute to the arrhythmogenic substrate underlying the Brugada syndrome.

The reduction in I_{Na} observed in Brugada syndrome linked to an *SCN5A* mutation leads to a reduction in the upstroke velocity of action potential phase 0, and, as a result, slowing in atrial and ventricular electrical conduction. This is often reflected by prolongation in AV and intraventricular conduction intervals (PR interval and QRS duration) on the ECGs of Brugada syndrome patients with an *SCN5A* mutation. Conduction slowing preferentially involves the RVOT, likely combined with ultrastructural abnormalities of the RVOT epicardium (interstitial fibrosis and altered expression of gap junction proteins). These depolarization abnormalities likely contribute to ST elevation, thus increasing the transmural gradient of the membrane potential.^{68,69}

The depolarization hypothesis is indirectly supported by several histological, imaging, ECG, and EP observations, including the presence of late potentials and fragmented electrograms recorded from the RVOT epicardium on high-density electroanatomical mapping, signal-averaged ECG, and body surface potential maps. Catheter ablation of these epicardial sites significantly reduced the arrhythmia vulnerability and ECG manifestation of the disease.^{68,69}

Mechanism of Ventricular Arrhythmias

The excessive increase in transmural dispersion of repolarization (between epicardium and endocardium) facilitates reentrant excitation waves between depolarized endocardium and prematurely repolarized epicardium. A significant outward shift in current can cause a prominent action potential notch causing more negative potentials during phase 1 of the action potential and loss of activation of I_{CaL} . As a consequence, loss of the action potential dome and marked abbreviation of the action potential develop in regions where I_{to} is prominent (epicardium) but not in other locations. The dome can then propagate from regions where it is maintained to regions where it is lost, giving rise to a very closely coupled extrasystole (phase 2 reentry) that in turn can initiate polymorphic VT or VF (Fig. 31.10).

Although the repolarization abnormalities facilitate the onset of polymorphic VT, it may be the depolarization disturbance (conduction slowing leading to wave break of the reentrant wave) that allows the VT to become sustained and to degenerate to VF. Because the RVOT is the critical area associated with depolarization and repolarization abnormalities, it is a frequent origin of VT and VF in the setting of Brugada syndrome.⁶⁴

Mechanism of Age and Gender Effects

The effects of age and gender on the Brugada syndrome phenotype (being more prevalent in adult males) may be due to intrinsic differences in Na^+ channel expression between men and women (e.g., higher

Fig. 31.9 Dispersion of Action Potential (AP) Repolarization in J Wave Syndromes. (A and B) Quantitation dispersion of AP and J wave parameters. (C) Measurement of dispersion of AP repolarization. (D) Measurement of dispersion of repolarization when the AP dome is lost at 1 epicardial (Epi) site but not the other. (From Gurabi Z, Koncz I, Patocskaï B, Nesterenko VV, Antzelevitch C. Cellular mechanism underlying hypothermia-induced ventricular tachycardia/ventricular fibrillation in the setting of early repolarization and the protective effect of quinidine, cilostazol, and milrinone. *Circ Arrhythmia Electrophysiol.* 2014;7:134–142.)

I_{to} densities in men) or due to differences in hormone levels (e.g., higher testosterone levels in men). The concentration of testosterone is reportedly higher in men with Brugada syndrome than in controls, and regression of the Brugada ECG pattern after castration in men with prostate neoplasia has been reported.

The phase 1 notch potentially mediates the effects of sex hormones on the phenotypic expressions of Na^+ channel dysfunction, thus contributing to the male predominance of Brugada syndrome. Estrogen suppresses the expression of the $K_v4.3$ channel, resulting in reduced I_{to} and a shallow phase 1 notch, whereas testosterone enhances the outward currents (I_{Kr} , I_{Ks} , I_{K1}) and reduces the inward current (I_{CaL}), thus deepening the phase 1 notch.

Mechanism of Temperature Sensitivity

Fever-induced Brugada is the term used to describe the aggravation of clinical and/or ECG characteristics of this syndrome during febrile states in susceptible individuals. In fact, fever has been reported to be

the precipitating factor of ventricular arrhythmias in 18% of cases in a large series of Brugada patients presenting with cardiac arrest. In one report, the prevalence of a type I Brugada ECG pattern in patients with fever was 20 times higher than in afebrile patients, emphasizing the potency of fever in uncovering this ECG phenomenon.⁷⁰

The exact mechanism by which fever triggers arrhythmias in Brugada syndrome remains unknown. It is possible that high temperatures result in worsening of the biophysical properties of the defective Na^+ channels, leading to further reduction of I_{Na} . Alternatively, fever-induced arrhythmias may be mediated by the effect of temperature on the normal (unaffected) channels. According to this model, normal Na^+ channels are less efficient at high temperatures, but this slight loss of function becomes clinically significant only in the presence of other factors that reduce the repolarization or depolarization reserve (e.g., heterozygosity with loss-of-function mutations). Of note, fever does not appear to prolong the PR interval or QRS duration as drug challenge does.⁷¹

Fig. 31.10 Potential Mechanism for Arrhythmogenesis in the Brugada and Early Repolarization Syndromes. (A) With enhanced repolarization in regions with prominent transient outward current (I_{to}), all-or-none repolarization can occur, creating a substrate for arrhythmias. (B) Simultaneous action potentials from two epicardial sites (Epi_1 and Epi_2) and one endocardial site ($Endo$), and surface electrocardiogram (ECG). A loss of the action potential dome in Epi_1 , but not in Epi_2 , leads to apparent propagation of the dome from Epi_2 to Epi_1 , inducing reentry. (From Benito B, Guasch E, Rivard L, Nattel S. Clinical and mechanistic issues in early repolarization of normal variants and lethal arrhythmia syndromes. *J Am Coll Cardiol*. 2010;56:1177–1186.)

Mechanism of Exercise-Induced Changes

Exercise can aggravate the ECG abnormalities in the Brugada syndrome, but does not appear to induce ventricular arrhythmia in these patients. The mechanisms underlying the ECG responses in the Brugada syndrome to exercise are complex, which may be related to different molecular-genetic mutations underlying the Brugada syndrome phenotype.

Brugada syndrome-linked loss-of-function mutations in *SCN5A* reduce I_{Na} more during tachycardia, likely secondary to accumulation of mutant Na^+ channels in the slow inactivated state. Na^+ channels activate on depolarization and inactivate within milliseconds thereafter. Before reopening, channels must recover from inactivation during diastole. At fast heart rates, the diastolic interval becomes too short for mutant channels to completely recover from the slow inactivated state, resulting in decreased availability of open channels and, as a consequence, accentuation of Na^+ channel loss of function produced by *SCN5A* mutations. Besides tachycardia associated with exercise, other factors (e.g., autonomic nervous system, ion current imbalances) also play a role.

Mechanism of Drug Effects

Pharmacological agents that primarily block I_{Na} but not I_{to} (flecainide, ajmaline, and procainamide) can further diminish I_{Na} that is already reduced by the Brugada mutations. This may explain the use of Na^+

channel blockers to unmask concealed forms of the Brugada syndrome and the potential proarrhythmic adverse effects of these and other pharmacological agents. In contrast, quinidine, in addition to blocking I_{Na} , has a relatively strong effect in blocking I_{to} . Hence, quinidine can effectively suppress ST elevation and ventricular arrhythmias in patients with the Brugada syndrome.

Beta-adrenergic stimulation augments the inward I_{CaL} and attenuates the excess of outward current, resulting in reduction of ST segment elevation in right precordial leads and potentially underlying the therapeutic benefit observed for isoproterenol infusion for prevention of ventricular arrhythmias in Brugada syndrome patients with electrical storm. In contrast, acetylcholine facilitates the loss of the action potential dome by suppressing I_{CaL} and/or augmenting K^+ current.

Epidemiology

The prevalence of the Brugada ECG pattern in an apparently healthy population varies depending on the demographics of the patient population studied, ranging from 0.017% in Europe and 0.005% to 0.1% in North America to 0.15% to 0.27% in Japan and 0.18% in the Philippines. However, because the Brugada ECG pattern can be intermittently present or concealed, it is difficult to estimate the true prevalence of the disease in the general population. For unclear reasons, the Brugada syndrome is either more prevalent or more penetrant in Eastern countries (mainly in Southeast Asia), where the disease occurs endemically and is the leading cause of death in men younger than 40 years.

The Brugada syndrome exhibits an autosomal dominant pattern of transmission with incomplete penetrance (i.e., the pathogenic mutation is inherited by 50% of the offspring, but not all will develop the disease). In up to 60% of patients the disease can be sporadic, that is, absent in parents and other relatives. A family history of unexplained SCD is present in approximately 20% to 40% of Brugada probands in Western countries and in a lower percentage of probands (15% to 20%) in Japan.⁶⁵

Although the disease is inherited as an autosomal dominant trait and the prevalence of gene carriers among males and females is similar, the vast majority of patients who actually develop symptoms are male (ratio of men to women, 8:1).

The age of onset of clinical manifestations (syncope or cardiac arrest) is the third to fourth decade of life (mean age of SCD occurrence, 41 ± 15 years). Brugada syndrome is rare in children and the elderly, but cases have been diagnosed in infancy and in patients in their 80s.^{64,72}

The prognosis of Brugada syndrome varies widely among patients with this disorder, ranging from benign to malignant. Patients with a history of cardiac arrest are at the highest risk of recurrent events (7.7% to 13.5% per year) in the absence of drug therapy.⁷³ The arrhythmic risk is intermediate (0.6% to 1.2% per year) for patients with “malignant” syncope, and small, but not trivial (0.5% per year) in asymptomatic patients.⁷⁴

Clinical Presentation

There are three main clinical presentations of the Brugada syndrome: (1) cardiac arrest secondary to polymorphic VT/VF; (2) syncope; and (3) no symptoms. Less frequently, patients can present with symptoms secondary to SND, AV conduction abnormalities, or supraventricular arrhythmias.

In contemporary practice, the majority (more than 60%) of Brugada syndrome patients are asymptomatic at the time of diagnosis, often discovered during routine evaluation (preoperative or before sports participation), family screening, or upon the observation of the abnormal ECG pattern during a febrile illness. Only a minority (less than 10% to 20%) of Brugada syndrome patients diagnosed today have a history of cardiac arrest, and about one-third present with syncope.⁶⁴

Symptoms associated with Brugada syndrome are related to polymorphic VT, VF. Cardiac arrest is often the first manifestation of arrhythmias in the Brugada syndrome. When the arrhythmia terminates spontaneously, patients can present with syncope, agonal respirations, nocturnal labored respiration with agitation, or “seizures.” About 25% of patients suffering from SCD had already experienced a syncopal episode.⁶⁵

The Brugada syndrome is a leading cause of SCD in men younger than 40 years of age, particularly in countries in which the syndrome is endemic. The Brugada syndrome is believed to be responsible for 4% to 12% of all SCDs, and at least 20% of those occurring in patients with structurally normal hearts. The Brugada syndrome has even been described as responsible for SIDS and sudden unexplained nocturnal death syndrome (SUNDS; also known as SUDS). Nevertheless, the majority of Brugada syndrome patients do not manifest life-threatening events; approximately 10% to 15% of clinically affected patients experience one or more cardiac arrests before age 60. In a meta-analysis of prognostic studies, patients with a Brugada ECG pattern have an approximately 10% risk of SCD, syncope, or ICD shock at an average follow-up time of 2.5 years, or approximately 3.8% per year. More recent data suggest a lower annual event rate (approximately 1.5%); the discrepancy is likely due to selection bias, as initial reports included patients at higher risk.⁶⁵

Cardiac arrhythmia and death in the Brugada syndrome seem to occur largely in the early morning hours during sleep and in the setting of bradycardia. Circadian variation of sympathovagal balance, hormones, and other metabolic factors are likely to contribute to this circadian pattern. Bradycardia resulting from altered autonomic balance or other factors likely contributes to the initiation of arrhythmia.

Some episodes of syncope or SCD can be triggered by large meals (gastric distention), alcohol and cocaine toxicity, drugs, and fever. In

fact, it now appears that many previously described episodes of “febrile seizures” may in fact represent bouts of polymorphic VT in patients with temperature-sensitive mutations. Some patients with the Brugada syndrome experience an electrical storm of VF, but with no obvious precipitating factors.

Syncope is common (28%) in patients with Brugada syndrome; however, a large proportion of those patients have nonarrhythmic (often vasovagal) causes of syncope. Clinical features allow distinction between suspected arrhythmogenic and nonarrhythmogenic causes of syncope in 70% of cases. The absence of prodromes, brief (less than 1 minute) loss of consciousness, and absence of specific triggers (e.g., hot and crowded surroundings, pain or other emotional stress, seeing blood, or prolonged standing) are suggestive of an arrhythmic etiology. Of note, palpitations are very common in patients with suspected nonarrhythmic syncope, likely because of the pronounced postural tachycardia occurring before an actual faint.⁷⁵

Approximately 20% of patients with Brugada syndrome develop supraventricular arrhythmias. AF is the most common, observed in 10% to 20% of patients, especially in those with more advanced disease. Atrioventricular nodal reentrant tachycardia and Wolff-Parkinson-White syndrome have also been reported.⁷⁶

The identification of concomitant AV and intraventricular conduction defects have been shown to correlate with the presence of *SCN5A* mutations. Therefore all *SCN5A*-positive patients should be closely monitored for the onset of conduction block.

Electrocardiographic Features

Brugada Electrocardiogram Patterns

Previously, three ECG repolarization patterns in the right precordial leads were recognized (Fig. 31.11). Type 1 is characterized by ST segment

Fig. 31.11 Brugada Electrocardiogram (ECG) Patterns. Note the ventricular ectopic beat in the left panel with a QRS morphology consistent with origin from the right ventricular outflow tract. See text for discussion.

elevation of at least 2 mm (0.2 mV) with a coved (downward convex) morphology, associated with an incomplete or complete right bundle branch block (RBBB) pattern and followed by a descending negative T wave, with little or no isoelectric separation. The type 2 pattern has a “saddleback” appearance with a high take-off ST segment elevation of at least 2 mm, a trough displaying an ST elevation greater than or equal to 1 mm, and then either a positive or biphasic T wave. The type 3 pattern has either a saddleback or coved appearance with an ST segment elevation of less than 1 mm. These three patterns can be observed spontaneously in serial ECG tracings from the same patient or after the introduction of specific drugs. Only the type 1 ECG pattern is diagnostic of the Brugada syndrome, with type 2 and type 3 ECG patterns being suggestive but not specific.⁶⁵

The most recent consensus statement recommended that only two Brugada ECG patterns be considered: type 1 (coved type) and type 2 (saddleback type). Given the minimal morphological differences between type 2 and 3 Brugada patterns and the lack of impact on prognosis and risk stratification, the new type 2 ECG pattern definition encompasses patterns 2 and 3 of the previous consensus. Type 1 remains identical to the classic type 1 described previously, but with some new measurements that may also help to quantify the difference in the r' wave morphology (Box 31.1; Table 31.12).^{77,78}

The ECG Brugada pattern type 1 with the above criteria is easily recognized; and when found in a patient without apparent structural heart disease, it is very specific and strongly supports the diagnosis of Brugada syndrome (see Box 31.1). The infrequent cases with a coved-type pattern that present a high takeoff of QRS-ST between 0.1 and 0.2 mV, but with negative T wave in leads V_1 - V_2 , have been considered suggestive of the type 1 Brugada pattern, and should be evaluated

with complementary ECG criteria testing to confirm the diagnosis (see Table 31.12).^{77,78}

Electrocardiogram Electrode Locations

The use of more cephalad placement of the right precordial (in the third or second intercostal spaces) can increase the sensitivity for detecting the Brugada ECG pattern (both in the presence or absence of a drug challenge), likely with no reduction in the specificity of the diagnosis. In fact, it has been reported that the superior displacement of V_1 - V_2 leads could reveal more than 20% of new Brugada syndrome cases. This is likely related to the normal projection of the RVOT (which harbors the abnormalities underlying the ECG changes) onto the anterior chest surface.^{79,80}

Therefore the standard position of leads V_1 - V_2 in the fourth intercostal space is not sufficient to exclude the presence of a Brugada ECG pattern; ECG recordings need to be obtained with the V_1 - V_2 electrodes positioned in the second and third intercostal spaces in all patients. Also, those electrodes should be positioned in the same diagnostic location when serial recordings are performed to allow comparative assessments.⁷⁹

Dynamicity of the Brugada Pattern

The ECG changes associated with the Brugada pattern can be dynamic, intermittent, and are sometimes concealed. In fact, it is rare for patients to present with uniformly diagnostic tracings. Therefore serial ECGs can be necessary for diagnostic evaluation in high-risk patients. Continuous Holter monitoring also can help assess ST segment elevation at night because such changes can be modified by autonomic tone.⁷⁷

BOX 31.1 ECG Alterations in Brugada Syndrome

ECG Diagnostic Criteria in Precordial Leads

- **Brugada pattern:** (usually, the pattern is seen only in leads V_1 - V_2 ; but in some cases, it is recorded only in V_1 or V_2 ; and, in others, it is observed from V_1 to V_3).
- **Type 1 Brugada pattern (coved pattern):** Initial ST elevation ≥ 2 mm, slowly descending and concave or rectilinear with respect to the isoelectric baseline, with negative symmetric T wave (see other characteristics in Table 31.12).
- **Type 2 Brugada pattern (saddleback pattern):** The high take-off terminal positive wave (r') is ≥ 2 mm with respect to the isoelectric line and is followed by ST elevation; convex with respect to the isoelectric baseline (saddleback pattern) with elevation ≥ 0.05 mV with positive/flat T wave in lead V_2 , and variable (mildly positive, flat, or mildly negative) T wave in lead V_1 . If there is some doubt (i.e., $r' < 2$ mm), it is necessary to record the ECG in the second and third intercostal space (see other characteristics in Table 31.12).
- New ECG criteria:
 - Corrado index (2010): The ratio between the peak height of the take-off of QRS-ST to the height of ST segment at 80 msec later in leads V_1 - V_2 is >1 (because the ST is downsloping). In athletes, the ST especially in lead V_2 is upsloping; hence, the index is <1 . The end of QRS (J point) often does not coincide with the high take-off of QRS-ST as was suggested by Corrado. However, using the high takeoff of QRS-ST for the application of the Corrado index is valid for discriminating the Brugada pattern and other conditions mimicking the Brugada pattern.

- The β angle formed by ascending S and descending r' is >58 degrees in the type 2 Brugada pattern (in athletes, it is much lower) (sensitivity, 79%; specificity, 84%).
- Duration of the base triangle of r' at 5 mm from the high takeoff is more than 3.5 mm in the type 2 Brugada pattern (sensitivity, 81%; specificity, 82%). This measurement is much shorter in healthy athletes with incomplete RBBB.

Other ECG Findings

- QT generally is normal but can be prolonged in right precordial leads.
- Conduction disorders: Sometimes, prolonged PR interval (long HV interval). The conduction delay located in the RV explains the r' and longer QRS duration in right precordial leads compared with mid/left precordial leads.
- Supraventricular arrhythmias. Mostly atrial fibrillation.
- Some other ECG findings may be seen: the presence of r' wave in lead aVR >3 mm, early repolarization pattern in inferior leads, fractioned QRS, alternans of T wave after ajmaline injection, etc.

Other ECG Techniques

- In some occasions, it is necessary or convenient to find some new diagnostic clues with exercise testing, late potentials, and impaired QT dynamics studied by Holter. Electrophysiological studies remain controversial for diagnosis and for risk stratification.

ECG, Electrocardiogram; RBBB, right bundle branch block; RV, right ventricle.

Modified from Bayés De Luna A, Brugada J, Baranchuk A, et al. Current electrocardiographic criteria for diagnosis of Brugada pattern: a consensus report. *J Electrocardiol*. 2012;45:433-442.

TABLE 31.12 Brugada Electrocardiogram Patterns in Leads V_1 - V_2 **Type 1: Coved Pattern**

High takeoff

Characteristics of the typical coved pattern in leads V_1 - V_2 :

- At the end of QRS, an ascending and quick slope with a high takeoff ≥ 2 mm followed by concave or rectilinear downsloping ST. There are few cases of coved pattern with a high takeoff between 1 and 2 mm.
- There is no clear r' wave.
- The high takeoff often does not correspond with the J point.
- At 40 msec of high takeoff, the decrease in amplitude of ST is ≤ 4 mm (≤ 0.4 mV). This is much less than the decrease observed in right bundle branch block because the downslope is slower.
- ST at high takeoff $>$ ST at 40 msec $>$ ST at 80 msec.
- ST is followed by negative and symmetric T wave
- QRS duration "mismatch:" The QRS duration is longer in V_1 - V_2 than in mid/left precordial leads (because of evidence of RV conduction delay), although this is sometimes difficult to determine.

Type 2: Saddleback PatternCharacteristics of the typical saddleback pattern in leads V_1 - V_2 :

- High takeoff of r' (that often does not coincide with J point) ≥ 2 mm.
- Descending arm of r' coincides with beginning of ST (often is not well seen).
- Minimum ST ascent ≥ 0.5 mm
- ST is followed by positive T wave in lead V_2 (Tpeak $>$ ST minimum > 0) and of variable morphology in lead V_1 .
- The characteristics of triangle formed by r' allow definition of different criteria useful for diagnosis.
 - β angle > 58 degrees
 - Duration of the base of the triangle of r' at 5 mm from the high takeoff greater than 3.5 mm
- The duration of QRS is longer in the type 2 Brugada pattern than in other cases with r' in lead V_1 , and there is a mismatch between V_1 and V_6 .

From Bayés De Luna A, Brugada J, Baranchuk A, et al. Current electrocardiographic criteria for diagnosis of Brugada pattern: a consensus report. *J Electrocardiol.* 2012;45:433–442.

When concealed, the ECG manifestations of the Brugada syndrome can be unmasked by stress, fever, various vagal stimuli (including gastric distention), vagotonic agents, a combination of glucose and insulin, electrolyte abnormalities (e.g., hyperkalemia, hypokalemia, hypercalcemia, hyponatremia), alcohol and cocaine toxicity, class I antiarrhythmic medications, and a number of other noncardiac medications.⁸¹

Furthermore, the ECG phenotype in the Brugada syndrome can be modified by autonomic changes. Adrenergic stimulation attenuates whereas acetylcholine accentuates the ECG abnormalities in affected individuals. Clinically, this correlates well with the propensity for cardiac events to occur at rest or during sleep.

QT Interval Prolongation

A slight prolongation of the QT interval is sometimes observed in association with ST segment elevation in patients with the Brugada syndrome. The QT interval is prolonged more in the right precordial leads than it is in the left leads, presumably because of a preferential prolongation of action potential duration in RV epicardium secondary to accentuation of the action potential notch.⁷⁸

QRS Fragmentation

In addition to the repolarization abnormality, the Brugada syndrome is associated with depolarization abnormalities and conduction disturbances. Fragmentation of the QRS complex (manifesting as multiple small spikes within the QRS complex) can be observed in 40% of patients with the Brugada syndrome and in the majority (85%) of those who had VF episodes. It has been proposed that the multiple

spikes within the fragmented QRS complex suggest the presence of an arrhythmogenic substrate that has multiple areas of conduction slowing, and can potentially predict a high risk of life-threatening ventricular arrhythmias. Notably, fragmentation of the QRS occurs preferentially in the right precordial leads, especially in the higher intercostal spaces, suggesting a localized conduction abnormality within the RVOT region. The use of a low-pass filter with a low cutoff frequency (greater than 25 Hz), as commonly employed to remove the electromyogram signal, can eliminate the QRS fragmentation. Thus a low-noise amplifier and a relatively high cutoff low-pass filter frequency (150 Hz) need to be used.⁷⁸

Of note, epsilon-like waves and localized prolongation of the QRS complex in the right precordial leads have been observed in some patients with a spontaneous or drug-induced type 1 Brugada ECG pattern, likely reflecting RV activation delay.

Conduction Abnormalities

Depolarization abnormalities, including prolongation of P wave duration, PR interval, and QRS duration, are frequently observed, particularly in patients with *SCN5A* mutations. PR interval prolongation likely reflects infranodal conduction delay. Of note, loss-of-function *SCN5A* mutations can also lead to isolated cardiac conduction defects or Lev-Lenègre disease, characterized by disturbances in any part of the conduction system without QT interval prolongation or Brugada ST segment elevation. In addition, prolonged sinus node recovery time and sinoatrial conduction time, slowed atrial conduction, and atrial standstill have been reported in association with the Brugada syndrome.⁷⁸

Diagnosis of the Brugada Syndrome

The 2013 consensus report recommended that Brugada syndrome is definitively diagnosed when a type 1 ECG pattern is observed, either spontaneously or after provocative drug testing (with IV administration of a sodium channel blocker such as ajmaline, flecainide, pilsicainide, or procainamide), in at least one right precordial lead (V_1 or V_2), placed in a standard or a superior position (i.e., in the fourth, third, or second intercostal space) (Fig. 31.12).^{1,82}

Although symptoms are no longer mandatory for diagnosis according to the consensus report, several investigators have suggested that when a type 1 ECG pattern is unmasked using a sodium channel blocker, a definitive diagnosis of Brugada syndrome should require that the patient also present with either symptoms (cardiac arrest, agonal nocturnal respiration, documented polymorphic VT or VF, or unexplained syncope) or positive family history (unexplained SCD at age younger than 45 years or diagnosed Brugada syndrome in a first-degree relative). Inducibility of VT/VF with 1 or 2 ventricular extrastimuli (VESs) at EP study supports the diagnosis of Brugada syndrome under these circumstances.^{65,77,82}

The type 2 Brugada ECG pattern is suspicious, but not diagnostic for Brugada syndrome, and requires further investigation. A drug challenge test to unmask a type 1 Brugada ECG pattern is recommended in those individuals only when the type 2 ECG pattern is accompanied by symptoms or positive family history, as specified above.⁶⁵

A diagnostic score system for Brugada syndrome (the Shanghai Brugada syndrome score, (Table 31.13) has been proposed based on the available literature, but validation by large-scale trials is lacking.⁶⁵

Provocative Drug Testing

Provocative testing with Na^+ channel blockers is used to unmask a Brugada ECG pattern in nondiagnostic cases (e.g., unexplained cardiac

arrest, unexplained syncope, or family screening). Up to 30% to 50% of the patients are diagnosed with Brugada syndrome after a positive drug challenge. Provocative drug testing is generally not performed if a patient displays an intermittently spontaneous type 1 ECG because the test does not offer additional diagnostic or prognostic value in these patients, and it is not devoid of risk for provoking arrhythmic events. It is also important to recognize that a negative provocative drug test does not exclude a latent form of Brugada syndrome.

The drug challenge test involves administration of ajmaline, flecainide, procainamide, or pilsicainide (Table 31.14) under close cardiac monitoring and in a setting that is fully equipped for resuscitation. The drug challenge test is terminated when (1) the diagnostic type 1 ST segment elevation develops (Fig. 31.13), (2) the ST segment elevation in the type 2 ECG pattern increases by at least 2 mm, (3) PVCs or other arrhythmias develop, or (4) the QRS widens by 30% or more.

Although the drug challenge test is considered safe if performed in a controlled environment, it can potentially precipitate malignant cardiac arrhythmias or advanced AV block, particularly in patients with pre-existing AV or intraventricular conduction abnormalities. Ventricular arrhythmias during or shortly after drug challenge have been reported in 0.3% to 15% of the tests, but are predominantly nonsustained and self-terminating. Sustained ventricular arrhythmias occur in about 1.8% of the patients during ajmaline challenge. Notably, such an occurrence in patients with Brugada syndrome does not appear to identify a category at higher risk of spontaneous arrhythmic events. Isoproterenol and sodium lactate can be effective antidotes in this setting.

The different Na^+ channel blockers exhibit different efficacies in unmasking the Brugada pattern ECG, mostly secondary to the different potency of inhibition of I_{to} and I_{Na} . Data suggest that ajmaline (a class IA Na^+ channel blocker) is the most efficacious and is likely safer than others because of its shorter half-life and stronger rate-dependent Na^+ channel blocking effects. In *SCN5A*-positive subjects with Brugada

Fig. 31.12 Diagnosis of the Brugada Electrocardiogram (ECG) Patterns. ECG leads V_1 and V_2 are shown. (A) Single-lead covered-type ECG exceeding 2 mm only in the third intercostal space (ICS). (B) Single-lead covered-type ECG exceeding 2 mm only at baseline and further accentuated upon 1 mg/kg ajmaline; in (A) and (B) Brugada syndrome can be diagnosed according to 2013 criteria. (C) Incomplete right bundle branch block with minimal ST segment abnormalities at baseline that are converted to a coved pattern after ajmaline, but ST segment elevation remains less than 2 mm. In this case the challenge is considered negative. Horizontal blue lines represent 2 mm. (From Curcio A, Mazzanti A, Bloise R, et al. Clinical presentation and outcome of Brugada syndrome diagnosed with the new 2013 criteria. *J Cardiovasc Electrophysiol*. 2016;27:937–943.)

TABLE 31.13 Proposed Shanghai Score System for Diagnosis of Brugada Syndrome

	Points
I. ECG (12-Lead/Ambulatory)	
A. Spontaneous type 1 Brugada ECG pattern at nominal or high leads	3.5
B. Fever-induced type 1 Brugada ECG pattern at nominal or high leads	3
C. Type 2 or 3 Brugada ECG pattern that converts with provocative drug challenge	2
<i>Only award points once for highest score within this category. One item from this category must apply.</i>	
II. Clinical History	
A. Unexplained cardiac arrest or documented VF/polymorphic VT	3
B. Nocturnal agonal respirations	2
C. Suspected arrhythmic syncope	2
D. Syncope of unclear mechanism/unclear etiology	1
E. Atrial flutter/fibrillation in patients <30 years without alternative etiology	0.5
<i>Only award points once for highest score within this category.</i>	
III. Family History	
A. First- or second-degree relative with definite BrS	2
B. Suspicious SCD (fever, nocturnal, Brugada aggravating drugs) in a first- or second-degree relative	1
C. Unexplained SCD <45 years in first- or second-degree relative with negative autopsy	0.5
<i>Only award points once for highest score within this category.</i>	
IV. Genetic Test Result	
A. Probable pathogenic mutation in BrS susceptibility gene	0.5
Score (requires at least one ECG finding)	
≥3.5 points: Probable/definite BrS	
2–3 points: Possible BrS	
<2 points: Nondiagnostic

TABLE 31.14 Drugs Used to Unmask Brugada Electrocardiogram Pattern

Drug	Dose
Ajmaline	1 mg/kg IV infusion over 10 min
Flecainide	2 mg/kg IV infusion over 10 min, maximum 150 mg; or 200–300 mg oral
Procainamide	10 mg/kg IV infusion over 10 min
Pilsicainide	1 mg/kg IV infusion over 10 min

IV, Intravenous.

syndrome and their relatives, ajmaline was reported to have a sensitivity of 80% and a specificity of 94%. Flecainide has been shown to have a lower efficacy compared with ajmaline, likely due to a greater inhibition of I_{to} . Pilsicainide, a pure class IC drug, is believed to be more potent than flecainide. The class IA Na^+ channel blocker procainamide is traditionally regarded as the least potent, likely due to a more rapid dissociation of the drug from the Na^+ channels resulting in comparatively less inhibition of I_{Na} . The choice of Na^+ channel blocker used, however,

is usually based on availability. Procainamide remains the only choice for IV pharmacological induction protocols in the United States.^{83,84}

Of note, the response to flecainide infusion exhibits time-dependent variability of ECG patterns and intervals. Although most of the induced type I ECG patterns are observed during the first 30 minutes of the initiation of provocative testing, a recent study showed that extended periods of recording time (100 to 120 minutes) increased the percentage of positive testing from 12% to 19%.⁸⁵

Signal-Averaged Electrocardiography

Signal-averaged ECG demonstrates late potentials in approximately 60% to 70% of clinically affected Brugada syndrome patients. In this setting, late potentials can be a clinical marker of the disease, representing the delayed second upstroke of the epicardial action potential, a local phase 2 reentry (failing to trigger transmural reentry), or an intraventricular conduction delay.⁶⁴

Exercise Testing

Treadmill exercise testing can potentially aggravate the ECG abnormalities in the Brugada syndrome, including widening of the QRS, prolongation of the QTc duration, and augmentation of precordial peak ST segment elevation (which reaches its maximal amplitude during the early phase of recovery from exercise). Nonetheless, exercise was not found to induce ventricular arrhythmias in Brugada patients.⁸⁶

Genetic Testing

Genetic testing is recommended to support the diagnosis in patients manifesting the clinical phenotype of the Brugada syndrome. Although the knowledge of a specific mutation may not provide guidance for determining prognosis or treatment in the index patient, identification of a disease-causing mutation in the family can lead to genetic identification of at-risk family members who are clinically asymptomatic and who may have a normal ECG. However, it is important to remember that a negative result of genetic testing does not exclude the presence of the disease and, therefore, only a positive genetic diagnosis is informative. Genetic screening of *SCN5A* in unselected patients with a diagnosis of Brugada syndrome has low yield (less than 30%) and may not be cost-effective. The yield of genotyping increases substantially in patients with type 1 Brugada ECG pattern and prolonged PR interval, suggesting that this subset of patients with Brugada syndrome should be screened.⁶⁴

Genetic testing is not recommended in the setting of an isolated type 2 Brugada ECG pattern. It is important to recognize that genetic testing can produce “false-positive” results. Although *SCN5A* mutations are the most common genetic cause of Brugada syndrome, *SCN5A* genetic testing is complicated by an approximately 3% to 5% “benign” variant frequency in the general population.⁶⁵

Electrophysiological Testing

In patients with Brugada syndrome, EP testing may be considered for: (1) risk stratification to guide ICD implantation decisions in patients who have no history of cardiac arrest (including asymptomatic patients and those presenting with syncope); (2) evaluation of the efficacy of quinidine to suppress inducibility of VF in patients with inducible VF who do not prefer ICD therapy; and (3) assessment of sinus node function, conduction disturbances, and inducibility of supraventricular arrhythmias in patients with syncope.⁸⁷

Differential Diagnosis

Acquired Brugada Phenotype

ECG patterns identical to the type 1 or type 2 Brugada pattern can be seen in the absence of known genetic factors and family history. Some

Fig. 31.13 Provocative Drug Testing to Unmask Brugada Electrocardiogram (ECG) Pattern. (A) ECG showing type 3 Brugada ECG pattern at baseline. (B) Type 1 Brugada ECG pattern developed post administration of flecainide.

investigators have labeled these “phenocopies,” indicating that they mimic the phenotype without a genetic predisposition. These acquired forms of Brugada phenotype can be elicited by a variety of pathological and physiological conditions (e.g., acute ischemia, pericarditis, myocarditis, pulmonary embolism, metabolic disorders, acidosis, ionic abnormalities, cocaine ingestion, some drugs, surgical RVOT manipulation) and disappear upon resolution of the underlying condition (Box 31.2). Characteristically, these patients lack symptoms, medical history, and family history suggestive of the true Brugada syndrome. Also, the ECG returns to normal upon resolution of the inciting environmental factors.²⁰

In some doubtful cases of type 2 Brugada pattern, provocative testing with a Na^+ channel blocker is recommended, which is typically negative in Brugada phenocopies.⁷⁷ Genetic testing may also be considered to rule out true Brugada syndrome, although it should be recognized that a negative genetic test result does not exclude the congenital Brugada syndrome.⁷⁸

Drug-Induced Brugada Electrocardiogram Pattern

A variety of pharmacological agents have been implicated in drug-induced Brugada ECG phenotype, although the likelihood of arrhythmias is unclear. In general, factors that increase outward currents (e.g., I_{to} , I_{KATP} , I_{Kr} , I_{Ks}) or decrease inward currents (e.g., I_{Na} , I_{CaL}) at the end of phase 1 of the action potential can potentially accentuate or unmask ST segment elevation similar to the ECG pattern observed in patients with the Brugada syndrome.³⁹

Among antiarrhythmic drugs, class IC agents (flecainide, propafenone, pilsicainide) and class IA drugs (ajmaline and procainamide) most effectively amplify or unmask ST segment elevation. On the other hand, class IB antiarrhythmic drugs (lidocaine, mexiletine) block fast I_{Na} primarily at fast heart rates (because of the rapid dissociation of these drugs from Na^+ channels). Therefore these drugs have little or no effect on fast I_{Na} at moderate or slow heart rates.³⁹

Several noncardiac drugs can potentially induce a Brugada-like ECG pattern secondary to block of I_{Na} , including psychotropic drugs, lithium, and cocaine. In addition, verapamil, H1 antihistamines, propofol, alcohol intoxication, vagomimetic agents, and beta-blockers and potentially nitrates can induce a Brugada-like ECG pattern (Table 31.15). Drug-induced Brugada syndrome from noncardiac drugs occurs predominantly in adult males, is frequently due to drug toxicity, and occurs late after the onset of therapy. However, the likelihood of drug-induced Brugada syndrome is difficult to predict in routine clinical practice.⁸⁸

Na^+ channel blocker provocation testing, family screening for Brugada syndrome, and possibly genetic analysis may be performed in a subject with an acquired form of Brugada ECG phenotype by noncardiac agents. Subjects with drug-induced Brugada syndrome by noncardiac agents should be advised to avoid the majority of class I and class III antiarrhythmic agents as well as beta-blockers and calcium channel blockers. Rigorous treatment of fever, a well-known trigger of arrhythmic events in Brugada syndrome, is also advised in subjects with an acquired Brugada syndrome ECG pattern by noncardiac agents.⁸⁹

BOX 31.2 Conditions Associated With Brugada-Like Electrocardiogram Pattern

Acute Conditions

- Acute pericarditis/myocarditis
- Acute myocardial ischemia or infarction (especially of the right ventricle)
- Pulmonary thromboembolism
- Prinzmetal angina
- Dissecting aortic aneurysm
- Hypothermia
- Postdefibrillation electrocardiogram
- Metabolic disorders
- Electrolyte abnormalities

Persistent Conditions

- Atypical right bundle branch block
- Left ventricular hypertrophy
- Early repolarization
- Athlete's heart
- Central and autonomic nervous system abnormalities
- Duchenne muscular dystrophy
- Friedreich ataxia
- Spinobulbar muscular atrophy
- Myotonic dystrophy
- Arrhythmogenic right ventricular dysplasia
- Chagas disease
- Mechanical compression of the right ventricular outflow tract (e.g., pectus excavatum, mediastinal tumor, hemopericardium)

Modified from Antzelevitch C, Yan GX, Ackerman MJ, et al. J-wave syndromes expert consensus conference report: emerging concepts and gaps in knowledge. *Heart Rhythm*. 2016;13:e295–e324.

TABLE 31.15 Drug-Induced Brugada Electrocardiogram Pattern

Drug Group	Example(s)
Class IC antiarrhythmic drugs	Flecainide, propafenone, pilsicainide
Class IA antiarrhythmic drugs	Ajmaline, procainamide, disopyramide
Calcium channel blockers	Verapamil, diltiazem, nifedipine
Beta-blockers	Propranolol
H1-Antihistamines	Dimenhydrinate
Tricyclic antidepressants	Amitriptyline, nortriptyline, desipramine
Tetracyclic antidepressants	Maprotiline
Selective serotonin reuptake inhibitors	Fluoxetine
Phenothiazines	Perphenazine, trifluoperazine
Local anesthetics	Bupivacaine
Other drugs	Lithium, nitrates, propofol

Whether the “acquired” form of Brugada syndrome unmasks clinically inapparent Brugada syndrome (“forme fruste”) or merely represents one end of a broad spectrum of responses to Na⁺ channel blockers is not known. The prognosis for asymptomatic patients with a drug-induced Brugada ECG pattern, but without a family history of SCD, appears to be benign once the offending agent is discontinued, provided the full-blown Brugada syndrome is not uncovered.⁸²

Conditions Associated With Right Precordial ST Elevation

A variety of pathophysiological conditions are associated with distinct right precordial abnormalities on the ECG that need to be distinguished

from the type 1 or type 2 Brugada ECG pattern. These include RBBB, LV hypertrophy, early repolarization, athlete's heart, and ARVC.

Right bundle branch block. Complete RBBB and the type 1 Brugada pattern are characterized by the presence of positive terminal deflections of the QRS and negative T waves in leads V₁-V₂. It is possible to distinguish between the two entities on the basis of the following^{77,78}:

1. The positive terminal r' wave is peaked in RBBB (β angle less than 58 degrees). Conversely, the high takeoff of r' in the Brugada pattern is rounded, wide, and usually of relatively low voltage, with a gradual slope of the descending arm of r'.
2. The terminal wave (r' or R') in RBBB observed in leads V₁-V₂ is synchronous with the broad S wave observed in leads I and V₆, and the QRS complex duration in leads V₁-V₂ is identical to that observed in lead V₆. In contrast, the QRS duration in the Brugada syndrome is longer in leads V₁-V₂ than in mid/left precordial leads (“QRS duration mismatch”) because the terminal deflection observed in lead V₁ (the r' wave overlying the RVOT) is not recorded by the V₆ electrode.
3. The ST segment in RBBB is not elevated in the right precordial leads.

Healthy athletes. Although lead V₁ in athletes can exhibit an r' wave, this wave is usually peaked and sharp (β angle less than 58 degrees) with no or only mild ST elevation (less than 1 mm), and the ST segment starts after the clear end of QRS and is often followed by a negative and sometimes deep T wave in lead V₁. Furthermore, the ST segment elevation observed in healthy athletes is upsloping, especially in lead V₂ (Corrado index less than or equal to 1).^{77,78}

Pectus excavatum. Mechanical compression of the RVOT in the setting of pectus excavatum can produce right precordial ECG abnormalities mimicking the Brugada pattern. The ECG pattern observed in pectus excavatum usually presents a narrow, very well defined r' wave in lead V₁, followed by a slight ST segment elevation. The T wave is usually negative or positive/negative in lead V₁ and positive in lead V₂.⁷⁸

Arrhythmogenic right ventricular cardiomyopathy. ARVC can produce repolarization and depolarization ECG abnormalities than can occasionally mimic the Brugada pattern. The depolarization abnormalities are caused by cellular uncoupling and altered tissue architecture due to fibrofatty infiltration, and typically manifest on the ECG as epsilon waves, RBBB, QRS fragmentation, localized QRS widening, and terminal S wave prolongation in right precordial leads. Repolarization abnormalities typically manifest as T wave inversion in the right precordial leads. T wave inversion in ARVC is observed in several precordial leads (V₁ to V₃-V₅), and not limited to leads V₁-V₂ as seen in the Brugada syndrome. In addition, the ECG pattern in ARVC is always fixed, in contrast to the dynamic Brugada pattern.⁷⁸

Although positive late potentials can be observed on signal-averaged ECG in both Brugada syndrome and ARVC, the prevalence is much higher in ARVC, and wavelet analysis demonstrates that the frequency level is higher in ARVC.^{77,78}

Risk Stratification

As noted, the risk of arrhythmic events varies widely among patients with Brugada syndrome, and is highest in patients with a history of cardiac arrest and intermediate in those with syncope. The risk of life-threatening arrhythmic events in patients who are asymptomatic when diagnosed is small, but not trivial (0.5% to 1.5% per year); therefore these patients are the main target of risk stratification strategies. However, risk stratification in these patients remains difficult because the event rate is low but the presenting symptom is often cardiac arrest.⁷⁴

Several criteria have been proposed for selecting asymptomatic patients with Brugada syndrome prone to a significant risk of malignant ventricular arrhythmias (Box 31.3). Gender, multiple ECG parameters,

BOX 31.3 Established and Potential Markers of Risk in Brugada Syndrome

Clinical Markers

- Aborted SCD
- Documented VT/VF
- Syncope likely due to VT/VF
- Nocturnal agonal respiration
- Male gender

Electrocardiogram Markers

- Spontaneous type 1 Brugada ECG pattern
- Early repolarization pattern in the inferolateral leads
- Increased Tpeak-Tend interval
- Fragmented QRS
- Prominent R wave in lead aVR
- Prominent S wave in lead I
- QRS duration ≥ 90 msec in lead V_6
- r-J interval ≥ 90 msec in lead V_2
- QRS duration ≥ 120 msec in lead V_2
- Late potentials on epicardial bipolar electrogram or signal-averaged ECG

Electrophysiological Markers

- Inducible VT/VF
- Short ventricular refractory period < 200 msec

ECG, Electrocardiogram; SCD, sudden cardiac death; VF, ventricular fibrillation; VT, ventricular tachycardia.

and VT/VF inducibility by programmed electrical stimulation have been reported to be useful in identifying high-risk patients; however, individual prediction performances of these parameters are limited. The presence of multiple independent risk factors likely provides additive prognostic information. Nevertheless, it is important to recognize that risk stratification in asymptomatic patients with Brugada syndrome has been a matter of continuous controversy.^{74,73}

Cardiac Arrest

Patients with a history of cardiac arrest are at the highest risk of recurrent events (35% at 4 years, 44% at 7 years, and 48% at 10 years). In a meta-analysis, the annual rate of arrhythmic events or SCD in these patients was estimated at 13.5%. The mean time from presentation to VF recurrence is 1.5 to 2 years, but late recurrence (5 years after the initial event) also can happen.⁷³

Syncope

Unexplained syncope (presumed to be of arrhythmogenic etiology, based on clinical characteristics) is considered a risk marker in patients with a spontaneous type I ECG at baseline (without conditions known to unmask the signature sign, i.e., drugs and fever).¹ In these patients, the risk of arrhythmic events during follow-up appears to be intermediate: about four times higher than the risk of asymptomatic patients but four times lower than that of patients presenting with cardiac arrest. In contrast, “nonarrhythmogenic” syncope (such as neurocardiogenic syncope, which is relatively common in Brugada patients) does not predict an increased arrhythmic risk. Therefore it is important to obtain a detailed clinical history because clinical features allow distinction between suspected arrhythmogenic and nonarrhythmogenic causes of syncope in 70% of cases.⁷⁵ Current guidelines state that ICD implantation can be useful in patients with a spontaneous type I ECG who have a history of syncope presumed to be of arrhythmic origin.⁷³

Gender

Male gender has consistently been shown to be associated with more arrhythmic events. However, male predominance is also observed in asymptomatic patients, which leads to a nonsignificant association with SCD.⁷³

Family History

Familial forms of the Brugada syndrome do not appear to be associated with a worse prognosis than are sporadic cases. In other words, a positive family history of Brugada syndrome does not predict outcome. Similarly, a positive family history for SCD is not a reliable predictor for poor outcome in asymptomatic patients with Brugada syndrome.

Genotype

Large registries have not found an association between specific genetic mutations and the risk of VF. Therefore genetic testing is not recommended for the sole purpose of risk stratification.⁷³

Invasive Electrophysiological Testing

The value of inducibility of ventricular arrhythmias by programmed stimulation as a predictor of poor outcome has been debated and remains unresolved. VF or sustained polymorphic VT can be induced in approximately 50% to 70% of Brugada patients during EP testing. Although large registries agree that VT/VF inducibility at EP study is greatest among Brugada syndrome patients with previous cardiac arrest or syncope, different studies arrived at different conclusions regarding the value of the EP testing for risk stratification in asymptomatic patients. These discrepancies are likely the result of differences in patient characteristics, subtle differences in the diagnostic criteria, and the use of nonstandardized or noncomparable stimulation protocols.

It is important to recognize that VF can be induced by programmed electrical stimulation in 6% to 9% of apparently healthy individuals and can represent a false-positive and nonspecific response, particularly when aggressive stimulation protocols are used. Limiting programmed ventricular stimulation to a maximum of two extrastimuli (while disregarding the induction of VF with three extrastimuli) delivered only from the RV apex (while avoiding pacing from the RVOT) has been suggested to increase the specificity of EP testing in Brugada patients. Although a negative study is a sign of good prognosis, the yield of a positive study remains controversial. Current guidelines consider the use of ventricular arrhythmia inducibility at EP study as an indication for ICD implantation in asymptomatic patients a class IIb indication.^{73,90}

In one report, a short ventricular effective refractory period (less than 200 milliseconds) was found to be a significant risk marker, but its use for clinical decision making awaits corroboration by further studies.

Electrocardiographic Parameters

Type 1 Brugada ECG pattern. In asymptomatic patients, spontaneous type 1 Brugada ECG pattern (recorded in whichever intercostal space) is a risk marker for fatal arrhythmias (0.5% to 0.8% per year), while the event rate of patients with drug-induced type 1 ECG is much lower (less than or equal to 0.35% per year). This observation is true for asymptomatic patients and for patients presenting with syncope.⁷³

A recent report found that the presence of a type 1 ECG pattern conferred a 3.5-fold increased risk of arrhythmic events in previously asymptomatic subjects. Because the Brugada ECG pattern is highly variable over time, it is imperative to obtain serial 12-lead ECG Holter recordings (at the fourth, third, and second intercostal spaces) to detect a spontaneous ECG pattern in asymptomatic subjects.⁷³

The risk of arrhythmic events in patients with fever-induced type 1 ECG pattern appears to be affected by the clinical presentation: the

annual event rate was 3.0% in patients with a history of VF, 1.3% in patients with a history of syncope, and 0.9% in asymptomatic patients.

Type 2 Brugada ECG pattern. Patients with a type 2 ECG pattern that did not convert to type 1 during drug challenge testing were found to have a good prognosis. However, in a recent report, the prognosis of probands with a type 2 Brugada ECG pattern (even after challenge with a Na⁺ channel blocker) was similar to that of patients with spontaneous or drug-induced type 1 ST elevation. Patients presenting with aborted cardiac arrest had a grim prognosis (annual rate of arrhythmic events of 10.6%), whereas those presenting with syncope or no symptoms had an excellent prognosis (annual rate of arrhythmic events less than or equal to 1.2%) irrespective of their ECG pattern (that is, type 1 vs. non-type 1). Also, a family history of SCD at an age younger than 45 years and coexistence of early repolarization in the inferolateral leads (observed in 8% to 11% of Brugada patients) were predictors of poor outcome. In contrast, VT/VF inducibility during programmed stimulation was not a predictor of outcome. Furthermore, men with a spontaneous type 1 ECG recorded only at the higher leads V₁ and V₂ showed a prognosis similar to that of men with a type 1 ECG when using standard leads.

Early repolarization. The prevalence of early repolarization in inferolateral leads is relatively high (11% in one report) among Brugada patients, and it appears to be associated with a worse outcome in both symptomatic and asymptomatic patients. The location of J waves in the inferior and lateral leads and horizontal ST segment morphology after the J wave may be related to a highly arrhythmogenic substrate in patients with Brugada syndrome.

Interval between the peak and the end of the T wave. The time interval between the peak and the end of the T wave (Tp-e interval) is thought to represent the difference in repolarization times between subendocardial and subepicardial myocardial cells and has been proposed as an ECG marker of transmural dispersion of repolarization when measured in the precordial leads. An increased Tp-e interval in the precordial leads has been shown to identify patients at higher risk of malignant arrhythmic events in various settings.⁹¹

The Tp-e interval was shown to be significantly longer from lead V₁ to V₄ in patients with Brugada syndrome presenting with malignant ventricular arrhythmia or syncope than in asymptomatic patients. A maximum Tp-e interval of at least 100 milliseconds in the precordial leads has been found to be highly and independently related to arrhythmic events in a large series of unselected patients with Brugada syndrome.⁹²

Furthermore, Tp-e interval dispersion (defined as the difference between the maximum and the minimum value of the Tp-e interval in leads V₁-V₆) has been reported to be useful in identifying high-risk patients.⁷⁴

S wave in lead I. The presence of a deep (greater than 0.1 mV) and/or large (greater than 40 milliseconds) S wave in lead I was found to be an independent predictor of arrhythmic events during follow-up. The S wave in lead I is generated by the terminal vector of ventricular activation, which is directed upward and somewhat to the right and backward. This vector is determined by electrical activation of the basal region of both ventricles and by depolarization of the RVOT. A prominent S wave in lead I is typically observed in cases of congenital heart disease, valvular heart disease, and cor pulmonale, which cause RV enlargement and fibrosis.

Of note, a large and prominent S wave in leads I and V₆ in adults is also a diagnostic criterion for RBBB, whereas an S_IS_{II}S_{III} pattern (i.e., an S wave is present in all three leads I, II, and III) and an S_IR_{II}R_{III} pattern with a QRS interval of less than 120 milliseconds can be produced by RV enlargement or zonal RV block. In the setting of Brugada syndrome, the presence of a prominent S wave in lead I could be related

to conduction delay over the RVOT and could be used to identify high-risk patients.⁶⁸

aVR sign. A prominent R wave in lead aVR (denoted “aVR sign”), defined as an R wave equal to or greater than or equal to 0.3 mV or an R/q ratio greater than or equal to 0.75 in lead aVR, has been suggested to reflect RV conduction delay. This association has not been confirmed in large studies.

Other ECG markers. QRS duration greater than or equal to 90 milliseconds in lead V₆, r-J interval greater than or equal to 90 milliseconds in lead V₂, QRS duration greater than or equal to 120 milliseconds in lead V₂, and fragmented QRS (defined as greater than or equal to 2 spikes within the QRS complex in leads V₁-V₃) have been reported to be useful in identifying high-risk patients.^{73,74,93}

Signal-Averaged Electrocardiogram

The presence of late potentials on signal-averaged ECG (which reflect ventricular conduction delay) has been reported to predict arrhythmic events during follow-up on univariate analysis; however, this finding remains unconfirmed.⁷³

Principles of Management

Implantable Cardioverter-Defibrillator

Currently, an ICD is the most effective treatment modality for the prevention of SCD in patients with Brugada syndrome. There is general consensus that ICD implantation is recommended in patients with type 1 Brugada ECG (either spontaneously or after Na⁺ channel blockade) and a history of aborted SCD (class I indication) (Fig. 31.14). The cumulative efficacy of ICD therapy (at least one appropriate defibrillation) in these patients is 18%, 24%, 32%, 36%, and 38% at 1, 2, 3, 4, and 5 years of follow-up, respectively.^{64,94}

In addition, ICD therapy is considered useful in Brugada patients with syncope, seizure, or nocturnal agonal respiration judged to be likely caused by ventricular tachyarrhythmias (class IIa indication). This group of patients, however, requires a thorough clinical assessment to exclude noncardiac causes of these symptoms before recommending ICD implantation. This is particularly important given the fact that most cases of syncope in Brugada patients have a nonarrhythmic mechanism, in whom the risk of life-threatening arrhythmic events is not higher than that in completely asymptomatic patients.

On the other hand, there is no similar consensus regarding the management of asymptomatic patients with the Brugada syndrome. Although some experts advocate close follow-up, others propose the evaluation of VT/VF inducibility by programmed stimulation for risk stratification in patients with spontaneous type 1 Brugada ECG. ICD implantation in those with inducible VT/VF is controversial and has a class IIb indication. For asymptomatic patients with normal baseline ECG and those with spontaneous type 1 Brugada ECG but noninducible VT/VF during programmed stimulation, a conservative approach (i.e., general precautions and follow-up) and reassurance are adequate management.⁸²

It is important to recognize that ICD therapy is not without complications, and the decision to implant an ICD prophylactically in asymptomatic patients must be examined in the context of the low rate of cardiac events (0.5% per year) and the high long-term risk of device-related complications (16%). This is relevant given that Brugada patients enjoy extended longevity post ICD implantation, and because of younger age and more activity, they have a greater propensity for lead fractures, require multiple generator exchanges over a lifetime, and experience quality-of-life issues from inappropriate shocks.⁹⁵

Inappropriate shocks are among the most important adverse effects of ICD therapy, occurring 2.5 times more frequently than appropriate shocks. In one report, inappropriate shocks at 10-years post ICD

Fig. 31.14 Consensus Recommendations for Implantable Cardioverter-Defibrillators in Patients Diagnosed With Brugada Syndrome. ECG, Electrocardiogram; ICD, implantable cardioverter defibrillator; SCD, sudden cardiac death; VF, ventricular fibrillation; VT, ventricular tachycardia. (From Priori SG, Wilde AA, Horie M, et al. HRS/EHRA/APHS expert consensus statement on the diagnosis and management of patients with inherited primary arrhythmia syndromes. *Heart Rhythm*. 2013;10:1932–1963.)

implantation were observed in 37% of ICD recipients. Inappropriate ICD therapies are usually triggered by supraventricular arrhythmias, lead fracture, and T wave oversensing. Several strategies can potentially reduce the frequency of inappropriate shocks, such as adding an atrial lead (for better discrimination between ventricular and supraventricular arrhythmias), modifying the arrhythmia detection settings (programming a single VF zone of more than 210 beats/min with or without a monitoring zone of more than 180 beats/min), and aggressive treatment of supraventricular arrhythmias. Of note, high rates of inappropriate shock have been reported even after careful device programming.^{1,95}

Catheter Ablation

In Brugada patients with frequent episodes of VT/VF, monomorphic PVCs originating predominantly in the RVOT or RV Purkinje network are often the trigger for VT, and focal radiofrequency (RF) ablation of the PVCs can be valuable in reducing the burden of arrhythmias and ICD therapies (Fig. 31.15). Furthermore, recent studies suggest that extensive ablation of the epicardial arrhythmogenic substrate in the RVOT and RV anterior wall can significantly reduce arrhythmia vulnerability and ECG manifestation of the disease in most patients. Ablation targets include sites displaying late potentials and low-voltage, fractionated bipolar electrograms, potentially representing depolarization abnormalities or concealed phase 2 reentry secondary to heterogeneous repolarization. Na⁺ channel blockade challenge (e.g., with flecainide, ajmaline, or procainamide) has been used to delineate the arrhythmic

substrate before ablation, and to ensure complete substrate elimination post ablation (Fig. 31.16).^{96,97}

The mechanism of the ameliorative effects of epicardial ablation in the setting of Brugada syndrome remains uncertain; nonetheless, recent experimental studies suggest that catheter ablation abolishes the cells with the most prominent action potential notch, thus eliminating sites of abnormal repolarization and the substrate for ventricular arrhythmias.⁹⁸

Catheter ablation therapy can be lifesaving in patients with refractory arrhythmias or those in whom ICD implantation is not feasible or not desired. The most recent expert consensus guidelines recommend ablation (class IIb) for patients with Brugada syndrome and frequent appropriate ICD shocks due to recurrent electrical storms (see Fig. 31.15).⁹⁶ Importantly, despite normalization of the spontaneous type 1 Brugada ECG pattern after epicardial ablation, VT/VF recurrence was observed in 27% of patients in one report, suggesting that ICD remains the cornerstone therapy for Brugada syndrome patients.⁹⁹

Pharmacological Therapy

Several pharmacological agents have been used for treatment and prevention of ventricular arrhythmias in patients with Brugada syndrome (see Fig. 31.15). Because of the critical role of I_{to} and I_{CaL} in the arrhythmogenesis in the Brugada syndrome, drugs such as quinidine that inhibit I_{to} or augment I_{CaL} have been shown to have a therapeutic value. Both groups of drugs can potentially restore the RV epicardial action potential dome, thus normalizing the ST segment and preventing phase 2 reentry and ventricular arrhythmias in the Brugada syndrome. Of note, amiodarone and beta-blockers are ineffective. Also, class IC (flecainide, propafenone) and some class IA antiarrhythmic agents (procainamide) with predominant Na⁺ channel blocking effects are contraindicated, as they can worsen ST elevation and arrhythmogenesis.

I_{to} blockade. No cardioselective I_{to}-specific blockers are currently available. Nonetheless, quinidine, a class IA Na⁺ channel blocker, has a relatively strong effect in blocking I_{to} and has been found effective in suppressing arrhythmia inducibility on EP testing in up to 76% of Brugada syndrome patients and in preventing the occurrence of spontaneous arrhythmias. In particular, quinidine has been extraordinarily effective in the treatment of VF storms in Brugada patients. Doses between 600 and 900 mg are recommended, if tolerated, but even lower doses can be beneficial.¹⁰⁰

The use of quinidine is recommended as adjunctive chronic treatment in ICD patients with frequent appropriate ICD therapies, and in patients with electrical storm. Also, quinidine should be considered in high-risk Brugada patients in whom ICD implantation is not feasible or not desired. Although quinidine has been proposed as a preventative measure in asymptomatic patients displaying a spontaneous type 1 ECG pattern, this has not been evaluated in large clinical trials.

Nonrandomized clinical studies suggest that EP-guided therapy with quinidine (or alternatively disopyramide) that effectively suppresses the induction of VF by programmed electrical stimulation can potentially be used as an alternative to ICD therapy under certain circumstances, especially in those patients who do not prefer device implantation. This approach requires that sustained polymorphic VT or VF is induced during EP testing, and that arrhythmia inducibility is eliminated by drug therapy despite aggressive stimulation protocol (less than or equal to 3 extrastimuli, less than or equal to 5 diastolic threshold, 2 RV sites, 2 pacing drive cycle lengths [CLs]). This strategy also requires tolerance and compliance to long-term drug therapy.^{100–102}

The experience with disopyramide (a class IA Na⁺ channel blocker) is much more limited but its efficacy seems to be acceptable. More recently, bepridil was shown to suppress VT/VF, mainly through I_{to} inhibition and I_{Na} augmentation. Tedisamil, an experimental potent I_{to}

blocker without the relatively strong inward current-blocking actions of quinidine, may become a therapeutic option.

I_{CaL} augmentation. Several drugs that augment I_{CaL} can potentially be effective for the treatment of ventricular arrhythmias associated with the Brugada syndrome. Beta-adrenergic agonists, such as isoproterenol, denopamine, and orciprenaline, have been shown to be useful. Isoproterenol infusion (dose titrated to achieve a 20% increase in heart rate), alone or in combination with quinidine, has been successfully used to decrease ST elevation and suppress repetitive episodes of VF in patients presenting with electrical storms (see Fig. 31.7). Before consideration of isoproterenol therapy, however, it is critical that the diagnosis of Brugada syndrome be clearly established as the underlying etiology of VF storm. Isoproterenol infusion can be devastating in patients with VF due to other mechanisms, especially CPVT. This is especially important to recognize because a Brugada-like ST segment elevation can occasionally appear for a brief period in a patient successfully defibrillated from VF.

The phosphodiesterase III inhibitors cilostazol and milrinone are other promising agents for suppressing ST elevation and arrhythmogenesis in Brugada syndrome, likely by augmenting I_{CaL} and by reducing I_{to} secondary to an increase in cAMP and heart rate.

I_{Na} augmentation. Agents that augment I_{Na} , including bepridil and dimethyl lithospermate B, have also been suggested to be of value in the pharmacological approach to therapy of Brugada syndrome. As noted, the antiarrhythmic effects of bepridil are likely mediated by inhibition of I_{to} as well as augmentation of peak and late I_{Na} .

Lifestyle Modifications

Education and lifestyle changes for the prevention of arrhythmias are critical in patients with Brugada syndrome (see Fig. 31.15). Patients need to be educated about the importance of seeking medical attention during febrile illnesses to ensure the rapid and aggressive treatment of pyrexia (often with cardiac monitoring in place). In addition, several drugs have been reported to exacerbate the ECG pattern of ST segment elevation in the Brugada syndrome and to trigger arrhythmias (as outlined at www.brugadadrugs.org), and should be avoided. Family members may consider basic life support training and operation of an automated external defibrillator for home use.

Participation in Sports

Currently available data are insufficient to make definitive recommendations for participation of asymptomatic Brugada patients in competitive sports. A clear association between exercise and SCD has not been established. Given the fact that the risk of an arrhythmic event in asymptomatic patients with Brugada syndrome is small and that malignant ventricular arrhythmias are usually unrelated to physical activity, participation of asymptomatic athletes with Brugada syndrome in competitive sports is not prohibited.¹⁰³

Competitive sports participation may also be considered for an athlete with previously symptomatic Brugada syndrome assuming appropriate disease-specific treatments are in place and that the athlete has been asymptomatic on treatment for at least 3 months.¹⁰³

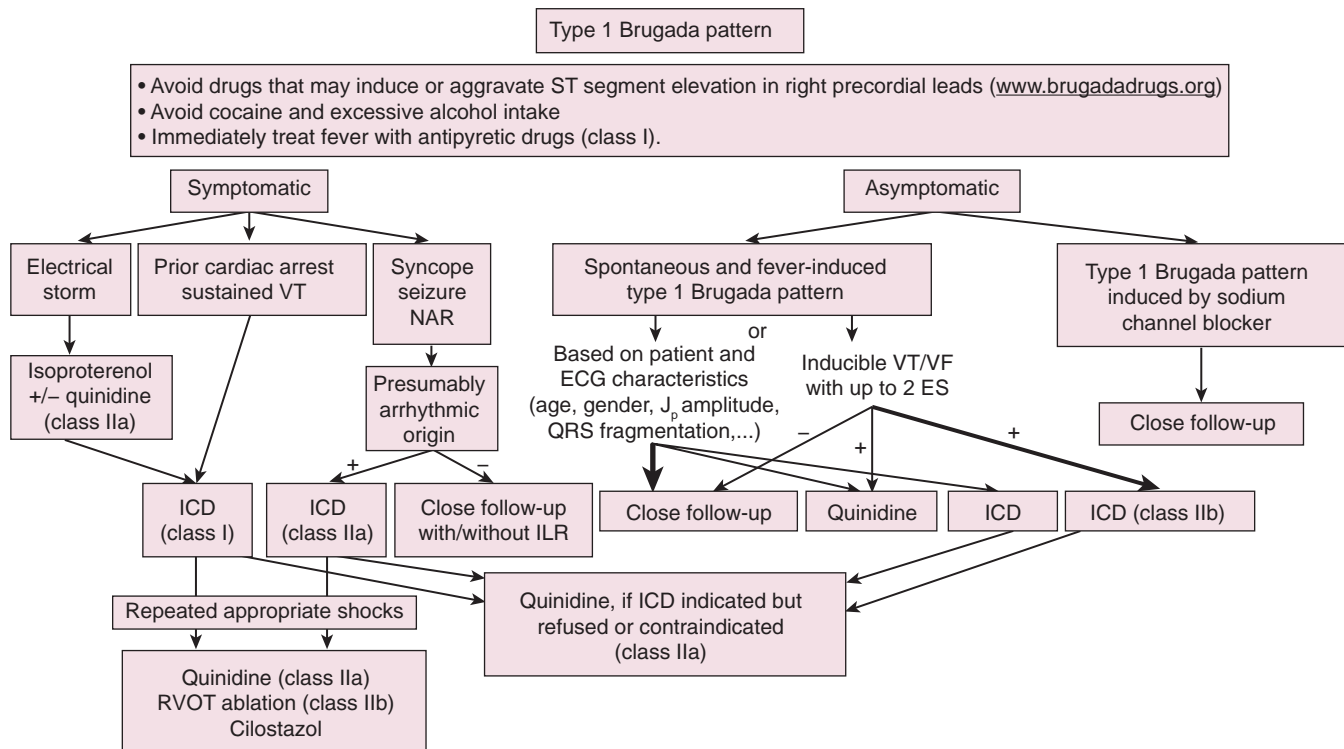

Fig. 31.15 Indications for Therapy of Patients With Brugada Syndrome. Recommendations with class designations are taken from Priori et al.¹ and Priori and Blomström-Lundqvist.¹⁵⁴ Recommendations without class designations are derived from expert consensus. ECG, Electrocardiogram; ES, extrastimuli at right ventricular apex; ICD, implantable cardioverter-defibrillator; ILR, implantable loop recorder; NAR, nocturnal agonal respiration; RVOT, right ventricular outflow tract; VF, ventricular fibrillation; VT, ventricular tachycardia. (From Antzelevitch C, Yan GX, Ackerman MJ, et al. J-wave syndromes expert consensus conference report: emerging concepts and gaps in knowledge. *Heart Rhythm*. 2016;13:e295–e324.)

Fig. 31.16 Brugada Syndrome (BrS) Phenotype Abolition by Epicardial Substrate Ablation. *Top*, Baseline BrS electrocardiogram (ECG) pattern and epicardial color-coded duration CARTO maps. A saddleback pattern is evident in V₂ (II intercostal space) with a corresponding small (2.2 cm²) purple area of abnormally prolonged potentials (210 msec in the example). The border-zone area (green/blue area >110 msec and <200 msec) shows potentials with relatively shorter duration (136 msec). *Middle*, BrS ECG pattern and color-coded duration maps after ajmaline. After type 1 ajmaline-induced ECG pattern, the abnormal purple area significantly increased to 21.5 cm². Examples of abnormal and prolonged electrograms found in the purple area after ajmaline test are shown beside the map (289 and 219 msec). *Bottom*, BrS ECG pattern and color-coded duration maps after radiofrequency ablation of epicardial substrate. After ajmaline rechallenge at the end of the procedure, the ECG showed a horizontal and ascendant ST segment elevation, with minimal intraventricular conduction delay characterized by slight QRS broadening with a more pronounced S wave in leads I and II and qR morphology in aVR. Abnormally prolonged fragmented and delayed electrograms disappeared (87 and 96 msec, light blue color). The two examples of ventricular electrograms were recorded from the previously abnormal area, and the red asterisks indicate disappearance of the late components. Electrogram panels are from the CARTO system and show ECG lead V₂ (white), distal (light blue), and proximal bipolar (yellow) and unipolar signals (yellow) at 200 mm/s speed, from top to bottom, respectively. Of note, in the middle, lead V₂ shows a typical coved-type pattern, which after ablation was modified into a horizontal and at ST segment elevation. (From Pappone C, Brugada J, Vicedomini G, et al. Electrical substrate elimination in 135 consecutive patients with Brugada syndrome. *Circ Arrhythmia Electrophysiol.* 2017;10:e005053.)

Importantly, appropriate precautionary measures should be undertaken to avoid exercise-related hyperthermia, dehydration, and electrolyte abnormalities, which can potentially trigger ventricular arrhythmias in Brugada patients. Also, athletes should be aware of the potential impact of postexercise increase in vagal tone on triggering cardiac events. Other considerations include the acquisition of a personal automatic external defibrillator as part of the athlete's personal sports safety gear, and establishment of an emergency action plan with the appropriate training facility and team officials.¹⁰³

Family Screening

Most individuals diagnosed with the Brugada syndrome have inherited the disease-causing mutation from a parent. Although a proband with the Brugada syndrome may have the disorder as the result of a *de novo* gene mutation, this is very rare (approximately 1%). Because the disease is caused by an autosomal dominant genetic defect, every offspring has a 50% chance of inheriting the disease-causing mutation. Nonetheless, the family history may appear to be negative because of failure to recognize the disorder in family members, low penetrance, early death of the parent before the onset of warning symptoms, or late onset of symptoms in the affected parent. Therefore the lack of a family history does not rule out a heritable disease.

When the causative mutation in the index patient is identified, genetic testing is recommended in all first-degree relatives. Family members who test positive for the familial mutation should receive baseline ECG and annual ECG screening examinations, and should be instructed to avoid medications that can induce ventricular arrhythmias and to seek medical attention immediately on occurrence of symptoms. On the other hand, mutation-negative family members and their descendants have no risk for developing the disease and do not need further evaluation. Genetic testing also can be used for prenatal diagnosis. All patients who undergo genetic testing should receive pretest and posttest genetic counseling to understand the implications of testing.

When genetic testing is not performed in the proband, or when genetic analysis fails to identify a definite disease-causing mutation (or only reveals one or more genetic variants of unknown significance), genetic testing in the related family members is not recommended. In this setting, it is recommended that at-risk individuals with a family history of Brugada syndrome should undergo ECG monitoring every 1 to 2 years. The presence of type 1 ST elevation should be further investigated.

TABLE 31.16 Molecular Basis of the Short QT Syndrome

	Gene	Protein	Functional Effect
SQT1	<i>KCNH2 (HERG)</i>	K _v 11.1	↑I _{Kr}
SQT2	<i>KCNQ1 (KvLQT1)</i>	K _v 7.1	↑I _{Ks}
SQT3	<i>KCNJ2</i>	Kir2.1	↑I _{K1}
SQT4	<i>CACNA1C</i>	Ca _v 1.2	↓I _{CaL}
SQT5	<i>CACNB2B</i>	Ca _v β2b	↓I _{CaL}
SQT6	<i>CACNA2D1</i>	Ca _v α2δ1	↓I _{CaL}

I_{CaL}, L-type Ca²⁺ current; I_{K1}, inward rectifier K⁺ current; I_{Kr}, rapidly activating delayed rectifier K⁺ current; I_{Ks}, slowly activating delayed rectifier K⁺ current; SQT1 to SQT6, short QT syndrome types 1 to 6, respectively.

SHORT QT SYNDROME

The SQTs, first described in 2000, is a highly arrhythmogenic inherited channelopathy occurring in young individuals with structurally normal hearts. Affected patients are characterized by constantly short QT intervals associated with AF, syncope, and/or SCD.¹⁰⁴

Genetics of the Short QT Syndrome

To date, mutation analysis has implicated six distinct genes in the etiology of a proportion of patients diagnosed with SQTs, although the majority of diagnosed cases do not have reported genetic associations. It is expected that further genes will be identified. Genetic studies reveal a genetically heterogeneous disease with gain-of-function mutations of voltage-gated K⁺ channel genes (Table 31.16). Loss-of-function mutation in the L-type Ca²⁺ channel genes have also been linked to SQTs, but in some cases might represent a clinical spectrum of Brugada or early repolarization syndromes. These mutations cause either an increase in the outward repolarizing K⁺ currents or a decrease in the inward depolarizing Ca²⁺ currents, leading to shortening of the action potential duration, the QT interval, and the effective refractory period.

Mutations Related to the Potassium Current

SQT1, the most common genotype, is caused by mutations of the *KCNH2* gene (*HERG*, encoding the α-subunit K_v11.1 of the I_{Kr}). A

gain-of-function mutation on *KCNH2* causes a shift of voltage dependence of inactivation of I_{Kr} by +90 mV out of the range of the action potential, which results in a significant increase in I_{Kr} during the action potential plateau. The resulting I_{Kr} augmentation achieved by altered gating hastens repolarization, thereby shortening the action potential duration and QT interval and facilitating reentrant excitation waves to induce atrial and/or ventricular arrhythmias. Of note, loss-of-function mutations in the *KCNH2* gene are responsible for LQT2.

SQT2 is caused by mutations of the *KCNQ1* gene (*KvLQT1*, encoding the α -subunit $K_{v7.1}$ of the I_{Ks}). A gain-of-function mutation of *KCNQ1* causes a shift in the voltage dependence of I_{Ks} activation by -20 mV and acceleration of activation kinetics, leading to enhancement of I_{Ks} and shortening of the action potential duration and QT interval. Of note, loss-of-function mutations in the *KCNQ1* gene are responsible for LQT1.

SQT3 is caused by a mutation in the *KCNJ2* gene (encoding the strong inwardly rectifying channel protein Kir2.1 of the I_{K1}). A gain-of-function mutation causes a significant increase in the outward I_{K1} at potentials between -75 and -45 mV, leading to shortening of the QT interval and asymmetrical T waves, with a normal ascending component and a rapid descending terminal phase. On the other hand, loss-of-function mutations in the *KCNJ2* gene, identified in patients with the Andersen syndrome, generate prolongation of the QT intervals (LQT7).

Because I_{Kr} , I_{Ks} , and I_{K1} each contribute differentially to cardiac repolarization, gene-specific mutations will differentially influence repolarization and the susceptibility to arrhythmia. However, detailed information regarding the genotype-phenotype correlation is currently limited by the rare nature of this disorder.

Mutations Related to the Calcium Current

SQT4-6 is caused by mutations in the *CACNA1C*, *CACNB2*, and *CACNA2D1* genes, encoding the $\alpha 1C$ -, $\beta 2b$ -, and $\alpha 2\delta 1$ -subunits of the cardiac L-type Ca^{2+} channel $Ca_v1.2$, respectively. Loss-of-function mutations of those genes result in major attenuation in I_{CaL} amplitude, leading to shortening of the action potential duration, and are associated with asymmetrical T waves, an attenuated QT-heart rate relationship, and AF. Three patients reported to harbor these mutations had a Brugada type 1 phenotype. In addition, loss-of-function mutations of the *CACNA1C* and *CACNB2* genes have recently been linked to a sudden death syndrome that combines the features of Brugada syndrome, including the characteristic ECG pattern, and a short QT interval. It was speculated that these mutations cause Brugada syndrome by aggravating transmural voltage gradients. Of note, loss-of-function mutations in L-type Ca^{2+} channel proteins can also, in certain cases, cause early repolarization syndromes. Conversely, a gain-of-function mutation of the L-type Ca^{2+} channel is known to generate the LQT8 (Timothy syndrome).¹⁰⁴

Pathophysiology of Short QT Syndrome

Reduced wavelength of activation and heterogeneous shortening of action potential duration (preferentially more in epicardial and endocardial layers, causing increased transmural dispersion of repolarization), predispose to functional reentry and play a role in the increased atrial and ventricular susceptibility to premature stimulation, leading to AF and VF.^{1,104}

Epidemiology

SQTS has been described in very few families worldwide; therefore all the information available is based on small numbers of cases. The majority (more than 75%) of affected subjects have been men, suggesting a sex-dependent penetrance (similar to the Brugada syndrome). Nonetheless, the prevalence of cardiac arrest appears equal in both genders,

suggesting that females should not be regarded at a lower risk for malignant arrhythmias. The age of presentation is quite variable, ranging from infancy to the eighth decade of life, with a mean age of 20 to 30 years. There seems to exist an age dependency in the susceptibility to arrhythmias, with a peak in the occurrence of cardiac arrest in the first year of life (incidence, 4% per year) and a second peak between 20 and 40 years of age (incidence, 1.3% per year). Up to 72% of patients with SQTS have a family history of SQTS or SCD.^{105,106}

Clinical Presentation

More than 60% of the subjects have symptoms at presentation, with cardiac arrest being the most frequent symptom, representing the first clinical manifestation in one-third of patients. Syncope is observed as a first clinical presentation less frequently (14%). AF has been documented in approximately 30% of patients with SQTS. No information is available on whether specific triggers precipitate cardiac events, and the majority of cardiac events appear to occur under resting conditions or during sleep.¹⁰⁷

Electrocardiographic Features

A short QT interval is the hallmark of SQTS. However, the definition of the lower limit of a "normal" QT interval and the diagnostic criteria sufficient to establish the diagnosis of SQTS remain to be determined unequivocally. Based on ECG analysis of 14,379 healthy individuals, some investigators proposed that a QTc interval less than 350 milliseconds (which is less than 88% of the mean predicted value, or less than 2 standard deviations below the mean) be considered short, and a QTc interval less than 320 milliseconds (which is less than 80% of the mean predicted value) be considered abnormally short. The prevalence of a QTc interval less than 88% of the mean was 2.5% and that of a QTc interval less than 80% of the mean was 0.03%.¹⁰⁴

Importantly, the mere presence of a short QT interval on the surface ECG does not necessarily translate into an increased risk of arrhythmias. In fact, in a study in a middle-aged Finnish population ($n = 10,822$) followed up for 29 ± 10 years, the prevalence of QTc less than 320 milliseconds (using the Bazett formula) was 0.1% and that of QTc less than 340 milliseconds was 0.4%. There was no difference in the all-cause or cardiovascular mortality between subjects with a very short QTc (less than or equal to 320 milliseconds) or short QTc (less than or equal to 340 milliseconds) and those subjects with a normal QTc interval (360 to 450 milliseconds). On the other hand, in a recent epidemiological study of a cohort of 1.7 million persons with 6.4 million ECGs, a QTc of 300 milliseconds or less was extraordinarily rare (0.7 per 100,000 ECGs) and was associated with significant ECG abnormalities and a 2.6-fold increased risk of death.¹⁰⁸

Of note, the physiological shortening of the QT interval during exercise-induced tachycardia can be blunted in patients with SQTS. This is relevant because impaired QT adaptation to heart rate changes makes the correction formulas such as those of Bazett or Fredericia inappropriate or of limited value in SQTS patients with heart rates above 100 beats/min or below 60 beats/min. The poor performance of correction formulas, in addition to the lack of a universal diagnostic cutoff value for an SQTS, makes it difficult to establish a diagnosis in cases of borderline shortened QT intervals.

Several other ECG markers can potentially be helpful to support the diagnosis of SQTS especially in patients with borderline QTc intervals (QTc intervals 330 to 370 milliseconds). In addition to constantly short QTc intervals, affected patients have in common a short or even absent ST segment, with the T wave initiating immediately from the S wave. Extreme abbreviation of the Jpoint-Tpeak interval (less than 120 milliseconds) can help distinguish patients with SQTS from healthy subjects with an apparent abbreviation of the ST segment and shortened QT

intervals (mean Jpoint-Tpeak interval of 188 ± 11 milliseconds). Furthermore, the increase in dispersion of repolarization in patients with SQTs results in increased Tp-e interval and ratio of Tp-e/QT.

In addition, high-amplitude, narrow, and symmetrical T waves in the precordial leads are frequently observed in SQTs patients; but asymmetrical T waves also can be observed, especially in SQT3 patients. Another ECG characteristic observed in most (81%) SQTs patients is PQ segment depression (greater than or equal to 0.05 mV), likely caused by heterogeneous shortening of atrial repolarization.¹⁰⁹

Diagnosis of the Short QT Syndrome

A diagnostic scoring system to facilitate the diagnosis of SQTs was proposed in 2011 by Gollob et al., based on a comprehensive review of 61 reported cases of the SQTs. The Gollob score incorporates ECG findings, clinical history, family history, and genotype findings (Table 31.17). In this system, all patients should have a QTc interval (using the Bazett formula) of no more than 370 milliseconds. Clinical events (cardiac arrest, nonsustained polymorphic VT or VF, syncope, AF) must occur in the absence of other identified clinical pathologies. Although these diagnostic criteria can potentially facilitate evaluation in suspected cases of SQTs, their value for evaluation of family members can poten-

tially be limited because of incomplete disease penetrance. Importantly, treatment considerations should be reserved for subjects receiving a high-probability score, whereas medical surveillance or expert opinion should be considered for intermediate- or low-probability cases.

More recently, in 2013, an expert consensus recommended that SQTs is diagnosed in the presence of a QTc of 330 milliseconds or less. SQTs also can be diagnosed in the presence of a QTc between 330 and 360 milliseconds in conjunction with at least one additional criterion including: (1) a pathogenic mutation, (2) family history of SQTs, (3) family history of SCD below age 40, or (4) survival of a VT/VF episode in the absence of heart disease.¹

Electrophysiology Testing

The role of EP study in diagnosis and risk stratification is not yet fully defined. During EP testing, atrial and ventricular effective refractory periods are significantly shortened, and VT/VF is inducible in 60% to 91% of patients. However, inducibility of ventricular arrhythmias does not appear to be predictive of adverse clinical outcome.

Genetic Testing

Genetic analysis may be considered for patients with a strong clinical index of suspicion for SQTs based on the personal and family history and the ECG phenotype. A mutation in genes related to SQTs is observed in 23% of probands, with SQTs1 being the most common. Genetic testing can help identify silent carriers of SQTs-related mutations; however, the risk of cardiac events in genetically affected individuals with a normal ECG is currently not known. Similarly, given the limited number of patients with SQTs so far identified, genetic analysis at present does not contribute to risk stratification.

Differential Diagnosis

Shortening of the QT interval can be encountered in a variety of pathophysiological states, including hyperkalemia, hypercalcemia, hyperthermia, acidosis, digitalis overdose, androgen use, increased vagal tone, administration of acetylcholine and catecholamines, and carnitine deficiency (an autosomal recessive disorder due to a defective transport of carnitine into the cell).^{104,110}

Risk Stratification

The optimal strategy for risk stratification of asymptomatic SQTs patients remains uncertain. SQTs patients with prior cardiac arrest are considered at high risk for SCD. However, no independent risk factors for life-threatening arrhythmias have been identified in asymptomatic patients. The degree of shortening of the QT interval at faster heart rates has not been found to be a prognostic indicator in asymptomatic patients. Although mutation carriers exhibited a significantly shorter QTc interval compared with noncarriers, this finding did not correlate with a different outcome. As noted, inducibility of ventricular arrhythmia during EP testing was found ineffective for predicting cardiac arrest (sensitivity of 37% and a negative predictive value of 58%). Also, the Gollob score was not a predictor of adverse cardiac events in this patient population.¹⁰⁶

Principles of Management

Implantable Cardioverter-Defibrillator

At present, ICD implantation is the therapy of choice for the prevention of SCD in symptomatic SQTs patients (survivors of cardiac arrest and those with spontaneous VT). The role of ICD therapy for primary prevention is uncertain, although ICD implantation may be reasonable in asymptomatic SQTs patients with a strong family history of SCD (class IIb). Importantly, patients with SQTs are potentially susceptible to inappropriate shocks because of oversensing of the tall, narrow T

TABLE 31.17 Diagnostic Criteria of the Short QT Syndrome

QTc	
• <370 msec	1
• <350 msec	2
• <330 msec	3
• Jpoint-Tpeak interval <120 msec	1
Clinical History	
• History of sudden cardiac arrest	2
• Documented polymorphic VT or VF	2
• Unexplained syncope	1
• Atrial fibrillation	1
Family History	
• First- or second-degree relative with high-probability SQTs	2
• First- or second-degree relative with autopsy-negative sudden cardiac death	1
• Sudden infant death syndrome	1
Genotype	
• Genotype positive	2
• Mutation of undetermined significance in a culprit gene	1

Notes:

- High-probability SQTs, ≥ 4 points; intermediate-probability SQTs, 3 points; low-probability SQTs, ≤ 2 points.
- Electrocardiogram: Must be recorded in the absence of modifiers known to shorten the QT.
- Jpoint-Tpeak interval must be measured in the precordial lead with the greatest amplitude T wave.
- Clinical history: Events must occur in the absence of an identifiable etiology, including structural heart disease.
- Points cannot be combined for the following three markers: cardiac arrest, documented polymorphic VT, and unexplained syncope.
- Family history: Points can only be received once in this section.
- A minimum of 1 point must be obtained in the electrocardiographic section to obtain additional points.

QTc, Corrected QT interval; SQTs, short QT syndrome; VF, ventricular fibrillation; VT, ventricular tachycardia.

waves and the high prevalence of AF. Therefore appropriate programming of the ICD is necessary.¹

Pharmacological Therapy

Of the pharmacological agents tested to date, quinidine seems the most effective at prolonging the QT interval in patients with SQTs. Quinidine was shown to prolong the QT interval, normalize atrial and ventricular effective refractory periods, and prevent inducibility of ventricular arrhythmias during EP testing in patients with SQT1, with a weaker and variable effect in the non-SQT1 patients. In a recent report, the incidence of arrhythmic events during follow-up was 4.9% per year in the patients without pharmacological prophylaxis, whereas no arrhythmic events occurred in those receiving hydroquinidine (even if previously symptomatic).

Hence, quinidine can potentially serve as an adjunct to ICD therapy in the treatment of paroxysmal AF or recurrent ventricular tachyarrhythmias in this subgroup of patients or as an alternative option to ICD in patients who cannot receive it (small children) or who decline the implant. Quinidine may also be considered primary prevention of cardiac arrest in asymptomatic SQTs patients with a family history of SCD.¹

Other drugs, including class III agents (e.g., sotalol), are not effective in prolonging the QTc interval in SQT1 patients, and efficacy in the other subtypes is unknown.¹

Participation in Sports

Until the phenotype of SQTs is better understood, a universal restriction from competitive sports, with the possible exception of class IA activities, seems to represent the most prudent recommendation.

CATECHOLAMINERGIC POLYMORPHIC VENTRICULAR TACHYCARDIA

CPVT, also known as familial polymorphic VT, is a rare but highly malignant inherited arrhythmia disorder characterized by exercise- and stress-induced polymorphic or bidirectional VT. CPVT is an important cause of syncope and SCD in individuals with a structurally normal heart.¹¹¹

Genetics of Catecholaminergic Polymorphic Ventricular Tachycardia

Mutations in genes that encode for four key Ca^{2+} regulatory proteins are currently implicated in the pathogenesis of CPVT (Table 31.18).

TABLE 31.18 Molecular Basis of Catecholaminergic Polymorphic Ventricular Tachycardia

Disease	Gene	Protein	Inheritance	% Probands
CPVT1	<i>RyR2</i>	Ryanodine receptor 2	Autosomal dominant	50%–55%
CPVT2	<i>CASQ2</i>	Calsequestrin	Autosomal recessive	2%–5%
CPVT3	<i>Unknown</i>	Unknown	Autosomal recessive	Rare
CPVT4	<i>CALM1</i>	Calmodulin	Autosomal dominant	<1%
CPVT5	<i>TRDN</i>	Triadin	Autosomal recessive	1%–2%

CPVT, Catecholaminergic polymorphic ventricular tachycardia.

CPVT1 is the most common genetic variant and is caused by mutations in the *RyR2* gene. *RyR2* is the major calcium release channel of the sarcoplasmic reticulum, mediating excitation-contraction coupling. Approximately 50% to 70% of patients with CPVT harbor *RyR2* mutations. CPVT mutant *RyR2*s typically show gain-of-function defects following channel activation by PKA phosphorylation (in response to beta-adrenergic stimulation or caffeine), resulting in uncontrolled Ca^{2+} release from the sarcoplasmic reticulum during electrical diastole, which facilitates the development of DADs and triggered arrhythmias.

Of note, missense mutations in *RyR2* have also been linked to a form of arrhythmogenic cardiomyopathy (ARVC-2) characterized by exercise-induced polymorphic VT that does not appear to have a reentrant mechanism, occurring in the absence of significant structural abnormalities. Patients do not develop characteristic features of ARVC on the 12-lead ECG or signal-averaged ECG, and global RV function remains unaffected. ARVC-2 shows a closer resemblance to familial CPVT in both etiology and phenotype; its inclusion under the umbrella term of ARVC remains controversial.

CPVT2 is much less common (accounting for less than 5% of CPVT index cases), and is associated with homozygous mutations in the *CASQ2* gene. Heterozygous carriers of one *CASQ2* mutation are usually healthy. Although *CASQ2* mutations are typically identified in consanguineous families, compound heterozygosity has been observed in nonconsanguineous families. *CASQ2* is a sarcoplasmic reticulum Ca^{2+} buffering protein associated with *RyR2*. *CASQ2* plays an active role in the control of Ca^{2+} release from the sarcoplasmic reticulum to the cytosol. Although some of *CASQ2* mutations are thought to compromise *CASQ2* synthesis and result in reduced expression or complete absence of *CASQ2* in the heart, other mutations seem to cause expression of defective *CASQ2* proteins with abnormal regulation of cellular Ca^{2+} homeostasis.

CPVT3 is caused by a mutation mapped to chromosome 7. The exact gene has not yet been identified. CPVT4 is caused by a mutation of the *CALM1* gene (encoding calmodulin). Calmodulin is a Ca^{2+} -binding protein that directly interacts with and regulates *RyR2* and L-type Ca^{2+} channels. Like CPVT1, CPVT4 is autosomal dominant. Of note, three genes (*CALM1–3*) in the human genome encode exactly the same calmodulin protein. Mutations in *CALM1–3* have also been linked to LQTS. In addition, mutations in *CALM1* were identified in a family with idiopathic VF.

CPVT5 is caused by mutations of the *TRDN* gene (encoding triadin). Triadin is a transmembrane sarcoplasmic reticulum anchoring protein of calsequestrin to the ryanodine channel. CPVT2, CPVT3, and CPVT5 are autosomal recessive.

Recently, three novel loss-of-function mutations of the *KCNJ2* gene (encoding for the strong inwardly rectifying channel Kir2.1 of the I_{K1}) have been found in patients with CPVT, and may represent a CPVT phenocopy. These patients had prominent U waves, ventricular ectopy, and polymorphic VT, but no dysmorphic features or skeletal muscle abnormalities. I_{K1} reduction may trigger arrhythmia by allowing inward currents, which are no longer counterbalanced by the strong outward I_{K1} , to gradually depolarize the membrane potential during phase 4. Membrane depolarization during phase 4 induces arrhythmia by facilitating spontaneous excitability.

Pathophysiology of Catecholaminergic Polymorphic Ventricular Tachycardia

Mechanism of Ventricular Arrhythmias

Abnormalities in the control of sarcoplasmic reticulum Ca^{2+} release constitute the central pathogenic abnormality in CPVT, although considerable controversy exists about the molecular mechanisms causing these defects. *RyR2* and *CASQ2* are both critically involved in the regulation of cardiac excitation-contraction coupling. Ca^{2+} influx via the

L-type Ca^{2+} channels in the cell membrane during the action potential plateau triggers more massive Ca^{2+} release (Ca^{2+} transients) from the sarcoplasmic reticulum into the cytosol via activation of RyR2. This amplifying process, termed calcium-induced calcium release (CICR), causes a rapid increase in cytosolic Ca^{2+} concentration to a level required for optimal binding of Ca^{2+} to troponin C and induction of contraction. During diastole, most of the surplus Ca^{2+} in the cytosol is resequestered into the sarcoplasmic reticulum by the sarcoplasmic/endoplasmic reticulum calcium ATPase (SERCA), the activity of which is controlled by the phosphoprotein phospholamban. In addition, some of the Ca^{2+} is extruded from the cell by the Na^{+} - Ca^{2+} exchanger to balance the Ca^{2+} that enters with the Ca^{2+} current. Recurring Ca^{2+} release-uptake cycles provide the basis for periodic elevations of the cytosolic Ca^{2+} concentration and contractions of myocytes, and hence for the orderly beating of the heart (see Fig. 1. 7).

The molecular mechanisms by which RyR2 mutations alter the physiological properties and function of RyR2 are not completely defined. It has been suggested that CPVT mutations in RyR2 reduce the binding affinity of RyR2 for the regulatory protein FKBP12.6 (calstabin-2), which stabilizes the closed conformational state of the RyR2 channel, thus enabling the channel to close completely during diastole (at low intracellular Ca^{2+} concentrations) and preventing aberrant Ca^{2+} leakage from the sarcoplasmic reticulum, ensuring muscle relaxation. PKA phosphorylation (induced by beta-adrenergic stimulation) of the mutant channels results in further worsening of the binding affinity of FKBP12.6 for the mutant RyR2, thus increasing the probability of an open state at diastolic Ca^{2+} concentrations. As a consequence, the mutant RyR2 channel fails to completely close during diastole, resulting in diastolic Ca^{2+} leak from the sarcoplasmic reticulum during stress or exercise.

An alternative hypothesis is that RyR2 mutations sensitize the channel to luminal (within the sarcoplasmic reticulum) Ca^{2+} such that under baseline conditions, where sarcoplasmic reticulum load is normal, there is no Ca^{2+} leak. Under beta-adrenergic (sympathetic) stimulation, sarcoplasmic reticulum Ca^{2+} concentration becomes elevated above the reduced threshold, causing Ca^{2+} to leak out of the sarcoplasmic reticulum. A third hypothesis is that mutations in RyR2 impair the intermolecular interactions between discrete RyR2 domains necessary for proper folding of the channel and self-regulation of channel gating.¹¹²

Calsequestrin is the most important Ca^{2+} storage protein in the sarcoplasmic reticulum and it forms a part of a large quaternary complex with RyR2, triadin, and junctin; together, these proteins play a major role in regulating intracellular Ca^{2+} . Calsequestrin represents a high-capacity, low-affinity Ca^{2+} -binding protein that is able to bind luminal Ca^{2+} (40 to 50 Ca^{2+} ions per molecule) during diastole, buffering Ca^{2+} within the sarcoplasmic reticulum and preventing diastolic Ca^{2+} release via RyR2 into the cytosol. CASQ2 mutations result in disruption of the control of RyR2s by luminal Ca^{2+} required for effective termination of sarcoplasmic reticulum Ca^{2+} release and prevention of spontaneous Ca^{2+} release during diastole, leading to diminished Ca^{2+} signaling refractoriness and generation of arrhythmogenic spontaneous Ca^{2+} releases (eFig. 31.4).¹¹²

Dysregulation of RyR2 likely underlies the disease mechanisms of calmodulin mutation-associated CPVT. Calmodulin is a small cytoplasmic Ca^{2+} -binding protein that regulates, directly or indirectly, the activity of proteins that play a key role in excitation-contraction coupling, and in particular, those responsible for the release and subsequent sequestration of cytosolic Ca^{2+} into the sarcoplasmic reticulum. The main binding partner of calmodulin in cardiac cells is the RyR2, which regulates Ca^{2+} release from the sarcoplasmic reticulum. Calmodulin inhibits RyR2 channel open probability. CPVT-linked calmodulin mutations result in defective calmodulin-RyR2 binding and impaired

calmodulin inhibition of RyR2 function. This can lead to excessive Ca^{2+} release from RyR2 channels, primarily from insufficient termination of RyR2-mediated Ca^{2+} release.^{5,6}

DADs and triggered activity have been proposed as the arrhythmogenic mechanism in CPVT because the bidirectional ECG pattern of this VT closely resembles the arrhythmias associated with intracellular Ca^{2+} overload and the DADs observed during digitalis toxicity. CPVT-related mutations lead to cytosolic Ca^{2+} overload, which results in activation of the Na^{+} - Ca^{2+} exchanger, which in turn generates a net inward current (the so-called transient inward current [I_{ti}]). I_{ti} underlies DADs, which may reach the threshold for Na^{+} channel activation and trigger abnormal beats.

When the DADs are of low amplitude, they are usually not apparent or clinically significant. Probably the most important influence that causes subthreshold DADs to reach threshold is a decrease in the initiating cycle length; fast heart rates increase both the amplitude and rate of the DADs. In addition, catecholamines can facilitate the development of DADs via several mechanisms, including (1) increasing the L-type Ca^{2+} current through stimulation of beta-adrenergic receptors and increasing cAMP, which results in an increase in transsarcolemmal Ca^{2+} influx and intracellular Ca^{2+} overload; (2) enhancing the activity of the Na^{+} - Ca^{2+} exchanger, thus increasing the likelihood of DAD-mediated triggered activity; (3) enhancing the uptake of Ca^{2+} by the sarcoplasmic reticulum, leading to increased Ca^{2+} stored in the sarcoplasmic reticulum and the subsequent release of an increased amount of Ca^{2+} from the sarcoplasmic reticulum during contraction; and (4) increasing the heart rate. These effects underlie the increased susceptibility to ventricular arrhythmias in CPVT patients during exercise and emotional stress associated with increased sympathetic stimulation and increased heart rates.

Importantly, in the setting of digitalis poisoning, the abnormal RyR2 behavior leading to spontaneous Ca^{2+} release and DADs is secondary to the elevation of the sarcoplasmic reticulum Ca^{2+} content (store overload-induced Ca^{2+} release, SOICR). In CPVT, on the other hand, spontaneous Ca^{2+} release and DADs can occur without Ca^{2+} overload. Mutations in RyR2 or CASQ2 lead to defective Ca^{2+} signaling that reduces the sarcoplasmic reticulum Ca^{2+} threshold for spontaneous Ca^{2+} release below the normal baseline level ("perceived" Ca^{2+} overload). A similar mechanism may underlie triggered arrhythmias in other disease conditions, including heart failure and ischemic heart disease, in which sarcoplasmic reticulum Ca^{2+} release regulation is compromised because of acquired defects in components of the RyR2 channel complex.

As expected with DAD-mediated triggered activity, a positive direct correlation has been observed between the coupling interval of ventricular arrhythmias and the preceding R-R interval. This observation can also suggest that supraventricular arrhythmias commonly observed prior to the onset of ventricular arrhythmias during exercise in CPVT patients may act as a trigger for the development of DADs and triggered activity in the ventricle.

Mechanism of the Bidirectional Morphology of Ventricular Tachycardia

The EP mechanisms leading to the characteristic bidirectional morphology of the VT are not clear. Changes in conduction direction from a single ventricular focus with every other beat, VT originating from one focus that triggers another focus, and double ventricular foci (from the right and left apical portions of the heart) are some of the proposed mechanisms. The QRS morphology of bidirectional VT is inconsistent in the same recording lead, suggesting that the focus of the arrhythmia can vary to some extent. Some investigators suggested that CPVT starts from a single focus or double foci, usually originating from the RVOT, whereas the ensuing beats tend to originate from the LV. Others found

eFig. 31.4 Calcium Cycling in Normal Myocytes and Myocytes Harboring Catecholaminergic Polymorphic Ventricular Tachycardia (CPVT) Calsequestrin (CASQ2) Mutations. (A) In normal myocytes, Ca^{2+} influx through L-type Ca^{2+} channels (LCC) during the action potential activates ryanodine receptor type 2s (RyR2s) and initiates the release of Ca^{2+} stored in the sarcoplasmic reticulum (SR) on CASQ2 polymers. SR Ca^{2+} release terminates when the drop in intra-SR $[\text{Ca}^{2+}]$ causes RyR2s to close because of inhibition by CASQ2 monomers at reduced $[\text{Ca}^{2+}]_{\text{SR}}$. The RyR2s stay refractory until $[\text{Ca}^{2+}]_{\text{SR}}$ is restored by sarco-plasmic/endoplasmic reticulum calcium ATPase (SERCA). The rate of $[\text{Ca}^{2+}]_{\text{SR}}$ recovery and thus the rate of restitution from luminal Ca^{2+} -dependent refractoriness depends on both SERCA activity and the Ca^{2+} -binding capacity of CASQ2. Ca^{2+} signaling refractoriness prevents spontaneous Ca^{2+} release during diastole. (B) Arrhythmogenic CASQ2 mutations disrupt Ca^{2+} handling through either one or a combination of decreased CASQ2 expression, reduced CASQ2 Ca^{2+} binding capacity (via disruption of CASQ2 polymerization), and impaired CASQ2 interaction with the RyR2 complex (via triadin [TRD]). Alterations in CASQ2 abundance and/or behavior result in diminished and shortened Ca^{2+} signaling refractoriness after each release through accelerating recovery of $[\text{Ca}^{2+}]_{\text{SR}}$, altering RyR2 gating dependency on $[\text{Ca}^{2+}]_{\text{SR}}$, or both. PKA-mediated stimulation of SERCA (via PLB) further accelerates SR refilling, accounting for the dependency of CPVT on adrenergic stimulation. Compromised RyR2 refractoriness results in spontaneous SR Ca^{2+} release, which in turn elicits delayed afterdepolarizations (DADs) through stimulation of Na^+ - Ca^{2+} exchange (NCX). that a left posterior inferior origin accounts for the majority of cases. In addition, the Purkinje network has been suggested as the site of origin of bidirectional VT, with alternating firing from the right and left branches of the Purkinje fibers.

A recent experimental model suggested a “ping-pong” mechanism may underlie ventricular arrhythmias in CPVT, whereby DAD-induced triggered activity develops at different heart rate thresholds in different regions of the His-Purkinje system (HPS) or ventricles. First, once the heart rate exceeds a certain threshold, ventricular bigeminy develops from a single site in the HPS or ventricular myocardium. The shortened R-R cycle length due to ventricular bigeminy induces DAD-triggered beats from a second focus within the HPS, with the latter reciprocally activating PVCs from the first focus; a process that is repeated back and forth, in a ping-pong pattern. “Reciprocating bigeminy” from the two sites produces the bidirectional VT characteristic of CPVT. Polymorphic VT results when three or more sites concurrently develop bigeminy, whereas monomorphic VT develops when repetitive DADs generate a run of triggered activity from a single site.

Mechanism of Drug Effects

As noted, activation of the adrenergic nervous system exerts profound effects on Ca^{2+} handling, and it is often the initiator of Ca^{2+} -mediated arrhythmogenesis. Hence, beta-adrenergic blockade plays an important role in the management of CPVT. It is likely that beta-blocker therapy inhibits the increase of Ca^{2+} content of the sarcoplasmic reticulum with reduced propensity to aberrant Ca^{2+} leakage from the sarcoplasmic reticulum during diastole. Also, beta-blockers attenuate the effect of adrenergic stimulation induced by exercise or emotion. In addition, because the amplitude of DADs is directly related to heart rate, the bradycardia induced by beta-blockers reduces the probability that a DAD would reach the threshold for triggering PVCs. Accordingly, the lower the heart rate achieved with beta-blocker therapy, the higher the probability of preventing malignant arrhythmias.

Flecainide (a Na^+ channel blocker) has recently been demonstrated to prevent lethal ventricular arrhythmias in CPVT. The mechanisms mediating those effects are still debated. It has been speculated that flecainide suppresses spontaneous sarcoplasmic reticulum Ca^{2+} release events via direct blockade of RyR2 channels, reducing Ca^{2+} spark amplitude. An alternative hypothesis is that flecainide prevents the development of abnormal threshold potentials through the inhibition of the Na^+ - Ca^{2+} exchange pump that contributes to the formation of premature and arrhythmogenic Ca^{2+} waves. The negative chronotropic effects of flecainide can also reduce ventricular arrhythmias during exercise by keeping the heart rate below the threshold of PVC initiation.

Epidemiology

The prevalence of CPVT has been roughly estimated at 1:10,000. Despite the low prevalence, CPVT is an important cause of sudden cardiac arrest in young individuals, and cardiac event rates as high as 80% before the age of 40 years have been reported if left untreated. The mean age at clinical presentation is between 7 and 9 years, although later onset has been reported. Approximately 30% of probands have a family history of stress-related syncope, seizure, or SCD before age 40 years. There is a high level of penetrance of the *RYR2*-related disease (75% to 80%); therefore asymptomatic individuals with *RYR2*-related CPVT are a minority.¹

Clinical Presentation

CPVT patients typically present with syncope triggered by exercise or emotion, and a distinctive pattern of reproducible, stress-related, bidirectional VT in the absence of structural heart disease or QT interval prolongation.

CPVT is one of the most malignant forms of ventricular arrhythmia. The majority of untreated CPVT patients develop symptoms (syncope, VT or VF) by age 40 and overall mortality is 30% to 50%. SCD can be the first manifestation of the disease in a significant proportion of cases.

Electrocardiographic Features

The resting ECG of patients with CPVT is often normal, without prolongation or shortening of the QT interval, atrioventricular and intraventricular conduction defects, or Brugada-like ST elevation. Sinus bradycardia and prominent U waves can be observed in some patients.

“Bidirectional VT,” the hallmark of CPVT, is characterized by an alternating QRS axis with 180-degree rotation on a beat-to-beat basis (Fig. 31.17). The typical bidirectional VT, however, is not present in all patients. In one report, bidirectional VT was documented in only 35% of probands, whereas other patients showed polymorphic VT or VF. Single PVCs during an exercise test can be the only finding recorded in some CPVT patients. Importantly, the morphology of VT, which is polymorphic or bidirectional, is strongly dependent on the ECG recording lead. When the maximal QRS vector changes in one lead during bidirectional VT, the axis perpendicular to the former lead shows polymorphic VT. However, unlike other polymorphic VTs, such as torsades de pointes, the QRS morphology is not chaotic but has some regularity.

A characteristic feature of CPVT is the progressive worsening of arrhythmias with increasing exercise workload. Ventricular arrhythmias during exercise stress testing appear quite consistently at a heart rate of 110 to 130 beats/min. Initially, monomorphic PVCs appear, which become polymorphic with continued exercise. Typically, the PVCs in CPVT are late-coupled and can exhibit an LBBB pattern with an inferior axis or RBBB pattern with a superior axis. Notably, PVC morphologies are usually reproducible in an individual patient. With increasing heart rates, ventricular bigeminy, ventricular couplets, and nonsustained VT develop. If exercise is not promptly discontinued, bidirectional VT may degenerate into polymorphic VT and VF. On termination of exercise, arrhythmias progressively diminish in terms of VT rate and VT duration until they disappear. Isolated premature atrial complexes (PACs), nonsustained SVT, and short runs of AF are usually observed during exercise, with an onset at a range of heart rates similar to or slower than that of ventricular arrhythmias.¹¹³

PVCs also can be observed in healthy subjects in response to exercise testing. Certain features of PVCs during an exercise test can potentially assist in distinguishing CPVT from healthy controls, including a larger number of PVCs, first appearance at higher workload, an LBBB pattern and an inferior axis, bigeminy or trigeminy at peak stress, QRS duration of more than 120 milliseconds, a coupling interval of more than 400 milliseconds, and disappearance in the first minute of the recovery.¹¹⁴

Diagnosis of Catecholaminergic Polymorphic Ventricular Tachycardia

A clinical diagnosis of CPVT is made based on symptoms (syncope or aborted SCD), family history, and unexplained exercise or catecholamine-induced bidirectional VT or polymorphic PVCs or VT in an individual (especially those younger than 40 years), in the presence of a structurally normal heart and normal baseline ECG. Ventricular arrhythmias can be observed (using a combination of Holter monitoring, exercise testing, and drug provocation) in more than 80% of patients.¹

In patients presenting with syncope or cardiac arrest, the CPVT diagnosis is frequently missed or delayed, unless exercise stress testing or ambulatory cardiac monitoring is performed to document ventricular arrhythmias. Not infrequently, syncopal episodes are considered as vasovagal in origin, and no further workup is performed. If the loss of consciousness is associated with convulsions, it can be misdiagnosed as epileptic seizures if a prolonged circulatory arrest resulted in brain

Fig. 31.17 Ventricular Arrhythmias in Catecholaminergic Polymorphic Ventricular Tachycardia (CPVT). This 12-lead electrocardiogram from a 9-year-old boy with ryanodine-positive CPVT shows a transition from bidirectional ventricular tachycardia followed by brief polymorphic ventricular tachycardia to ventricular fibrillation. (From Roses-Noguer F, Jarman JWE, Clague JR, Till J. Outcomes of defibrillator therapy in catecholaminergic polymorphic ventricular tachycardia. *Heart Rhythm*. 2014;11:58–66.)

ischemia. Unexplained cardiac arrest is also frequently misdiagnosed as idiopathic VF.

CPVT should be suspected when a syncopal episode induced by exercise or emotion occurs in a child or in a young patient with a normal resting ECG and no structural heart disease. In addition, CPVT should be considered in all cases of idiopathic VF and unexplained cardiac arrest (normal coronary arteries, normal ventricular function, and normal ECG), especially if an adrenergic trigger is present.¹¹⁵

Exercise Stress Testing

A standardized exercise stress test is the most important step for diagnosis of CPVT. In at least 80% of CPVT patients, exercise stress testing induces ventricular arrhythmias, which typically appear when the sinus rate exceeds an individual threshold rate (usually at 110 to 130 beats/min). The progressive worsening of arrhythmias during exercise is highly reproducible and is a diagnostic marker of CPVT. Sometimes, the exercise-provoked arrhythmias can be demonstrated only after a delay of months or more after the first syncopal episode has occurred, emphasizing the necessity of repeated exercise stress tests when there is a high suspicion of CPVT.

Ambulatory Cardiac Monitoring

Continuous ambulatory monitoring can reveal arrhythmias typical for CPVT if the sinus rate of the patient exceeds the individual arrhythmia-inducing threshold during monitoring. Ambulatory monitoring can be very useful in young children, whenever performing a maximal exercise stress test is difficult. Implantation of a loop recorder can also be valuable in some cases.

Provocative Drug Testing

Catecholamine provocation testing can help diagnose patients with concealed CPVT. Progressive ventricular arrhythmias can also be provoked by IV infusion of isoproterenol or epinephrine. The protocol for epinephrine infusion is similar to that described for LQTS. The test is considered positive for CPVT if epinephrine provoked three or more beats of polymorphic VT or bidirectional VT and borderline if polymorphic couplets, PVCs, or nonsustained monomorphic VT is induced.

Electrophysiological Testing

Invasive EP testing is of no value in the diagnosis or risk stratification in patients with CPVT. Arrhythmias are seldom inducible by programmed electrical stimulation.

Genetic Testing

Genetic testing is recommended in all probands with definitive clinical diagnosis of CPVT and is also considered in subjects with idiopathic VF when an adrenergic trigger is identified. Using a comprehensive screening approach, the percentage of successfully genotyped CPVT patients is approximately 55% to 60%. Mutations in *RYR2* are identified in approximately 60% of patients with a strong CPVT phenotype. The yield of *RYR2* genetic testing drops to 5% to 38% in patients with a possible clinical diagnosis in CPVT. Of note, because the *RyR2* gene (which underlies the most common form of CPVT) is one of the largest genes in the human genome, genetic testing can be time-consuming and costly. Genetic screening for disease-causing mutations in the calsequestrin (*CASQ2*) and triadin (*TRDN*) genes, which underlie the

autosomal recessive form of CPVT, is advisable in all pedigrees compatible with a recessive pattern of inheritance but also in all apparently sporadic CPVT cases with negative *RyR2* screening even in the absence of parental consanguinity.

Differential Diagnosis

Other inherited arrhythmogenic cardiac disorders that can cause malignant ventricular tachyarrhythmias should also be excluded. A QTc interval less than 320 milliseconds should raise a suspicion of SQTS. On the other hand, a prolonged QTc suggests LQTS. Although the onset of clinical symptoms of LQTS is often around puberty, the first syncopal events in CPVT patients tend to occur during childhood. Importantly, induction of arrhythmias during exercise is very rare in LQTS patients. Furthermore, LQTS patients develop torsades de pointes (characterized by the twisting of the points of the QRS complexes), in contrast to CPVT patients who manifest with the typical bidirectional VT with a beat-to-beat 180-degree rotation of the QRS complex.

Bidirectional VT can also occur in patients with LQT7 (Andersen-Tawil syndrome) linked to mutations in the *KCNJ2* gene, which may be considered a CPVT phenocopy, particularly in patients with Andersen-Tawil syndrome having borderline QT interval prolongation and lacking the extracardiac features of the syndrome (e.g., periodic paralysis, facial and limb dysmorphism). Distinguishing between LQT7 and CPVT is important; patients with Andersen-Tawil syndrome show a much more benign course than those with other forms of CPVT, and SCD is rare among Andersen-Tawil syndrome patients and *KCNJ2* mutation carriers.

Ankyrin-B syndrome can also manifest with catecholamine-mediated ventricular arrhythmias. Loss-of-function mutations in the *ANK2* gene (encoding cardiac ankyrin-B, a structural membrane adapter protein) result in increased intracellular concentration of Ca^{2+} and, sometimes, fatal arrhythmia. Although this syndrome has been categorized under LQTS (LQT4), the inconsistent QT interval prolongation and the varying degrees of cardiac dysfunction and arrhythmias observed (including bradycardia, sinus arrhythmia, idiopathic VF, adrenergically mediated VT, and SCD) distinguishes ankyrin-B syndrome as a clinical entity distinct from classic LQTS.

Exercise-provoked arrhythmias also can develop in ARVC, but the typical ECG pattern of ARVC and the structural abnormalities of the RV distinguish ARVC from CPVT. The typical arrhythmia in ARVC, monomorphic VT with an LBBB pattern, is clearly different from the polymorphic PVCs or VT in CPVT.

In contrast to CPVT, patients with Brugada syndrome do not manifest polymorphic PVCs on physical effort; rather, arrhythmias in Brugada syndrome usually appear at rest or during sleep. Furthermore, the absence of ST segment elevation in the precordial ECG leads at baseline and after provocation testing with Na^+ channel blockers helps distinguish CPVT from Brugada syndrome.

Risk Stratification

CPVT is one of the most malignant forms of ventricular arrhythmias, with a high mortality rate. CPVT patients with prior cardiac arrest and those in whom symptoms are not completely suppressed by pharmacological therapy are considered at high risk for SCD. Also, diagnosis in childhood is a predictor of adverse outcome. However, the optimal strategy for risk stratification for SCD in asymptomatic CPVT patients or mutation carriers remains uncertain. Programmed electrical stimulation typically fails in inducing ventricular arrhythmias, and is of no value for risk stratification. Furthermore, the predictive value of inducibility of ventricular arrhythmias by catecholamine infusion or exercise for risk stratification has not been demonstrated.¹

Principles of Management

Pharmacological Therapy

Beta-blockers. Beta-blockers without intrinsic sympathomimetic activity combined with exercise restriction are the first line of treatment for CPVT and should be promptly initiated to prevent occurrence of ventricular tachyarrhythmias (see Fig. 31.7). Because of the poor prognosis of untreated CPVT, drug therapy is indicated for all clinically diagnosed patients and usually also for all silent carriers of a CPVT mutation.

Differences in the pharmacodynamics and pharmacokinetics of the various beta-blockers (including their beta-1 selectivity, half-life, and lipophilicity) appear to be relevant. Studies found nadolol superior to beta-1 selective (cardioselective) beta-blockers (e.g., metoprolol succinate and bisoprolol) in preventing arrhythmias in patients with CPVT. This may be explained, at least in part, by a stronger negative chronotropic effect as well as the longer half-life (20 to 24 hours) of nadolol, which reduces the risk of breakthrough symptoms during potential drug noncompliance. Nonetheless, other mechanisms, such as membrane-stabilizing effects of nadolol, have been speculated. The efficacy of other nonselective beta-blockers (such as propranolol and carvedilol) has not been investigated.

Presently, there is a strong consensus that the nonselective beta-blocker nadolol (1 to 2.5 mg/kg per day) is the preferred antiarrhythmic, antiadrenergic therapy for CPVT patients. When nadolol is not available or not tolerated, the choice should be guided by the ability of the beta-blocker to suppress ventricular ectopy on the exercise test. Propranolol (3 to 4 mg/kg per day) has been widely used in these situations. IV propranolol is the treatment of choice for acute management of CPVT.^{52,116,117}

Exercise stress testing and Holter monitoring can help determine the adequate beta-blocker dosage for arrhythmia control. It should be noted, however, that the absence of exercise-provoked arrhythmias does not completely exclude the risk of arrhythmia recurrence, and the maximal tolerated dose of beta-blockers should be prescribed to maximize control of arrhythmias with a goal to avoid the heart rate exceeding the threshold rate for CPVT. Furthermore, compliance with regular therapy is extremely important because missing even a single dose can potentially lead to arrhythmias and increase the risk of SCD. In fact, in one report, poor adherence contributed to 48% of arrhythmic events in children with CPVT.

It should be recognized that the efficacy of beta-blockers in CPVT is not sufficiently protective and appears to be lower than that seen in patients with LQT1. The annual rate of arrhythmic events on beta-blocker therapy ranges between 3% and 11% per year (27% over 8 years).¹ Of note, recent reports found that beta-blocker therapy was unable to modify the arrhythmic pattern during exercise testing in 30% to 43% of patients, especially those with less severe arrhythmias.¹¹³

Flecainide. Recent studies show that the addition of flecainide to beta-blocker therapy can effectively reduce exercise-induced ventricular arrhythmias in CPVT patients not controlled by beta-blocker therapy alone. Thus flecainide should be regarded as the first addition to beta-blockers when control of arrhythmias seems incomplete.¹ Flecainide monotherapy may be considered in selected CPVT patients truly intolerant of beta-blockade.¹¹⁸

Verapamil. Limited data suggest that verapamil (an inhibitor of *RyR2*) can be an alternative option for treatment of CPVT. Also, verapamil can potentially provide additional protection when used in combination with beta-blockers. However, because of the small number of patients and the limited follow-up in these studies, there is no conclusive evidence for recommending verapamil alone or in combination with beta-blockers, and its impact on prognosis remains unknown.¹

Implantable Cardioverter-Defibrillator

Given that no drugs can be effective in providing complete protection from SCD, ICD therapy is recommended for CPVT patients who have survived a cardiac arrest and those who continue to have symptoms (syncope or sustained or hemodynamically unstable VT) despite adequate beta-blocker therapy.¹¹⁵

Patients with CPVT experience a high rate of appropriate ICD therapies; approximately half of ICD recipients experience an appropriate shock to terminate VT during 2 years of follow-up. Importantly, the efficacy of ICD therapy in CPVT patients depends on the mechanism of the arrhythmia treated. VF episodes are almost always terminated by ICD shocks; in contrast, ICD discharges nearly always fail to terminate polymorphic and bidirectional VT.^{115,119,120} Therefore it is important to maintain the maximal tolerated dose of beta-blockers in ICD patients to help reduce the risk of arrhythmic storms and ICD shocks.

The risks and benefits of ICD therapy in patients with CPVT should be carefully considered before device implantation, particularly for primary prevention. Inappropriate shocks, electrical storm, and ICD complications are common. Inappropriate ICD therapy is often triggered by supraventricular arrhythmias or spontaneous termination of a ventricular arrhythmia before the ICD discharge. Also, it is important to note that ICDs can potentially have proarrhythmic effects in patients with CPVT. The stress and catecholamine surge caused by the painful ICD shocks (whether appropriate or inappropriate) can evoke an electrical storm.¹¹⁵

Careful device programming can help improve effectiveness of ICD therapies and decrease related comorbidities. Extending detection intervals and altering reconfirmation rates (to avoid therapy delivery in response to frequent PVCs and spontaneously terminating arrhythmias), as well as adjusting ICD detection rates to shorter CLs (for detection of VF rather than VT) can potentially improve outcomes for CPVT patients.¹²⁰

Catheter Ablation

When ventricular arrhythmias are triggered by monomorphic PVCs, catheter ablation of the focus of PVCs can be attempted to help reduce the frequency and burden of arrhythmias and ICD shocks. Not infrequently, the initiating beat of VT exhibits an LBBB–inferior axis pattern, suggestive of a ventricular outflow tract origin.

Left Cervicothoracic Sympathectomy

Left cervicothoracic sympathectomy involves resection of the lower half of the left stellate ganglion and the first two to four thoracic ganglia (T1 to T4). In recent reports, left cardiac sympathetic denervation successfully reduces major arrhythmic events by almost 90%, including cardiac arrest and SCD, in CPVT patients. Therefore left cardiac sympathetic denervation can be considered in patients with recurrent symptoms despite pharmacological therapy or those experiencing frequent ICD shocks or intractable arrhythmic storms.¹²¹

Although left cervicothoracic sympathectomy can be associated with frequent side effects (including left-sided dryness, unilateral facial flush with exercise, contralateral hyperhidrosis, and ptosis), generally these symptoms are fairly tolerated and patient satisfaction with surgical outcome remains high.^{56,57}

Participation in Sports

Symptomatic CPVT patients and asymptomatic patients (detected as part of familial screening) with documented exercise- or isoproterenol-induced VT should refrain from all competitive sports with the possible exception of minimal contact, class IA activities. A less restrictive approach may be possible for the genotype-positive/phenotype-negative (asymptomatic, no provokable VT) athlete.

Family Screening

Given the severe clinical manifestations and poor prognosis of CPVT, once CPVT diagnosis is made in a proband, it is essential to expand the evaluation to both first- and second-degree relatives to find other potential CPVT patients. Exercise testing and Holter monitoring are used for screening family members. Importantly, some CPVT patients may not have arrhythmias during exercise testing during early childhood, but a change in the phenotype occurs later in life. Therefore regular follow-up with repeated exercise stress tests is indicated, for example, for younger siblings of a CPVT patient.

Screening of family members by genetic testing is recommended when a gene mutation has been identified in the proband. Considering the early age of manifestation of CPVT and its association with SIDS, confirmatory genetic testing should be performed at birth. Genetic evaluation facilitates diagnosis in silent carriers and allows implementation of preventive pharmacological therapy and reproductive risk assessment. Approximately 50% of *RYR2* mutation-carrying relatives identified by cascade screening have a CPVT phenotype.

It is suggested that genetically positive family members without clinical manifestations of CPVT (concealed mutation-positive patients) should receive beta-blockers, even after a negative exercise test, although the natural history of these individuals and the efficacy of beta-blockers on their prognosis have not been studied.¹

IDIOPATHIC VENTRICULAR FIBRILLATION

Idiopathic VF is a rare primary arrhythmia syndrome of unknown genetic origin.¹²² The 2013 expert consensus on inherited arrhythmia defined idiopathic VF as “a resuscitated cardiac arrest victim, preferably with documentation of VF, in whom known cardiac, respiratory, metabolic and toxicological etiologies have been excluded through clinical evaluation.”¹

Genetics of Idiopathic Ventricular Fibrillation

Three familial forms of idiopathic VF have recently been linked to the *DPP6* gene (encoding dipeptidyl-peptidase 6), the *CALM1* gene (encoding calmodulin), and the *RYR2* gene (encoding ryanodine receptor).

In several Dutch families heavily affected by SCD attributed to familial idiopathic VF, the arrhythmic events were associated with a risk haplotype on chromosome 7 harboring the arrhythmia gene *DPP6* gene as a founder effect (i.e., the families are descendants of the same ancestor). Higher *DPP6* expression in *DPP6* risk haplotype-positive individuals was proposed as a likely pathogenetic mechanism. *DPP6* is a putative regulatory β -subunit of the transient outward current (I_{to}) channel complex in the heart. The arrhythmia syndrome typically occurs between the age of 20 and 60 years, with an autosomal dominant inheritance. The penetrance of idiopathic VF is high: 50% of the male *DPP6* haplotype carriers experienced (aborted) SCD before the age of 58 years. Importantly, despite comprehensive cardiac evaluation, no relevant differences between haplotype-positive and haplotype-negative individuals were observed, and no clinical parameters could be linked to SCD risk other than their genetic predisposition.¹²³

Another familial form of idiopathic VF was linked to mutations in the *CALM1* gene, with autosomal dominant transmission. Calmodulin is a Ca^{2+} -binding protein with ubiquitous expression that has a regulatory function for numerous calcium-dependent processes. Calmodulin inhibits *RyR2* channel open-state probability. Defective calmodulin–*RyR2* binding results in impaired calmodulin inhibition of *RyR2* function and consequent dysregulation of sarcoplasmic reticulum Ca^{2+} release. Calmodulin mutations have been previously described in LQTS and CPVT4.^{5,6}

Recently, two different heterozygous mutations in the *RYR2* gene have been identified in a family with multiple idiopathic VF victims. Those mutations resulted in a phenotype distinct from classic *RYR2*-related CPVT.^{124,125}

Pathophysiology of Idiopathic Ventricular Fibrillation

The mechanism(s) underlying idiopathic VF remain to be elucidated. Monogenic mutations have been identified in a small subset of patients with idiopathic VF. Polygenic mutations (i.e., mutations involving two or more genes) and subclinical structural abnormalities currently undetectable with the available diagnostic modalities, have also been speculated. Those underlying substrates can be silent and manifest with VF only during particular pathophysiological processes (e.g., minimal electrolyte disturbances).

Recent evidence suggests that the Purkinje network and the RVOT play a pivotal role in both the initiation and perpetuation of VF. PVCs with short-coupled intervals (i.e., R-on-T phenomenon) originating from the RVOT or HPS have been frequently implicated as the trigger of VF or torsades de pointes, at least in a subset of patients with idiopathic VF. The short-coupled PVCs can cause phase 2 reentry and thereby elicit VF. It is likely that idiopathic VF is initiated by an interaction between triggering PVCs and a susceptible ventricular substrate that is prone to transmural reentry.^{123,126}

The exact arrhythmogenic mechanism of how DPP6 overexpression causes idiopathic VF is uncertain. Idiopathic VF associated with the DPP6 risk haplotype is predominantly elicited by monomorphic short-coupled PVCs from the RV apex or inferior free wall. It has been hypothesized that DPP6 overexpression in DPP6 risk haplotype-positive individuals significantly alters the inactivation kinetics of both $K_{4.2}$ and $K_{4.3}$ channels and preferably increases I_{to} in the Purkinje network more so than in ventricular cardiomyocytes, resulting in a more negative phase 1 and an abnormal plateau phase of the Purkinje action potentials. Because the I_{to} only increases in the Purkinje fibers, a strong local repolarization gradient is created with the adjacent ventricular myocardium that results in local ectopy and short-coupled PVCs. DPP6 overexpression does not result in discernible ECG changes, as Purkinje activity is not recorded on the surface ECG.¹²²

Dysregulation of RyR2 likely underlies the disease mechanisms of *RYR2* and *CAM1* mutation-associated CPVT. These mutations can lead to excessive Ca^{2+} release from RyR2 channels and DADs.^{5,6}

Epidemiology

Idiopathic VF accounts for up to 10% of victims of SCD, mainly in the young. The proportion of “unexplained” or “idiopathic” VF among victims of cardiac arrest has been declining, thanks to the advances in genetic testing and cardiac imaging techniques, and the expanding recognition of new disease entities, which improved the ability to diagnose distinct primary inherited arrhythmia syndromes, thereby excluding idiopathic VF (Fig. 31.18).^{122,127}

The mean age at presentation is approximately 35 to 45 years, and two-thirds of patients are men. A family history of SCD or idiopathic VF is present in up to 20% of patients, suggesting that at least a subset of idiopathic VF is hereditary.

Clinical Presentation

Idiopathic VF manifests as syncope or cardiac arrest that is typically not related to physical or emotional stress. VF often occurs at night, when heart rate is slower and vagal tone is augmented. The recurrence of VF in patients with idiopathic VF is approximately 30%, and the proportion of patients presenting with cardiac arrest as opposed to syncope appears to be much higher in idiopathic VF than in other channelopathies, suggesting that ventricular arrhythmias in other chan-

(From Visser M, van der Heijden JF, Doevendans PA, Loh P, Wilde AA, Hassink RJ. Idiopathic ventricular fibrillation: the struggle for definition, diagnosis, and follow-up. *Circ Arrhythm Electrophysiol*. 2016;9:e003817.)

nelopathies are more likely to terminate spontaneously, whereas idiopathic VF tends to be sustained. Electrical storm occurs in approximately 10% of patients.

Electrocardiographic Features

Typically, the resting ECG of patients with idiopathic VF is normal, without prolongation or shortening of the QT interval, AV and intra-ventricular conduction defects, or Brugada-like ST elevation. Nonetheless, VF storms in idiopathic VF patients appear to be associated with J waves that show augmentation prior to VF onset. The J waves disappear during follow-up. However, the early repolarization pattern in patients with idiopathic VF does not fulfill the criteria for “early repolarization syndrome,” which is considered a separate disease entity with a distinctive phenotype.¹²⁸ VF onset is not related to bradycardia or preceding ventricular pauses.¹²²

Arrhythmic events in idiopathic VF frequently occur at rest or during sleep (similar to Brugada and early repolarization syndromes). A circadian pattern of VF occurrence has been observed in idiopathic VF patients, with two peaks: early morning and late evening. J waves also exhibit circadian rhythmicity, with nocturnal augmentation, likely a result of enhanced vagal activity or slowing of the heart rate.^{126,129}

Characteristically, idiopathic VF is triggered by short-coupled PVCs predominantly originating from the HPS or from the RVOT. Short-coupled PVCs may elicit torsades de pointes or immediate VF. PVCs originating from the RVOT display an inferior axis with an LBBB pattern. PVCs originating in the right Purkinje system display relatively uniform ECG morphologies and typically have an LBBB pattern with a left superior axis and a relatively short QRS duration. On the other hand, PVCs arising in the left Purkinje system produce more variable 12-lead ECG patterns, and generally exhibit a positive vector in lead V_1 and a relatively narrow QRS duration (less than 120 milliseconds).

Diagnosis of Idiopathic Ventricular Fibrillation

The diagnosis of idiopathic VF is based on exclusion of an underlying structural or primary electrical heart disease, and exclusion of respiratory, metabolic, and toxicological causes (Fig. 31.19). Therefore the

diagnosis of idiopathic VF requires extensive diagnostic testing. Systematic advanced testing allows determination of a specific diagnosis in approximately half of initially unexplained cardiac arrest patients, with the majority (more than two-thirds) having a potentially inherited mechanism of disease.¹³⁰ Differentiation from structural cardiac disease and other primary arrhythmia syndromes is critical to provide targeted medical treatment and prevention of arrhythmic events in the proband and to identify other potentially treatable cases in family members.¹

Fig. 31.19 Proposed Flowchart for the Diagnosis and Follow-up (FU) of Patients With Idiopathic Ventricular Fibrillation (IVF). ^aIn young patients (less than 45 years) without risk factors for coronary artery disease, coronary computed tomography (CT) angiography is an alternative diagnostic tool to exclude coronary artery disease. The sensitivity is 85% and 99%, respectively, the specificity is 90% and 64%, respectively, the positive predictive value is 91% and 86%, respectively, and the negative predictive value is 83% and 90%, respectively. Coronary CT angiography has a higher sensitivity compared with MRI in detecting coronary stenosis; therefore CT is a better alternative for coronary angiography. ^bProposed genetic testing consists of a basic panel of *SCN5A*, the most common LQTS genes (*KCNQ1* and *KCNH2*), *RyR2*, and *CALM1* in patients with exercise-induced VF. In patients with a negative phenotype, *SCN5A*, *KCNQ1*, and *KCNH2* screening is recommended. ECG, Electrocardiogram. (From Visser M, van der Heijden JF, Doevendans PA, Loh P, Wilde AA, Hassink RJ. Idiopathic ventricular fibrillation: the struggle for definition, diagnosis, and follow-up. *Circ Arrhythm Electrophysiol.* 2016;9:e003817.)

Exclusion of Structural Heart Disease

Echocardiography, stress testing, coronary angiography, and cardiac magnetic resonance (CMR) need to be considered to exclude structural cardiac disease, such as coronary artery disease, congenital coronary anomalies, dilated or hypertrophic cardiomyopathy, ARVC, cardiac sarcoidosis, myocarditis, and left apical ballooning. In addition, ergonovine or acetylcholine provocation can be necessary to exclude coronary artery spasm. Metabolic disorders, electrolyte abnormalities, and drug intoxication also need to be excluded.^{1,122}

Exclusion of Primary Arrhythmia Syndromes

A thorough clinical and family history is critical; subtle information regarding the triggers and circumstances of arrhythmic events can point to distinct arrhythmia syndromes. Also, careful analysis of the surface 12-lead ECG is mandatory to exclude primary electrical heart disease. Abnormal shortening or prolongation of the QT interval can suggest SQTs or LQTS, respectively. Repolarization abnormalities in the right precordial leads can suggest the Brugada syndrome. The presence of ventricular preexcitation can suggest preexcited supraventricular tachyarrhythmias, usually AF with very rapid ventricular rates, as the underlying cause of VF. It is important to understand that all these disorders can manifest with minor or borderline ECG abnormalities, and recording serial ECGs, recording of modified precordial leads (such as in the Brugada ECG pattern), recording the ECG during exercise or after drug challenge, and/or continuous ambulatory cardiac monitoring can be necessary to unmask diagnostic ECG abnormalities. Pharmacological drug challenge to exclude the Brugada syndrome, and exercise stress testing or catecholamine infusion to exclude CPVT, should be considered.¹²²

Given the variable penetrance among gene carriers in the same family, some studies have suggested a role for family screening with ECG and echocardiogram as a diagnostic tool when conventional tests, including pharmacological tests, have not identified the cause of unexplained cardiac arrest in the proband.¹³¹

Electrophysiological Testing

Invasive EP testing may be considered, especially when SND, AV conduction abnormalities, or the presence of a bypass tract (BT) is suspected. However, routine invasive EP testing is not currently recommended for the diagnosis and risk stratification of idiopathic VF. Inducibility of VF with programmed electrical stimulation is associated with limited sensitivity and specificity (43% and 64% respectively).¹²²

Genetic Testing

The role of extensive genetic testing in patients with idiopathic VF is uncertain. Currently, the routine screening of large gene panels is not recommended because of the relatively low yield (about 15%) and the frequent detection of variants of uncertain clinical significance, which can potentially lead to unnecessary treatment and anxiety among patients. Nonetheless, targeted genetic testing is recommended when certain electrical syndromes are suspected based on clinical evaluation of the patient or family members. Testing for idiopathic VF-related mutations is only recommended in the presence of a strong family history of idiopathic VF or unexplained SCD. It should be recognized, however, that a negative genetic test result does not exclude concealed primary arrhythmia syndromes or a genetic origin of idiopathic VF.^{1,122,127}

Certain clinical information can help guide targeted genetic testing. For example, arrhythmic events (VF or prior syncope episodes) triggered by exercise should point to CPVT or LQT1, whereas those triggered by emotion suggest CPVT or LQT2. Arrhythmic events occurring during sleep suggest Brugada syndrome or LQTS. Fever-associated arrhythmias favor Brugada syndrome. Furthermore, polymorphic PVCs on Holter monitoring or exercise test suggest CPVT. The concomitant potentially arrhythmogenic drugs should raise the suspicion of LQTS and Brugada syndrome.¹³¹

Principles of Management

Pharmacological Therapy

Data from controlled trials or experimental studies are largely lacking. Preliminary clinical experience with quinidine (a class IA antiarrhythmic agent with potent inhibition of I_{to}) is promising. Beta-adrenergic agonists are beneficial in idiopathic VF, particularly for arrhythmic storm. Amiodarone has limited efficacy. Beta-blockers, lidocaine, mexiletine, and verapamil are generally not beneficial (see Fig. 31.7).¹

Acceleration of the heart rate (up to 120 beats/min) by isoproterenol infusion or by atrial or ventricular pacing can be very effective for the acute control of ventricular arrhythmias. Deep sedation may also be considered in refractory cases.

Implantable Cardioverter-Defibrillator

ICD implantation is recommended in patients with prior cardiac arrest due to VF given the high risk of recurrence of ventricular arrhythmias (11% to 45% mean follow-up of 3.2 to 5.3 years) and the fact that neither medical therapy nor catheter ablation provides absolute protection from SCD.^{1,122,127}

In patients with ICDs and frequent nonsustained ventricular arrhythmias or recurrent sustained arrhythmias precipitating frequent ICD therapies, adjuvant antiarrhythmic therapy with quinidine can be helpful. Of note, patients with VF and early repolarization have shown a higher risk of VF recurrence than those without early repolarization (43% vs. 23% during 5 years of follow-up). ICD recipients also experience a high rate of inappropriate shocks (14% to 44%; mean follow-up, 1.9 to 8.8 years), frequently precipitated by AF.^{1,122,127}

In view of the lack of specific risk factors and the absence of abnormalities on the ECG or imaging studies in patients with idiopathic VF, identification of at-risk asymptomatic subjects is currently not possible. In addition, the optimal management of asymptomatic family relatives and mutation carriers is uncertain. Nonetheless, ICD implantation may be considered in the presence of unexplained syncope in a first-degree relative of an idiopathic VF victim, but only after careful work-up of the cause of syncope and patient counseling.^{1,123}

Catheter Ablation

Recent evidence suggests an important role of specific triggers for initiation of idiopathic VF (Fig. 31.20). Distal Purkinje fibers have been recognized as the most frequent site of VF-triggering PVCs occurring during the vulnerable period of cardiac repolarization. The culprit PVCs have also been demonstrated to originate from sites other than the HPS, including the RVOT, LVOT, and papillary muscles.¹³²

PVCs originating from the RVOT, although generally considered “benign,” can initiate polymorphic VT and VF in some patients with idiopathic VF. Distinguishing between the “malignant” forms and the benign form of RVOT PVCs is often challenging. Data suggest that shorter CLs during monomorphic VT, short coupling intervals

Fig. 31.20 Polymorphic Ventricular Tachycardia (VT) Triggered by Premature Ventricular Complexes (PVCs). The telemetry rhythm strips show normal sinus rhythm with PVCs that trigger an episode of polymorphic VT. Note that the morphology of the triggering PVCs is similar to that of the isolated PVC.

of the PVCs, and a history of syncope with malignant characteristics, can potentially predict the coexistence of VF or polymorphic VT in patients with idiopathic RVOT VT/PVCs. However, significant overlap exists.

When ventricular arrhythmias are triggered by monomorphic PVCs, catheter ablation of the PVC focus can potentially prevent further episodes of VF or reduce the burden of arrhythmias. In the setting of PVCs arising from the Purkinje network, a presystolic low-amplitude and high-frequency signal (Purkinje potential) is typically recorded at the successful ablation site, whereby the Purkinje potential precedes and is closely coupled with the ventricular signal of the culprit PVC (eFig. 31.5). Abolition of the local Purkinje potentials and suppression of the targeted PVCs have been shown in a small series to significantly reduce the frequency of VF.¹³²

The presence of frequent PVCs during the ablation procedure can significantly improve the success of ablation. Not infrequently, the optimal time for ablation is at the time of an arrhythmic storm when the PVCs tend to be frequent. When the PVCs are absent at the time of the procedure, provocative maneuvers (including the use of isoproterenol or programmed electrical stimulation) are not usually helpful. Pace mapping can be used in cases of monomorphic ventricular ectopy when a clear 12-lead recording of the clinical PVCs initiating VF has been obtained (eFigs. 31.6 and 31.7).¹³²

Catheter ablation of focal PVCs may be considered especially in patients with frequent episodes of syncope or repeated ICD shocks refractory to drug therapy. Nonetheless, ablation therapy is not a substitute for ICD therapy because of the risk of recurrence of VF (in 18% of patients) triggered by PVCs either from the original focus or from new foci.¹

It is worth noting that recent studies found a concordance between the site of origin of VF-triggering PVCs and the location of the early repolarization pattern on the surface ECG. Patients with early repolarization recorded in inferior leads alone had PVCs originating from the inferior LV wall, whereas those with early repolarization recorded in both inferior and lateral leads had PVCs originating from multiple regions.

Participation in Sports

Restriction from competitive sports is appropriate in patients with idiopathic VF.⁶⁰

Periodic Evaluation

Importantly, the initial diagnosis of idiopathic VF can change during follow-up, despite comprehensive clinical investigation at the time of the index event. Phenotypic findings of other primary electric diseases or latent structural causes are often dynamic and may not be present at initial evaluation.¹³⁰ In fact, 11% to 38% of patients initially diagnosed with idiopathic VF reveal a specific disease (e.g., ARVC or Brugada syndrome) during follow-up. Therefore the diagnosis of idiopathic VF should be periodically reassessed with clinical history, physical examination, ECG, and possibly other tests, as guided by clinical suspicion. An annual assessment including an ECG is recommended, with repeat imaging, ambulatory monitoring, and exercise testing every 2 to 3 years, and with any change in arrhythmia burden.^{127,133}

Family Screening

Unlike other arrhythmia syndromes, such as Brugada syndrome and LQTS, no cardiac abnormalities are observed in idiopathic VF patients, apart from the early repolarization ECG pattern, which is also not infrequently observed in the general population. Hence, family members who may be at risk cannot be identified and the penetrance of idiopathic VF cannot be assessed on the basis of an ECG phenotype.¹²²

As noted, phenotype penetrance of inherited arrhythmogenic syndromes can vary among gene carriers in the same family; hence, it is recommended to evaluate first-degree relatives of all idiopathic VF victims with resting ECG, exercise stress testing, and echocardiography.¹³¹ In addition, Holter monitoring, and signal-averaged ECGs, CMR, and provocative testing with class IC antiarrhythmic drugs and epinephrine infusion may also be considered, especially in relatives with unexplained syncope. Furthermore, even when the initial assessment is normal, periodic clinical assessment is indicated in young family members of idiopathic VF victims (as young patients may only manifest symptoms or signs of the disease at an older age and certain diseases have age-related penetrance) and in all family members whenever additional suspicious sudden deaths are identified in the family.¹

The recent identification of mutations of the *DPP6* and *CALM1* genes as a potential familial component in idiopathic VF may allow presymptomatic identification of individuals at risk. Cascade family screening should be considered when a pathogenic mutation is found (e.g., *DPP6* or *CALM1*) or a specific diagnosis is revealed.¹²²

EARLY REPOLARIZATION SYNDROMES

Early repolarization ECG patterns, consisting of a distinct J wave or J point elevation, or a notch or slur of the terminal part of the QRS, are predominantly found in healthy young men and have traditionally been viewed as totally benign, “normal variants.” However, this concept has been challenged by several recent studies, which demonstrated that early repolarization patterns in apparently healthy subjects could represent a marker of increased dispersion of repolarization and arrhythmogenesis, and of the presence of a relationship between certain repolarization patterns and some cases of unexplained VF and SCD.^{65,134}

Genetics of Early Repolarization Syndrome

Several studies have suggested the early repolarization pattern is a heritable phenotype. Familial early repolarization has been reported to have an autosomal dominant inheritance pattern with incomplete penetrance. Variants in genes encoding cardiac ion channels have been identified in individuals and families with early repolarization syndrome (Table 31.19). Gain-of-function mutations in *KCNJ8* and *ABCC9* genes (encoding the pore-forming and ATP-sensing subunits of the I_{K-ATP} channel) and the *KCNE5* gene (encoding the I_{to} channel) have been reported in patients with early repolarization syndrome. Loss-of-function variations in the $\alpha 1$, $\beta 2$, and $\alpha 2\delta$ subunits of the cardiac L-type Ca^{2+} channel (encoded respectively by the *CACNA1C*, *CACNB2*, and *CACNA2D1* genes) and the $\alpha 1$ subunit of $Na_v1.5$ and $Na_v1.8$ (*SCN5A*, *SCN10A*) have been reported in patients with early repolarization syndrome.

TABLE 31.19 Molecular Basis of the Early Repolarization Syndrome

	Gene	Protein	Functional Effect	% of Probands
ERS1	KCNJ8	Kir6.1	$\uparrow I_{K-ATP}$	
ERS2	CACNA1C	$Ca_v1.2$	$\downarrow I_{CaL}$	4.1%
ERS3	CACNB2B	$Ca_v\beta 2b$	$\downarrow I_{CaL}$	8.3%
ERS4	CACNA2D1	$Ca_v\alpha 2\delta$	$\downarrow I_{CaL}$	4.1%
ERS5	ABCC9	SUR2A	$\uparrow I_{K-ATP}$	Rare
ERS6	SCN5A	$Na_v1.5$	$\downarrow I_{Na}$	Rare
ERS7	SCN10A	$Na_v1.8$	$\downarrow I_{Na}$	

I_{CaL} , L-type Ca^{2+} current; I_{K-ATP} , ATP-activated inward rectifier K^+ current; I_{Na} , Na^+ current; ERS1 to ERS7, early repolarization syndrome types 1 to 7, respectively.

eFig. 31.5 Sinus Rhythm (*Left*) and Premature Ventricular Complexes (PVCs, *Right*) in a Patient With Idiopathic Ventricular Fibrillation. Dashed lines denote the onset of QRS complexes. Blue arrows indicate Purkinje potentials, and red arrows indicate His potentials. During sinus rhythm, His potentials precede Purkinje potentials, the sequence of which is reversed in the PVCs.

eFig. 31.6 Pace Mapping of Premature Ventricular Complexes (PVCs) in a Patient With Idiopathic Ventricular Fibrillation. *Left*, Sinus rhythm (SR) and a PVC in a patient with idiopathic ventricular fibrillation are shown. *Right*, Pacing at the PVC site of origin closely mimics the PVC.

eFig. 31.7 Catheter Ablation of Premature Ventricular Complexes (PVCs) in a Patient With Idiopathic Ventricular Fibrillation. Three seconds after the onset of radiofrequency energy delivery at the site of PVC origin, a burst of ectopy occurs having the same QRS configuration as the spontaneously occurring PVC (see eFigs. 31.5 and 31.6).

Recently, gain-of-function mutations in the genes encoding the major channel subunits of I_{to} , *KCNQ2* and *KCNQ3*, have been described in Brugada syndrome and an atypical anterior J wave syndrome associated with SCD.^{134–136}

Pathophysiology of Early Repolarization Syndromes

Mechanism of Early Repolarization and J Waves

The exact ionic and cellular mechanisms for the J wave and early repolarization pattern are still under investigation. Heterogeneity in the distribution of I_{to} channels across the myocardial wall, being more prominent in ventricular epicardium than endocardium, results in the shorter duration, prominent phase 1 notch, and “spike and dome” morphology of the epicardial action potential as compared with the endocardial action potential. The resultant transmural voltage gradient during the early phases (phases 1 and 2) of the action potential is thought to be responsible for the inscription of the J wave on the surface ECG (see Fig. 31.9).^{137,138}

An outward shift of currents, secondary to a decrease in the inward currents (I_{Na} and I_{CaL}), an increase in the outward K^+ currents (I_{to} , I_{Kr} , I_{Ks} , I_{KACH} , I_{KATP}), or both, can cause accentuation of the action potential notch, leading to augmentation of the J wave or the appearance of ST segment elevation on the surface ECG. An outward shift of currents that extends beyond the action potential notch not only can accentuate the J wave, but also lead to partial or complete loss of the dome of the action potential, leading to a protracted transmural voltage gradient that manifests as greater ST segment elevation and gives rise to J wave syndromes. The type of ion current affected and its regional distribution in the ventricles determines the particular phenotype (including the Brugada syndrome, early repolarization syndrome, hypothermia-induced ST segment elevation, and infarction-induced ST segment elevation).¹³⁹ Male predominance can potentially result from larger epicardial I_{to} density versus that in women.¹³⁵

It should be mentioned that not all investigators are in complete agreement about the EP basis of J waves and whether the mechanism responsible for abnormal J waves is related to depolarization abnormalities (i.e., slow impulse conduction) rather than repolarization abnormalities.¹³⁵ However, while there is evidence that depolarization abnormalities are involved in the formation of a Brugada-type ECG (i.e., conduction delay to the RVOT) and ischemia-related early repolarization (conduction delay through ischemic myocardial zones) and contribute to the arrhythmias in those diseases, there is less evidence for depolarization abnormalities in patients with inferolateral early repolarization and hypothermia-related early repolarization.¹⁴⁰

Mechanism of Arrhythmogenesis

The exact relationship of an early repolarization pattern and malignant ventricular arrhythmias remains unclear. It is likely that the increased transmural heterogeneity of ventricular repolarization (i.e., dispersion of repolarization between epicardium and endocardium), which is responsible for J point elevation and the early repolarization pattern on the surface ECG, is also responsible for the increased vulnerability to ventricular tachyarrhythmias. A significant outward shift in current can cause partial or complete loss of the dome of the action potential in regions where I_{to} is prominent (epicardium), with the consequent loss of activation of I_{CaL} . The dome of the action potential can then propagate from regions where it is preserved (midmyocardium and endocardium) to regions where it is lost (epicardium), giving rise to phase 2 reentry, which can generate short-coupled PVCs (falling on the descending limb of the T wave: the R-on-T phenomenon) that interacts with a susceptible ventricular substrate to trigger transmural reentry and polymorphic VT or VF (see Fig. 31.10). This phenomenon is also observed during “ischemic VF,” Brugada syndrome, and idiopathic

VF. J wave appearance represents an initial response to acute ischemia, resulting from the loss of the transient outward potassium current–mediated epicardial action potential dome triggering VF. This might explain why early repolarization is a marker for increased arrhythmic mortality across a heterogeneous clinical spectrum.^{139,141,142}

Notably, this pathophysiology is analogous to the mechanism operative in the Brugada syndrome. Although the ECG location of early repolarization in Brugada syndrome is thought to be secondary to the presence of increased transmural dispersion of repolarization in the RVOT mediated by increased epicardial I_{to} , the location of early repolarization and associated J waves involving inferolateral leads caused by heterogeneity in action potential morphology and duration across the LV wall. Higher intrinsic levels of I_{to} in the inferior LV wall likely accounts for the greater vulnerability of this region for developing VF.¹³⁴

Importantly, the J wave in early repolarization syndrome increases markedly just before arrhythmic events, an occurrence which is now recognized as a hallmark of the disease. J wave amplitude is augmented by slow heart rate and increased vagal activity, which can potentially explain why VF in these patients often occurs during sleep or at a low level of physical activities.¹³⁴

Modulation of Early Repolarization Pattern

Patients with early repolarization syndrome can display dynamic J point elevation. Factors that influence the kinetics of I_{to} or the other repolarization currents (including heart rate, heart rhythm, autonomic tone, and drugs) can modify the manifestation of the J wave on the ECG. J wave amplitude increases during slow heart rates as well as a short-long-short sequence and a pause, which is likely related to augmentation of I_{KACH} and IK-A P (secondary to increased vagal tone) as well as augmentation of I_{to} (facilitated by bradycardia). It is important to note that during episodes of high vagal tone, a degree of elevation of the J point can be a physiological finding in normal individuals. In patients with early repolarization syndrome, however, bradycardia-mediated J point elevation is markedly amplified. On the other hand, acceleration of the heart rate, which is associated with reduction of I_{to} (because of the slow recovery of I_{to} from inactivation), results in a decrease in the magnitude of the J wave.¹⁴³ Circadian variation of the J-wave amplitude is also known to occur, and its augmentation is in concordance with a vagal tone.

J waves can be augmented or induced by hypothermia and fever; however, the development of arrhythmias in early repolarization syndrome is much more sensitive to hypothermia, whereas arrhythmogenesis in Brugada syndrome appears to be promoted only by fever.

Quinidine, which inhibits both I_{to} and I_{Na} , reduces the magnitude of the J wave and normalizes ST segment elevation. Quinidine was found to be effective in partially reversing the repolarization abnormalities, thus restoring electric homogeneity and abolishing the arrhythmogenic substrate.^{135,144}

Na^+ channel blockers (ajmaline, procainamide, pilsicainide, propafenone, flecainide, and disopyramide), which reduce the inward I_{Na} , unmask or accentuate J wave manifestation in Brugada syndrome but attenuate the J wave amplitude in early repolarization patients. Although this differential effect of Na^+ channel blockers initially invoked a potentially different pathophysiology of early repolarization from that of the Brugada syndrome, a recent study demonstrated that J waves recorded with unipolar LV epicardial leads introduced into the left lateral coronary vein in early repolarization syndrome patients were indeed augmented, even though J waves recorded in the lateral precordial leads were diminished, principally because of engulfment of the surface J wave by the widened QRS. Na^+ channel blockade results in slowing of conduction and delay of the terminal ventricular activation whereby the S waves superimpose the J waves. These S waves represent an opposing force

to the J waves and depending on their amplitude and duration, can decrease or completely obscure the J waves.^{144,145}

Via beta-adrenergic stimulation, isoproterenol augments I_{CaL} by increasing the mean channel open time and probability of channel opening. In addition, because of slow recovery from inactivation, I_{to} is rate dependent with decreasing current magnitude at higher heart rates, and isoproterenol decreases I_{to} via an acceleration of heart rate. The combined effect of increasing Ca^{2+} influx (via I_{CaL} augmentation) and reducing K^+ efflux (via I_{to} inhibition) counteracts some of the primary mechanisms thought to underlie the formation of J waves and early repolarization. The observed effects of isoproterenol are most compatible with the repolarization disorder hypothesis for early repolarization. Depolarization abnormalities are expected to worsen, rather than improve, at faster heart rates.

Cilostazol and milrinone inhibit the activity of phosphodiesterase III, increasing the intracellular concentrations of cAMP, which in turn results in augmentation of I_{CaL} . Milrinone has much greater potency than cilostazol, possibly because milrinone blocks both phosphodiesterase III and phosphodiesterase IV.^{138,144}

Bepridil is a Ca^{2+} channel antagonist with lidocaine-like rapid kinetic blocking effects of Na^+ channels. Bepridil also blocks most types of K^+ currents, including I_{to} . Bepridil can decrease the number of VF episodes in patients with idiopathic VF (including those with Brugada syndrome).

Epidemiology

The prevalence of the early repolarization pattern in the general population varies from 1% to 13%, depending on age (predominant in children and young adults), race (highest among African-Americans and Southeast Asians), gender (predominant in men), and the criterion for J point elevation (0.05 mV vs. 0.1 mV).¹ The prevalence of an early repolarization pattern is several-fold higher in athletes (ranging from 10% to 90%) than in the general population. In athletes, this ECG pattern is thought to be related, at least in part, to heightened vagal tone.¹⁴⁶

Early repolarization is more frequent in patients with idiopathic VF than in control subjects, occurring in 15% to 70% of the idiopathic VF cases. Further, the prevalence of inferolateral J point elevation is higher in the family members of sudden arrhythmic death syndrome probands compared with the general population (23% vs. 11%). Importantly, among patients with idiopathic VF, those with early repolarization are more likely to have a history of syncope or SCD than those without early repolarization. Moreover, the presence of an early repolarization pattern, especially in the inferior or inferolateral leads, has recently been recognized as associated with vulnerability to VF and a 1.7 relative risk for SCD. In the 35- to 45-year-old age range of maximal early repolarization-related SCD incidence, a J wave is estimated to increase idiopathic VF risk from 3.4 per 100,000 to 11 per 100,000.^{135,146}

However, it is important to recognize that although early repolarization is a common entity, idiopathic VF itself is very rare. Therefore the incidental discovery of a J wave on routine screening should not be interpreted as a marker of “high risk” for SCD because the odds for this fatal disease would still be approximately 0.01% (and well less than 0.1% among asymptomatic individuals with J waves with the most “malignant” morphology), which is significantly less than the estimated 1% annual risk of spontaneous VF among asymptomatic adults with a type I Brugada ECG.¹

In addition to reports of SCD in otherwise healthy patients, the presence of early repolarization on the ECG appears to be a modulator of arrhythmic risk in patients with other cardiac disorders. An early repolarization ECG pattern has been associated with an increased risk of malignant arrhythmias and SCD in patients with Brugada syndrome, acute myocardial infarction (MI), chronic ischemic heart disease, heart failure, and hypothermia.¹³⁴

Early repolarization appears to be a heritable phenotype; offspring of early repolarization-positive parents have a 2.5-fold increased risk of presenting with early repolarization on the surface ECG. In addition, genetic contributions to SCD-associated early repolarization are suggested by common familial SCD histories in symptomatic early repolarization patients. Several reports demonstrated a high familial aggregation of sudden death in early repolarization syndrome patients; a family history of sudden death is reported in about one-fifth of patients with VF and early repolarization. Geographic differences in distribution have also been described, with early repolarization-related SCD being particularly prevalent among Southeast Asians.¹³⁶

Clinical Presentation

The vast majority of individuals with an early repolarization ECG pattern remain asymptomatic, and are usually found to have an early repolarization pattern as an incidental finding. Idiopathic VF patients (e.g., survivors of unexplained cardiac arrest) who are found to have clear ECG evidence of early repolarization are now defined as early repolarization syndrome patients. Early repolarization syndrome is extremely rare, but these patients have a high risk of recurrent cardiac events. Life-threatening arrhythmias are often the first and unexpected manifestation of early repolarization syndrome, and usually occur at a young age (typically less than 40 years).^{1,135}

Electrocardiographic Features

There has been considerable variation in the use of the terms “early repolarization” and “J point.” Historically, the term “early repolarization” was used to describe two ECG phenomena: (1) an upward deflection of the J point (or terminal part of the QRS complex) termed “J point elevation” or “J wave” and (2) ST segment elevation not associated with pathological conditions such as MI. More recently, after the emergence of reports associating early repolarization with idiopathic VF, most studies used the term “early repolarization” to describe an elevation of the QRS-ST segment junction (J point) greater than or equal to 0.1 mV in greater than or equal to 2 contiguous inferolateral leads (I, II, III, aVL, aVF, and V_4 to V_6), excluding right precordial leads. The morphology of the J point can be slurring (a smooth transition from the QRS segment to the ST segment) or notching (a positive J deflection inscribed on the S wave). Also, there is a consensus that the pattern of end-QRS notching and slurring may, on occasion, be due to late depolarization rather than early repolarization. Therefore some investigators suggest that the term “early repolarization” should be replaced by “J waves.”^{135,147}

Terminology

An expert consensus report published in 2015 proposed a standardized terminology and definition of ECG manifestations of early repolarization. It is recommended that the peak of an end-QRS notch and/or the onset of an end-QRS slur be designated as Jp, and that the onset of the end-QRS notch or J wave be designated as Jo and the end of a notch or slur as Jt. In the case of a slur, Jo and Jp are electrocardiographically the same point (Fig. 31.21).^{65,147}

The pattern of ST segment elevation after the J point can be classified as horizontal or downward sloping (if the amplitude of the ST segment 100 milliseconds after Jt is less than or equal to the amplitude at Jt) or upward sloping (if the amplitude of the ST segment 100 milliseconds after Jt is greater than the amplitude at Jt). ST segment elevation in the absence of a slur or notch should not be reported as early repolarization.^{65,147}

Definition

Early repolarization is present if all of the following criteria are met:^{65,147}

1. There is an end-QRS notch or slur on the downslope of a prominent R wave (with and without ST segment elevation). If there is a notch,

Fig. 31.21 Standardized Terminology and Definition of Electrocardiogram Manifestations of Early Repolarization. (A) In case of an end-QRS notch, the peak of the notch is designated as J_p , the onset of the notch is designated as J_o , and the end of a notch as J_t . (B) In the case of an end-QRS slur, J_o and J_p are electrocardiographically the same point. (Modified from MacFarlane PW, Antzelevitch C, Haissaguerre M, et al. The early repolarization pattern: a consensus paper. *J Am Coll Cardiol.* 2015;66:470–477.)

it should lie entirely above the baseline. The onset of a slur must also be above the baseline.

2. The peak of the notch or J wave (J_p) is greater than or equal to 0.1 mV in more than two contiguous leads of the 12-lead ECG, excluding leads V_1 to V_3 .
3. QRS duration (measured in leads in which a notch or slur is absent) is less than 120 milliseconds.

If the ST segment is upward sloping and followed by an upright T wave, the pattern should be described as “early repolarization with an ascending ST segment.” If the ST segment is horizontal or downward sloping, the pattern should be described as “early repolarization with a horizontal or descending ST segment.”

Right precordial leads (V_1 to V_3) have been excluded from the new definition of early repolarization to avoid confusion with the Brugada pattern.

An end-QRS notch is a notch that occurs on the final 50% of the downslope of an R wave occurring as the final segment of the QRS complex; that is, it links with the ST segment of the waveform (Fig. 31.22A). It should be distinguished from a notch midway on the downslope of an R wave (see Fig. 31.22B) because this may be due to

Fig. 31.22 QRS Notching and Slurring. (A) Electrocardiographic leads showing end-QRS notching in lead V_4 progressing to end-QRS slurring in lead V_6 . End-QRS slurring is also present in leads I and aVL. The arrows localize the notching or slurring. (B) Leads III and aVF show notching. In lead III, the notch peak is greater than 50% of the R wave amplitude and could be regarded as fragmentation. In lead II, appearances on the R wave downslope take the form of a slur, and there is also a notch in lead aVF. They are most probably due to the same underlying physiological process. The arrows indicate the location of the notches and slur. (From MacFarlane PW, Antzelevitch C, Haissaguerre M, et al. The early repolarization pattern: a consensus paper. *J Am Coll Cardiol.* 2015;66:470–477.)

fragmentation. Similarly, an end-QRS slur is an apparent slowing of the inscription of the waveform at the end of the QRS complex that merges with the ST segment of the complex. Likewise, a slur should occur in the final 50% of the R wave downslope.¹⁴⁷

Importantly, ST segment elevation is not a required criterion (Fig. 31.23). In the absence of any end-QRS notching or slurring, it is recommended that the finding of ST segment elevation be described as nonspecific ST segment elevation and not described as early repolarization (Fig. 31.24).¹⁴⁷

The early repolarization pattern can vary in response to autonomic tone and heart rate. Bradycardia and increased vagal tone (e.g., during sleep) accentuate ST segment elevation. Contrariwise, tachycardia and adrenergic stimulation (e.g., exercise testing or the infusion of isoproterenol) suppress J wave amplitude and ST segment elevation. In addition, hypothermia can induce prominent J waves (“Osborn waves”).

Fig. 31.23 End-QRS Notching and Slurring With and Without ST Segment Elevation. The upper salmon line indicates the notch or slur amplitude, J peak (Jp), while the lower purple line indicates the baseline used as a reference with respect to which amplitudes should be measured. The blue lines indicate tangents to the initial component of the R wave downslope. All of these waveforms are illustrations of the early repolarization pattern. (From MacFarlane PW, Antzelevitch C, Haissaguerre M, et al. The early repolarization pattern: a consensus paper. *J Am Coll Cardiol.* 2015;66:470–477.)

Localization of Early Repolarization

Based on the localization of the early repolarization pattern on the 12-lead ECG and its potential association with risk for life-threatening arrhythmias, some investigators classified early repolarization patterns into three types¹³⁴:

Type 1: The early repolarization pattern manifests predominantly in the lateral precordial leads (V₄–V₆). This pattern is rarely seen in cases of idiopathic VF, is highly prevalent among healthy young adults and athletes, and is thought to be associated with a relatively low level of risk for arrhythmic events.

Type 2: The early repolarization pattern is localized to the inferior or inferolateral leads. This pattern is less common in the general

Fig. 31.24 Nonspecific ST Segment Elevation. An illustration of an electrocardiogram showing moderate ST segment elevation in leads I, II, and aVF and more marked ST segment elevation in leads V₄–V₆, in the absence of any end-QRS notching or slurring. It is recommended that this finding not be described as early repolarization. The arrows indicate the points of ST segment elevation. (From MacFarlane PW, Antzelevitch C, Haissaguerre M, et al. The early repolarization pattern: a consensus paper. *J Am Coll Cardiol.* 2015;66:470–477.)

population, but is observed in approximately 50% of cases of idiopathic VF. Early repolarization in the inferior leads is also associated with an increased risk of cardiovascular death from any cause.

Type 3: Early repolarization is more global, involving the inferior, lateral, and right precordial leads. This pattern is the rarest and carries the highest risk of malignant ventricular arrhythmias.

Diagnosis of Early Repolarization Syndrome

According to a recent expert consensus, an “early repolarization pattern” can be diagnosed in the presence of J point elevation greater than or equal to 1 mm in more than two contiguous inferior and/or lateral leads of a standard 12-lead ECG. An “early repolarization syndrome” is diagnosed in the presence of early repolarization pattern in a patient resuscitated from otherwise unexplained VF/polymorphic VT or in an SCD victim with a negative autopsy and medical chart review.¹

A scoring system (the Shanghai Score) has been proposed for the diagnosis of early repolarization syndrome (Table 31.20). This system is based on evidence available in the literature to date, but is yet to be validated in future studies.

TABLE 31.20 Shanghai Score System for Diagnosis of Early Repolarization Syndrome

	Points
I. Clinical History	
A. Unexplained cardiac arrest, documented VF or polymorphic VT	3
B. Suspected arrhythmic syncope	2
C. Syncope of unclear mechanism/unclear etiology	1
<i>Only award points once for highest score within this category.</i>	
II. Twelve-Lead ECG	
A. ER >0.2 mV in >2 inferior and/or lateral ECG leads with horizontal/descending ST segment	2
B. Dynamic changes in J point elevation (≥0.1 mV) in ≥2 inferior and/or lateral ECG leads	1.5
C. ≥0.1 mV J point elevation in at least 2 inferior and/or lateral ECG leads	1
<i>Only award points once for highest score within this category.</i>	
III. Ambulatory ECG Monitoring	
A. Short-coupled PVCs with R on ascending limb or peak of T wave	2
IV. Family History	
A. Relative with definite ERS	2
B. ≥2 first-degree relatives with a II.A. ECG pattern	2
C. First-degree relative with a II.A. ECG pattern	1
D. Unexplained sudden cardiac death <45 years in a first- or second-degree relative	0.5
<i>Only award points once for highest score within this category.</i>	
V. Genetic Test Result	
A. Probable pathogenic ERS susceptibility mutation	0.5
Score (requires at least one ECG finding)	
≥5 points: Probable/definite ERS	
3–4.5 points: Possible ERS	
<3 points: Nondiagnostic	

ECG, Electrocardiogram; ER, early repolarization; ERS, early repolarization syndrome; PVC, premature ventricular contraction; VF, ventricular fibrillation; VT, ventricular tachycardia.

From Antzelevitch C, Yan GX, Ackerman MJ, et al. J-wave syndromes expert consensus conference report: emerging concepts and gaps in knowledge. *Heart Rhythm*. 2016;13:e295–e324.

Importantly, the diagnosis of “early repolarization syndrome” in survivors of cardiac arrest requires a complete evaluation to exclude underlying structural or other primary electrical heart disease, and exclusion of respiratory, metabolic, and toxicological etiologies. This typically necessitates extensive diagnostic testing, as discussed previously for idiopathic VF.¹ Furthermore, other causes of J point elevation (ischemia, hypokalemia, hypercalcemia, hypothermia) need to be excluded. Genetic testing for early repolarization syndrome is still of questionable benefit and, until validated in future studies, is considered investigational.^{1,135,147}

No consensus exists regarding the evaluation of asymptomatic individuals incidentally found to have an early repolarization pattern on the surface ECG. Currently, in the absence of syncope or a strong family history of juvenile SCD, the finding of the early repolarization pattern does not merit further investigation.^{1,135,147}

Differential Diagnosis

Early repolarization ECG patterns can be observed in a spectrum of acquired and congenital disorders, collectively referred to as “J wave syndromes,” which include the Brugada syndrome, hypothermia, and acute myocardial ischemia, in addition to the early repolarization syndrome. Those syndromes appear to share similar pathophysiology and arrhythmogenic mechanisms characterized by polymorphic VT or VF triggered by short-coupled PVCs.^{134,140}

In hypothermia (including therapeutic hypothermia), J waves (Osborne waves) can manifest diffusely in all leads or be confined to selected leads. Rarely, hypothermia can induce ECG changes that mimic those of Brugada syndrome.¹⁴⁰

The early repolarization syndrome shares a number of features with Brugada syndrome (Table 31.21). Both syndromes are associated with vulnerability to polymorphic VT and VF in young adults without apparent structural heart disease. However, in the Brugada syndrome, the region most affected by the disease is the anterior RVOT, and ST segment elevation is limited to the right precordial leads. Of note, a Brugada pattern on the surface ECG can be missed in patients with an inferolateral early repolarization pattern unless appropriate ECG recordings from the high intercostal space region are obtained. The presence of the Brugada ECG pattern was found to be a marker of poor outcome in patients with early repolarization; similarly, the presence of an inferolateral early repolarization ECG pattern was found to be a marker of poor outcome in patients with Brugada syndrome.^{134,148}

In addition, several cardiac and noncardiac conditions can produce ECG changes that can potentially thus masquerade as a J wave (Box 31.4).

Risk Stratification

Despite the reports linking early repolarization with sudden death, only a very small minority (1:10,000) of patients with this pattern on the ECG will have sudden cardiac arrest, while the majority remain asymptomatic. The identification of this minority of patients before they experience sudden death continues to be a challenge.

Currently, the identification of the “malignant” variant of the early repolarization pattern relies on several parameters, including the amplitude, distribution, and dynamicity of J point elevation, as well as the morphology of the ST segment, pause-dependent augmentation of J point elevation, and the presence of short-coupled PVCs, among others. However, the sensitivity and specificity of these parameters remain limited. Although the presence of those markers is predicted to progressively augment the cumulative risk of SCD (Fig. 31.25), the absolute risk conferred for an asymptomatic patient remains too small to justify an aggressive approach in the absence of symptoms. Nonetheless, the presence of early repolarization should attract careful attention in certain groups of patients.

TABLE 31.21 Similarities and Differences Between BrS and ERS and Possible Underlying Mechanisms

	BrS	ERS	Possible Mechanism(s)
Similarities Between BrS and ERS			
Male predominance	Yes (>75%)	Yes (>80%)	Testosterone modulation of ion currents underlying the epicardial AP notch
Average age of first event	30–50	30–50	
Associated with mutations or rare variants in <i>KCNJ8</i> , <i>CACNA1C</i> , <i>CACNB2</i> , <i>CACNA2D</i> , <i>SCN5A</i> , <i>ABCC9</i> , <i>SCN10A</i>	Yes	Yes	Gain of function in outward currents (I_{K-ATP}) or loss of function in inward currents (I_{Ca} or I_{Na})
Relatively short QT intervals in subjects with Ca channel mutations	Yes	Yes	Loss of function of I_{Ca}
Dynamicity of ECG	High	High	Autonomic modulation of ion channel currents underlying early phases of the epicardial AP
VF often occurs during sleep or at a low level of physical activity	Yes	Yes	Higher level of vagal tone and higher levels of I_{to} at the slower heart rates
VT/VF trigger	Short-coupled PVC	Short-coupled PVC	Phase 2 reentry
Ameliorative response to quinidine and bepridil	Yes	Yes	Inhibition of I_{to} and possible vagolytic effect
Ameliorative response to isoproterenol, denopamine and milrinone	Yes	Yes	Increased I_{Ca} and faster heart rate
Ameliorative response to cilostazol	Yes	Yes	Increased I_{Ca} , reduced I_{to} and faster heart rate
Ameliorative response to pacing	Yes	Yes	Reduced availability of I_{to} due to slow recovery from inactivation
Vagally mediated accentuation of ECG pattern	Yes	Yes	Direct effect to inhibit I_{Ca} and indirect effect to increase I_{to} (due to slowing of heart rate)
Effect of sodium channel blockers on unipolar epicardial electrogram	Augmented J waves	Augmented J wave	Outward shift of balance of current in the early phases of the epicardial AP
Fever	Augmented J waves	Augmented J waves (rare)	Accelerated inactivation of I_{Na} and accelerated recovery of I_{to} from inactivation.
Hypothermia	Augmented J waves mimicking BrS	Augmented J waves	Slowed activation of I_{Ca} leaving I_{to} unopposed. Increased phase 2 reentry but reduced pVT due to prolongation of APD. ³⁵⁸
Differences Between BrS and ERS			
Region most involved	RVOT	Inferior LV wall	Higher levels of I_{to} and/or differences in conduction
Leads affected	V_1 – V_3	II, II a, VF, V_4 , V_5 , V_6 ; I, aVL, Both: inferolateral	
Regional difference in prevalence			Europe: BrS = ERS Asia: BrS > ERS
Incidence of late potential in signal-averaged ECG	Higher	Lower	
Prevalence of atrial fibrillation	Higher	Lower	
Effect of sodium channel blockers on surface ECG	Increased J wave manifestation	Reduced J wave manifestation	Reduction of J wave in the setting of ER is thought to be due largely to prolongation of QRS. Accentuation of repolarization defects predominates in BrS, whereas accentuation of depolarization defects predominates in ERS.
Structural changes, including mild fibrosis and reduced expression of Cx43 in RVOT or fibrofatty infiltration in cases of arrhythmogenic right ventricular cardiomyopathy. Imaging studies have also revealed wall motion abnormalities and mild dilation in the region of the RVOT.	Higher in some forms of the syndrome	Unknown	Some investigators have hypothesized that some of these changes may be the result of, rather than the cause of, the BrS substrate, which may create a hibernation-like state due to loss of contractility in the RVOT secondary to loss of the AP dome.

AP, Action potential; APD, action potential duration; BrS, Brugada syndrome; ECG, electrocardiogram; ERS, early repolarization syndrome; RVOT, right ventricular outflow tract; PVC, premature ventricular contraction; pVT, polymorphic ventricular tachycardia; VF, ventricular fibrillation; VT, ventricular tachycardia.

J Wave Amplitude

Evidence suggests that the height of J point elevation, rather than its mere presence, can potentially provide important risk stratification information. A slurred or notched J point elevation greater than 0.2 mV in the inferior leads predicts a 2.9-fold increase in SCD risk, whereas

an elevation of at least 0.1 mV predicts a more modest (1.4-fold) increase in risk of arrhythmic death. A similar phenomenon was also observed in survivors of primary VF. It is worth noting that J point elevation greater than 0.2 mV seems to be rare (0.3% to 0.7%) in the normal population, but was observed in 16% of patients with idiopathic VF.^{1,139}

BOX 31.4 Differential Diagnosis of Early Repolarization Pattern

- Juvenile ST pattern
- Pericardial disease (pericarditis, pericardial cyst, pericardial tumor)
- Hypothermia
- Hyperthermia
- Myocardial tumor (lipoma)
- Hypertensive heart disease
- Athlete's heart
- Myocardial ischemia
- ST segment elevation myocardial infarction
- Fragmented QRS (terminal notching)
- Hypocalcemia
- Hyperkalemia
- Thymoma
- Aortic dissection
- Arrhythmogenic right ventricular cardiomyopathy
- Takotsubo cardiomyopathy
- Neurological causes (intracerebral bleeding, acute brain injury)
- Myocarditis
- Chagas disease
- Cocaine use

Fig. 31.25 Risk Stratification of Patients With Early Repolarization. The highest risk corresponds to the top of the pyramid, whereas the lowest risk is at the bottom. The estimated prevalence of the risk factor corresponds to the width of the pyramid. *SQTS*, Short QT syndrome; *VPBs*, ventricular premature beats. (From Mahida S, Derval N, Sacher F, et al. History and clinical significance of early repolarization syndrome. *Heart Rhythm*. 2015;12:242–249.)

J Wave Distribution

The distribution of J waves has been reported to influence the risk of sudden death in early repolarization patients. Several studies demonstrated that a lateral distribution of early repolarization portends the lowest risk, whereas an inferior and combined inferior and lateral J

wave distribution confers a progressively increased risk of arrhythmic death. Also, in asymptomatic individuals, early repolarization is most prominent in midprecordial leads (V_2 to V_4), a pattern that is especially predominant among athletes and is thought to confer a more benign prognosis.¹³⁹

J Wave Morphology

A recent report suggested a potential role of J wave duration and slope as markers of an increased arrhythmic risk. A delayed and prolonged J wave, a marker of a transmural dispersion of repolarization, may represent a new discriminant able to distinguish between benign and malignant early repolarization.¹⁴⁹

J Wave Amplitude Fluctuation

Although the pattern of J point elevation on baseline measurement remains constant during long-term follow-up in the majority of subjects, the magnitude of J point elevation can fluctuate even without drug provocation or exercise. Marked spontaneous accentuation of J wave amplitude, bradycardia- or pause-dependent dynamicity of the J wave, and spontaneous beat-to-beat fluctuation in the morphological pattern of early repolarization are frequently observed during periods of electrical storm (including frequent PVCs and episodes of VF). Transient and marked augmentation of J wave amplitude can potentially portend a high risk for VF in patients with early repolarization.^{135,139}

ST Segment and T Wave Morphology

For early repolarization patterns in the inferior or lateral leads, the presence of horizontal or downward-sloping ST segments after the J point predicts an increased risk for arrhythmic death, especially if accompanied by a high-amplitude (greater than 0.2 mV) J point elevation. In contrast, the presence of rapidly upsloping ST segments after the J point, followed by an upright T wave (which is the most common pattern observed in young athletes) is associated with a benign prognosis.^{134,147}

The rapidly ascending ST segment variant is universal in populations with benign prognosis (such as athletes); in contrast, cohorts with increased arrhythmic risk (such as patients with ischemic VF or idiopathic VF) have J waves predominantly followed by a horizontal ST segment without ST segment elevation.

A recent study reported that in patients with idiopathic VF, the prominent J wave is followed not only by a flat ST segment but also by a low-amplitude T wave (defined as T waves in leads I, II, or V_4 – V_6 that were inverted, biphasic, or smaller than 1 mm), and a low T wave-to-R wave amplitude ratio (in lead II or V_5). In fact, a low-amplitude ratio (T wave amplitude less than or equal to 10% of the R wave amplitude in the same lead) performed superior to J wave amplitude and ST segment pattern in differentiating malignant from benign inferolateral early repolarization.¹⁵⁰

Short-Coupled Premature Ventricular Complexes

The presence of frequent and short-coupled PVCs (which can potentially act as a trigger of polymorphic VT or VF) on ECG or during cardiac monitoring confers a significantly increased arrhythmic risk in early repolarization patients.

Syncope

More than one-third of early repolarization syndrome patients with SCD have experienced a previous episode of syncope. However, the presence of syncope has a low specificity in predicting future events and, although syncope is common in the early repolarization population, sudden death is a rare event. Nonetheless, a history of syncope in a patient with early repolarization merits detailed evaluation. The

presence of unexplained syncope, especially when occurring at rest or agonal respiration while sleeping, especially in a patient with a strong family history of sudden death, may identify a subset of early repolarization patients who are at high risk for arrhythmic events.

Family History

A number of studies have reported familial clustering of early repolarization syndrome and SCD. Approximately one-fifth of early repolarization syndrome patients with VF have a family history of sudden death. However, there is currently insufficient evidence to quantify the risk conferred by a positive family history in asymptomatic individuals.

Coexisting Arrhythmia Syndromes

In the presence of other cardiac conditions, the EP substrate leading to early repolarization and J wave formation can potentially reduce the threshold for malignant ventricular arrhythmias. Besides idiopathic VF, recent studies showed that the presence of a J wave was associated with a higher incidence of malignant ventricular arrhythmias in patients with Brugada syndrome and SQTs.¹⁴⁸

Furthermore, the presence of early repolarization (especially early repolarization in the inferior leads and without ST segment elevation) appears to increase the vulnerability to fatal arrhythmia risk in patients with structural cardiac disease, and was found to be a predictor of increased VT/VF or sudden death in patients with chronic ischemic heart disease, acute and subacute MI, vasospastic angina, heart failure (regardless of the etiology), noncompaction cardiomyopathy, and Takotsubo cardiomyopathy.^{151,152}

Exercise Testing

Exercise suppresses the early repolarization pattern both in symptomatic and asymptomatic subjects, especially early repolarization patterns in the lateral leads or those with an ascending ST segment. Therefore exercise testing does not seem to provide prognostic information.¹⁴⁵

Invasive Electrophysiological Testing

Invasive EP testing is not helpful for risk stratification. VF induction by programmed ventricular stimulation has been found to be a poor predictor of arrhythmic risk in symptomatic and asymptomatic patients with early repolarization. Patients with early repolarization do not exhibit significantly higher inducibility with programmed ventricular stimulation than those without early repolarization. Furthermore, VF is inducible during EP testing in only 22% to 34% of the patients with a clinical history of cardiac arrest secondary to VF. In addition, VF inducibility is not correlated with known risk factors, such as the degree of J point elevation, the distribution of J waves, or the ST segment morphology on the surface ECG.¹³⁶

Genetic Screening

The early repolarization pattern is associated with sudden death and has been shown to be heritable. Genetic contributions to SCD-associated early repolarization are suggested by common familial SCD histories in symptomatic early repolarization patients. As noted, several genes have been associated with early repolarization. However, so far, the genetic markers to differentiate benign and arrhythmic forms of early repolarization have not been identified, and the clinical benefit of genetic testing in these patients is currently questionable.

Principles of Management

Patients With Early Repolarization Syndrome

ICD implantation is recommended for secondary prevention in survivors of cardiac arrest or those with documented sustained ventricular arrhythmias and early repolarization pattern. Quinidine is considered an alter-

native therapy when an implanted ICD is not feasible or not preferred. A proposed algorithm for an approach to patients with early repolarization is shown in Fig. 31.26.^{1,135,147}

For acute suppression of ventricular arrhythmias in a patient with an electrical storm, acceleration of the heart rate (20% increase in heart rate or an absolute heart rate greater than 90 beats/min) by isoproterenol infusion or by atrial or ventricular pacing can be very effective. Deep sedation may also be considered in refractory cases (see Fig. 31.7).^{1,134}

For long-term suppression of VF in patients with recurrent arrhythmias or frequent ICD therapies, quinidine has been shown to ameliorate the early repolarization pattern and prevent VF recurrence. The combination therapy of cilostazol and bepridil may be considered an alternative therapy when quinidine is not available or not tolerated.¹³⁵

Syncope Patients With Early Repolarization Pattern

Management decisions for patients with syncope and family history of SCD in the context of early repolarization can be problematic, and should be individualized. The underlying etiology of syncope should be thoroughly investigated. Vasovagal syncope is not uncommon in patients with early repolarization patterns. When etiology of syncope is equivocal, ambulatory cardiac monitoring and loop recorder implantation should be considered. If malignant arrhythmias are highly suspected, ICD implantation may be considered in the patient with a strong family history of SCD.^{1,135,146,147}

Asymptomatic Patients With Early Repolarization Pattern

There is not yet a clear consensus on the specific risk factors that identify asymptomatic early repolarization subjects in whom the probability of SCD is sufficiently high to warrant an ICD for primary prevention. Pending further research, the finding of the early repolarization pattern in the absence of syncope or a strong family history of juvenile SCD does not merit further investigation, regardless of J wave amplitude or ST segment slope. With a strong family history for juvenile SCD, ICD implantation may be considered in subjects with high-risk ECG features of early repolarization.^{1,135,147}

Participation in Sports

Restriction from competitive sports is appropriate in patients with idiopathic VF. However, no information is available about lifestyle modification in asymptomatic patients with early repolarization ECG pattern. Given the high prevalence of early repolarization patterns (especially in leads V₂ to V₆) in athletes, occurring in 20% of noncompetitive athletes and in up to 90% of high-performance athletes, and because the midprecordial location of early repolarization is generally believed to be benign, and in the absence of reliable risk-stratifying parameters, a universal restriction from competitive sports does not seem warranted in asymptomatic athletes with early repolarization and a negative family history of SCD.¹⁴⁶

Nonetheless, certain restrictions may be considered in highly active patients with resting bradycardia and prominent early repolarization patterns localized to the inferior or inferolateral leads and a strong family history of SCD, although definitive guidelines are still lacking.¹⁴⁶

Family Screening

No consensus exists concerning the screening of families of individuals with symptomatic or asymptomatic early repolarization pattern. There are no established provocative tests to diagnose a concealed early repolarization ECG pattern in family members of early repolarization syndrome patients, although preliminary observations suggest that the Valsalva maneuver can potentially assist in identifying concealed early repolarization cases.

Fig. 31.26 Indications for Therapy of Patients With Early Repolarization Syndrome. ECG, Electrocardiogram; ER, early repolarization; ICD, implantable cardioverter-defibrillator; NAR, nocturnal agonal respiration; VT, ventricular tachycardia. (From Antzelevitch C, Yan GX, Ackerman MJ, et al. J-wave syndromes expert consensus conference report: emerging concepts and gaps in knowledge. *Heart Rhythm*. 2016;13:e295–e324.)

A number of drugs also have been tested as potential provocative agents, including verapamil, epinephrine, ATP, cibenzoline, and pilsicainide, and have been reported to have a minimal effect on the degree of J point elevation. In contrast to the Brugada syndrome, Na⁺ channel blockers result in a paradoxical attenuation, rather than accentuation, of J point elevation in early repolarization syndrome patients.^{139,145}

Reported rates of major complications following contemporary catheter ablation procedures vary by as much as five- to eightfold between various types of ablation procedures, ranging from 0.8% for supraventricular tachycardia (SVT), 3.4% for idiopathic ventricular tachycardia (VT), 5.2% for atrial fibrillation (AF), and 6.0% for VT associated with structural heart disease. Death is a rare complication of catheter ablation, occurring in 0.11% to 0.30% of patients with regular SVT, and in 0.31% of those with VT. Transseptal catheterization appears to contribute to the cause of death in 0.2% of procedures.

LOCAL VASCULAR COMPLICATIONS

Incidence

Complications related to vascular access are among the most common problems observed following catheter ablation procedures, and these complications directly impact patient morbidity and increase health care costs. The reported incidence of local vascular complications varies between different studies because of differences in definition of minor and major complications, different types of procedures performed, and

different patient population characteristics. The risk of local vascular complications is higher among females, older adults, obese patients, and those with preexisting peripheral vascular disease. In addition, the risk is related to the type of procedure performed (right or left heart catheterization), the size and number of sheaths used during the procedure, as well as the associated periprocedural use of anticoagulant or antiplatelet therapy. The rates of complications related to the site of vascular access are higher following catheter ablation of AF (1% to 13%) and VT (0.7% to 4.7%) compared with ablation of SVT (0.4%).¹

Detection and Management

Hematomas

Bleeding is the most common vascular complication. Acute bleeding generally can be controlled with prolonged manual compression. Vascular laceration can cause large hematomas in the groin and thigh. Groin hematomas usually resolve in 1 to 2 weeks if ongoing bleeding is stopped. Large hematomas can require blood transfusion, but surgical repair is rarely required. Arteriovenous fistulas and pseudoaneurysms need to be excluded in the setting of large or continually expanding

hematomas. Retroperitoneal hematomas are often the result of arterial puncture above the inguinal ligament, allowing bleeding and hematoma to extend to the retroperitoneal space. Retroperitoneal hematomas should be suspected in the setting of a marked drop in hematocrit or unexplained hypotension or flank pain. Abdominal computed tomography (CT) scanning or ultrasound is required to confirm the diagnosis. Retroperitoneal bleeds are generally managed conservatively (bed rest, blood transfusion). Catheter or surgical interventions, however, can occasionally be required.

Pseudoaneurysms

Femoral artery pseudoaneurysms form when a hole through all the layers of the artery at the puncture site fails to seal, allowing persistent blood flow outside the vessel into a space contained by the surrounding tissue. This is in contrast to a hematoma, which has clotted blood outside the vessel with absence of flow. Pseudoaneurysms lack a fibrous wall and are contained by a surrounding shell of hematoma and the overlying soft tissues. Risk factors for pseudoaneurysm development include the use of large vascular sheaths, potent postprocedure anticoagulation, inadequacy of initial effort at hemostasis after removal of sheaths, and punctures of the femoral artery that are too distal—that is, at the level of bifurcation of the femoral artery or below. In addition, multiple attempts at vascular access (arterial or venous) with inadvertent arterial puncture appear to increase the risk for pseudoaneurysm formation; repeated damage to the arterial wall may result in weakening that leads to pseudoaneurysm development.

A pseudoaneurysm typically manifests as a painful pulsatile mass with a systolic bruit or thrill, and the diagnosis is confirmed by duplex ultrasonography. Pseudoaneurysms can be complicated by rupture or distal embolization. Pseudoaneurysms that are less than 2 cm in size and not enlarging often resolve without intervention, and serial imaging is recommended to confirm spontaneous resolution. On the other hand, pseudoaneurysms that are enlarging or are greater than 2 cm in size can be treated by ultrasound-guided compression of the “neck,” connecting the pseudoaneurysm with the vessel or by percutaneous thrombin injection. Occasionally, surgical repair is required, especially for large pseudoaneurysms with a wide connection to the parent artery.

Arteriovenous Fistulas

Femoral arteriovenous fistulas commonly result when bleeding from the arterial puncture tracks into the adjacent venous puncture. Arteriovenous fistulas are more likely to arise when arterial and venous punctures are performed on the same side or when femoral venous puncture is performed below the common femoral artery, where several superficial branches of the femoral artery overlie the femoral vein. The diagnosis is made on examination with the finding of a continuous “to and fro” bruit, and is confirmed by ultrasound. Many of the iatrogenic arteriovenous fistulas are small and close spontaneously within 1 year, but ultrasound-guided compression or surgical repair can be necessary. Because cardiac volume overload and limb damage are highly unlikely with persistent arteriovenous fistulas, conservative management for at least 1 year is reasonable.

Vascular Thromboembolism

Deep venous thrombosis and pulmonary embolism are rare but can result from venous injury, especially during prolonged procedures requiring multiple venous lines, or in the setting of venous compression by a large arterial hematoma. Femoral arterial thrombosis is rare and occurs more commonly in the setting of a small vessel lumen, the use of a large-diameter sheath, preexisting peripheral vascular disease, diabetes mellitus, female gender, and occasionally with vascular closure devices.

Prevention

Accurate vascular puncture and effective initial control of bleeding after sheath removal are the best measures to prevent local vascular complications. Early diagnosis and management of local access site complications are essential to reduce morbidity and improve outcome.

Traditionally, vessel puncture has relied upon an anatomical landmark technique using palpation of local arterial and bony landmarks. However, significant heterogeneity exists in the anatomical relationship of the femoral vein and artery. Overlap of the femoral artery and the common femoral vein occurs along some portion of their course in two-thirds of patients. In addition, high bifurcation of the common femoral artery at the level of the mid femoral head is not uncommon. Such anatomical variation cannot be appreciated using the anatomical landmark techniques, predisposing to accidental puncture of the artery during intended venous cannulation, and increasing the risk of pseudoaneurysm and AV fistula formation.²

Real-time ultrasound guidance allows direct visualization of femoral vein size and location relative to the femoral artery, and identification of anatomical variations in arterial and venous spatial relationships, minimizing the risk of inadvertent arterial puncture. Ultrasound also allows easy identification of venous bifurcations, which are unsuitable targets for vascular access. Further, visualization of the vein and of the needle tip trajectory during the puncture allows directing the needle tip into the center of the vein and avoidance of a glancing approach toward the periphery of the vessel.

Although evidence on the value of ultrasound guidance is more robust for internal jugular vein cannulation, several recent nonrandomized studies have found the use of ultrasound to guide femoral venous cannulation in the electrophysiological (EP) laboratory to significantly (by more than 60%) reduce the risk of major and minor vascular access complications, decrease cannulation times, and reduce both the number of unsuccessful attempts and the number of unintended arterial punctures. Using micropuncture needle kits has also decreased vascular complications to a degree, especially in the event of inadvertent arterial access (that resolves more quickly after small-needle entry than with a larger needle).^{1,3}

CARDIAC PERFORATION

Incidence

Previous studies reported the incidence of cardiac perforation with catheter-based interventions as follows: 0.8% for all procedures, 1.5% to 4.7% for valvuloplasty, 0.5% to 0.8% for angioplasty-atherectomy, 0.01% for diagnostic catheterization, 0.1% to 0.2% for EP studies, 0.2% for SVT ablation, 0.4% to 2.7% for VT ablation, and 0.5% to 4.0% for left atrium (LA) ablation.

The incidence of procedure-related cardiac tamponade has increased with the increasing number of catheter ablation procedures for the treatment of AF, which typically involves one or more atrial septal punctures, extensive intracardiac catheter manipulation and ablation within the thin-walled LA, and the need for high levels of systemic anticoagulation during the procedure.⁴

Bleeding into the pericardial space is the most common complication of epicardial ablation procedures using the subxiphoid percutaneous approach. While approximately 10% to 20% of patients experience pericardial bleeding, particularly if inadvertent right ventricular (RV) puncture has occurred, pericardial bleeding of more than 80 mL is observed in up to 7%, though cardiac tamponade and severe bleeding are infrequent. Pericardial bleeding related to the epicardial access procedure is most commonly related to RV puncture. The proximal coronary arteries are covered by epicardial fat along the atrioventricular (AV)

groove and the interventricular septum, located away from the typical path of the access needle and thus are less vulnerable to injury. Occasionally disruption of epicardial fat can result in limited bleeding. Pericardial bleeding also can develop later during the mapping and ablation procedure. Laceration of the myocardium or epicardial vessels can occur during manipulation of the pericardial sheath or catheter or as a result of radiofrequency (RF) ablation.⁵⁻⁸

Mechanism

Cardiac perforation can be caused by mechanical trauma secondary to catheter manipulation, myocardial tissue rupture due to RF ablation, or inadvertent injury during atrial septal puncture. Extensive catheter manipulation, especially in areas with thin walls such as the LA roof, RV free wall, right ventricular outflow tract (RVOT), RV apex, and atrial appendages, can cause mechanical tear of the chamber wall. Cardiac perforation can also occur away from the area of mapping and ablation, usually caused by penetration of an unattended RV catheter in the setting of rapid and vigorous heart action because of high-dose isoproterenol infusion. Inadvertent puncture of the right atrium (RA) free wall or lateral LA wall can occur during atrial transseptal puncture.

High RF power application can cause excessive tissue heating and boiling of water within the tissue under the electrode. As a result, evaporation and rapid steam expansion can occur intramurally, and a gas bubble can develop in the tissue under the ablation electrode. Continuous application of RF energy causes the bubble to expand and its pressure to increase, which can lead to eruption of the gas bubble (causing a popping sound) through the path with the least mechanical resistance that leaves behind a gaping hole (the so-called steam pop). This often occurs toward the heat-damaged endocardial surface (leading to crater formation) or, infrequently, across the myocardial wall (resulting in myocardial perforation). Steam pops are often associated with a sudden, although small (<10 Ω) impedance rise and a sudden drop in electrode temperature. When steam pops burst toward the endocardial surface, an intense shower of microbubbles is often detected on intracardiac echocardiography (ICE). The risk of steam pops is relatively low with temperature-controlled standard 4-mm-tip RF catheter ablation, since the electrode temperature, which approximates tissue temperature, is limited to a safe level. However, when there is significant discrepancy between tissue and electrode temperature, due to passive or active electrode cooling, tissue temperature can reach the boiling point without being detected by the monitoring electrode temperature.

Detection

Prompt recognition and management of cardiac perforation are critical to prevent the development of cardiac tamponade and potentially life-threatening hemodynamic collapse. Although the presentation often is dramatic with abrupt hypotension, it is often insidious, with a more gradual fall in blood pressure. Continuous blood pressure monitoring using an arterial line can help detect early hemodynamic compromise. Sinus tachycardia is common in the setting of cardiac tamponade that gradually develops. Nonetheless, the absence of tachycardia does not exclude cardiac tamponade; in fact, sinus bradycardia is often observed secondary to a vagal reflex in the setting of a rapidly developing cardiac tamponade, and patients who are dependent on ventricular pacing will not show this. Any chest pain that persists beyond the completion of an ablation lesion, especially if associated with hypotension and diaphoresis, should alert the operator to the possible development of pericardial effusion.

Assessment of the cardiac silhouette fluoroscopically can provide the first clue, especially if a similar assessment was made at baseline. Decreased excursion of the lateral heart border on fluoroscopy in the left anterior oblique (LAO) projection, indicating accumulating pericardial

effusion, usually can be seen well before a drop in blood pressure and prior to progression to cardiac tamponade. Cineangiography often reveals a double layer in which the epicardial fat can be visualized separate from the outer pericardial shadow. Some operators obtain a baseline LAO cine image at the onset of a procedure to serve as a reference for comparison during the procedure, followed by intermittent evaluation of the same fluoroscopic projection during the procedure.⁹

Transthoracic echocardiography is the most definitive method for confirming the development of pericardial effusion. ICE, commonly used to guide transseptal puncture for LA procedures, can enable early detection of pericardial effusions before the emergence of tamponade physiology. Most of the pericardial space is not visualized from the RA imaging perspective used to visualize the interatrial septum; advancing the ICE catheter into the RV and rotating the transducer against the interventricular septum can readily identify pericardial effusions (Fig. 32.1).

Perforation without tamponade can occur during placement of diagnostic catheters, or while accessing the LA by transseptal catheterization. Detection of pericardial effusion at this time can prevent progression to tamponade but requires a high index of suspicion. Several clues should alert the operator to the possibility of cardiac perforation, including a ventricular catheter that reaches the edge of the cardiac silhouette, high pacing thresholds at sites despite normal electrograms and apparent good tissue contact on fluoroscopy, right bundle branch block pattern during “RV” pacing, and a catheter tip position discordant from where it should be (i.e., an RV catheter too far leftward with intended RV apical location; eFig. 32.1).

With atrial septal puncture for accessing the left heart chambers, the aorta can be inadvertently entered; if only the needle enters the aorta and this is recognized before advancing the dilator and sheath, the needle can be withdrawn and the patient monitored for stability of vital signs and with echocardiography. The procedure can be continued if there is no accumulation of pericardial fluid after 15 to 30 minutes of monitoring. If the dilator and sheath have been advanced into the aortic root before the error is recognized, it is imperative that the sheath not be removed at this time, as this can result in immediate and perhaps irreversible hemodynamic collapse due to intractable bleeding into the pericardial space. A cardiothoracic surgeon should be consulted immediately, who can then remove the sheath and repair the defect in the aortic wall under direct vision.

Fig. 32.1 Intracardiac Echocardiography (ICE) Imaging of Pericardial Effusion. The phased-array ICE transducer is positioned in the right ventricle, showing a short-axis view of the left ventricle (LV) and a moderate pericardial effusion (PE). IVS, Interventricular septum.

eFig. 32.1 Cardiac Perforation During Electrophysiological Study. Surface electrocardiogram and intracardiac recordings from a patient who was undergoing electrophysiological study. Recordings show poor capture from a catheter intended for the right ventricular apex (*RVA*); captured complexes have a right bundle branch block pattern. These features are explained by the accompanying right anterior oblique fluoroscopic image showing that the *RVA* catheter (*arrow*) has perforated the RV anterior wall and is pacing the anterolateral left ventricular epicardium. *His_{dist}*, Distal His bundle; *His_{prox}*, proximal His bundle; *HRA*, high right atrium.

In addition, during attempted atrial septal puncture, the needle and dilator can climb higher on the right atrial septal wall, where puncture of the free wall occurs, and with continued advancement of the trans-septal apparatus, it immediately enters the LA, at which time a left atrial pressure tracing will be observed and fluoroscopic and ICE appearance shows stable LA placement. Only when the sheath is removed later in the procedure does pericardial bleeding occur. Similarly, other catheters (RV, coronary sinus [CS]) may perforate at the time of initial placement and “plug their own hole” until the end of the procedure when they are removed, allowing bleeding into the pericardium.

Management

Cardiac tamponade is the most dramatic complication observed during catheter ablation procedures and can be associated with increased mortality if not managed promptly.

The management of pericardial effusion is largely determined by its relative size and hemodynamic effect. Trivial pericardial effusions, if recognized early during the procedure, should be monitored continuously but do not warrant termination of the procedure. For larger effusions, the procedure should be terminated and anticoagulation, if administered, should be reversed. Protamine is used to reverse the effects of heparin, idarucizumab for dabigatran, four-factor prothrombin complex concentrate for direct factor Xa inhibitors, and activated factor VII, fresh frozen plasma, and vitamin K can be used in patients with therapeutic anticoagulation with warfarin. IV fluids, vasopressors, and transfusion of blood products can be required, depending on the extent of the effusion and the severity of hemodynamic decompensation. IV atropine can be of value in patients with increased vagal tone.¹⁰

If perforation without tamponade is recognized, an echocardiogram should be obtained as a baseline. If the offending catheter is a standard 5 or 6 Fr shaft, it can often be withdrawn back into the heart while monitoring the echocardiogram for accumulation of pericardial fluid. Most often, there will be no further bleeding into the pericardial space and the procedure can be continued. If systemic anticoagulation is planned for left-sided catheterization, the operator must decide how important it is to continue the procedure with the risk of bleeding into the pericardium. If a larger catheter or large vascular sheath has been inadvertently placed in the pericardial space, echocardiography should be obtained along with immediate cardiothoracic surgical consultation. In many if not most cases, the sheath can be safely withdrawn into the heart without adverse consequences, but the team must be ready to transport the patient to an operating room for repair of a hole or tear in the wall of the affected heart chamber. In some cases, especially when the patient is fully anticoagulated, it may be prudent to transport the patient to the operating room and prepare for urgent sternotomy before removing the catheter/sheath, so as to be able to rapidly enter the chest if hemodynamic collapse occurs.

Although pericardiocentesis typically is required for large pericardial effusions and for smaller effusions manifesting signs of cardiac tamponade, and can effectively restore hemodynamic function, it carries the potential risk of cardiac chamber laceration, inadvertent puncture of the RV, pneumothorax, and infection. In a subset of patients (especially older female patients with a small to moderate amount of pericardial effusion who are not anticoagulated), a conservative approach incorporating administration of IV fluids and vasopressors to address the hemodynamic consequences of cardiac tamponade was found in a recent report to be a reasonable initial strategy and could obviate the need for emergency pericardiocentesis.

Pericardiocentesis

Pericardiocentesis should be performed promptly when indicated because there is usually a narrow therapeutic time window for intervention

before critical hemodynamic compromise ensues. The procedure can be performed under fluoroscopic guidance. Echocardiography can also be used to guide pericardiocentesis. When echocardiography is not readily available, fluoroscopy is usually adequate to establish the diagnosis and guide a safe procedure, and reliance on transthoracic echocardiography should not lead to unnecessary delay in diagnosis or therapy. The technique of percutaneous pericardial access via the sub-xiphoid approach is discussed in **Chapter 4**.

Some investigators have proposed the insertion of two drains in the pericardial sac to allow for faster evacuation of blood, followed by continuous aspiration with negative pressure manual suction. This technique can potentially allow the pericardium to abut and oppose the perforation site and “seal” of the bleeding source. Furthermore, rapid evacuation of the pericardial effusion can help prevent the formation of an intrapericardial thrombus (Fig. 32.2).⁹

Autotransfusion of blood removed from the pericardial space can be of value in patients with persistent bleeding, and is best done using an autologous blood recovery system (Cell Saver) because direct autotransfusion can result in a systemic inflammatory response.⁹

Complete drainage of pericardial effusion can be confirmed by ICE, transthoracic echocardiography, or contrast injection into the pericardium. In most patients, an indwelling catheter is required for a short interval after initial drainage to confirm that the bleeding has stopped and that no effusion is reaccumulating. Traditionally the drain is left in the pericardial space for approximately 12 to 24 hours, although recent reports suggest that early removal of drains (within 1 to 4 hours of ensuring cessation of bleeding) is a safe practice and is associated with less patient discomfort and shorter hospitalization.¹¹ Of note, coagulation of the pericardial blood and intrapericardial thrombus formation can impede effective pericardial drainage and cause restrictive effects on cardiac chamber filling; if this is even a moderate volume, urgent surgical exploration can be warranted, since any additional bleeding that can further compromise the circulation may be difficult to detect and impossible to evacuate with percutaneous drainage. High-dose protamine, especially when combined with prothrombin complex concentrate, can potentially be thrombogenic.¹⁰

Early pericarditis after cardiac perforation is common. In one report, 53% of patients with cardiac perforation had persistent chest pain (suggestive of pericardial inflammation) after effusion evacuation and removal of the pericardial catheter. Subacute reaccumulation of pericardial fluid (suggestive of post cardiac injury syndrome or inflammatory pericarditis) can also occur, requiring repeat pericardiocentesis. Several measures have been suggested to help reduce the severity of pericardial inflammation: (1) injection of steroids (e.g., 0.5 to 1.0 mg/kg of methylprednisolone or 2.0 mg/kg of triamcinolone) into the pericardial space at the conclusion of the procedure has been shown in animal models to be effective in reducing postprocedural pericarditis and adhesion formation; (2) postprocedural use of colchicine has been shown in small series to reduce postsurgical pericardial inflammation; (3) an administration of antibiotic therapy as long as the pericardial drain is in place; and (4) early removal of pericardial drains.^{8,12,13} Some patients have persistent mild hypotension and bradycardia for 1 to 2 days after drainage of blood from the pericardial space, causing concern for fluid reaccumulation. This may be due to a prolonged vagal reaction and typically resolves spontaneously.

Surgical Repair

There is currently no consensus on the threshold for surgical exploration and repair of cardiac perforation. Even large effusion (up to 2 L) can be managed with percutaneous pericardiocentesis without surgical intervention. However, continuing intrapericardial bleeding and rapid reaccumulation of pericardial effusion after initial evacuation can suggest

Fig. 32.2 Intrapericardial Thrombus. Transthoracic echocardiography (A) and contrast pericardiography (B) in a patient who developed cardiac perforation and hemopericardium following catheter ablation of atrial fibrillation. Reversal of heparin effects with protamine and pericardiocentesis was performed via the subxiphoid pericardial access approach. A pigtail catheter pericardial drain was inserted in the pericardial space, and pericardiography was performed by contrast injection through the drain. Note the large intrapericardial thrombus (arrowheads) overlying the left ventricle (LV).

cardiac chamber wall laceration rather than microperforation, and should prompt consideration of immediate surgical exploration. Up to 16% of LA perforations during AF ablation require surgical closure.⁹

It is often helpful to identify the potential site of cardiac perforation to guide appropriate surgical exploratory approach. This can often be indicated by the techniques used during the procedure and cardiac chambers being catheterized. However, cardiac perforation caused by a catheter remote from the site of ablation should also be considered.⁹

Measurement of oxygen saturation of aspirated pericardial blood can be helpful diagnostically to assess for venous (right-sided) versus arterial (left-sided) bleed. In addition, the location of the effusion or superimposed thrombus within the intrapericardial space sometimes can suggest the site of cardiac perforation (e.g., posterior effusion in the setting of LA perforation, and anterior effusion in the setting of RV perforation).⁹

THROMBOEMBOLISM

Systemic thromboembolism can complicate EP procedures in the left side of the heart. The rate of thromboembolic events is 0.4% to 2.1% for AF ablation and up to 2.8% for ablation of VT originating in the LV. In patients undergoing AF ablation, a history of a prior cerebrovascular event is the most potent individual risk factor for postablation cerebrovascular events and is associated with a ninefold increased risk of periprocedural stroke. In addition, the incidence of periprocedural stroke increases in a stepwise fashion with an increasing CHADS2 score.

Mechanism

Potential sources of emboli include thrombus formation on high-profile wires, catheters, and sheaths inserted in the LA or LV, char formation at the tip of the ablation catheter or at the site of ablation, thrombi or air passing through a patent foramen ovale or transseptal puncture, and dislodgment of a preexistent LA or LV thrombus by catheter manipulation. In addition, new LA appendage thrombi can develop in patients with persistent AF after planned or inadvertent conversion to normal sinus rhythm (NSR), especially in the setting of insufficient levels of anticoagulation before, during, or after ablation. Furthermore, endocardial disruption from the ablation lesions can potentially become a

nidus for thrombus formation. Also, aortic atheroembolism can occur during retrograde transaortic LV access for ablation of VTs or AV bypass tracts (BTs), and it tends to be associated with difficulty in the manipulation of catheters within a severely diseased aorta.

Thromboembolic events typically occur within 24 hours of the ablation procedure, with the high-risk period extending for the first 2 weeks following ablation. Cerebral thromboembolism is most common, but emboli can also involve the coronary, abdominal, or peripheral vascular circulations. In addition, recent studies demonstrated a high incidence of asymptomatic cerebral emboli (detected on brain magnetic resonance imaging [MRI] in up to 50% of patients) in the first 24 to 48 hours following AF ablation. The pathogenesis and clinical significance of these lesions remain uncertain.¹

Prevention

Prevention remains the best strategy in minimizing cerebrovascular events during left heart mapping and ablation, and this may be achieved by the following: (1) exclusion of intracardiac thrombi with preprocedural transesophageal echocardiography (TEE) in patients with AF (and transthoracic echocardiography in patients with ischemic VT and cardiomyopathy); (2) aggressive intraprocedural anticoagulation, including early heparin administration (preferably before catheterization of the left heart), followed by continuous infusion to maintain the activated clotting time at greater than 300 seconds; (3) meticulous attention to sheath management, including constant infusion of heparinized saline and air filters; (4) minimizing char formation during lesion creation by regulating power delivery to prevent abrupt impedance rise; and (5) using ICE during AF ablation for early detection of intracardiac thrombi and accelerated bubble formation consistent with endocardial tissue disruption with RF application.

Open-irrigation RF ablation or cryoablation, compared with standard 4- or 8-mm solid tip or closed irrigation electrodes, can potentially decrease the formation of char and thrombus at the tip of the ablation catheter. Administration of large doses of protamine on completion of the ablation procedure to reverse heparin abruptly can potentially promote thrombogenesis and warrants further evaluation to confirm its safety. Also, an uninterrupted oral anticoagulation strategy at the time of AF ablation eliminates a period of inadequate anticoagulation immediately

following the ablation procedure, a critical period for thromboembolic risk because of the inflammation and irritation inherently associated with ablation. In patients with severe disease of the aorta, using a long vascular sheath to advance the ablation catheter directly into the LV can potentially reduce the risk of aortic atheroembolism.

AIR EMBOLISM

Vascular air embolism is a potentially life-threatening event that can occur during left and right heart procedures. Because many cases of venous air embolism go unnoticed, the true incidence of this complication is unknown. Air embolism has been reported in the interventional radiology literature at an incidence of 0.13%.

Mechanism

Small amounts of air embolized in the venous circulation are generally broken up in the pulmonary capillary bed and absorbed from the circulation without significant sequelae. Embolization of large volumes of air (>5 mL/kg) can cause severe complications (shock or cardiac arrest). However, complications have been reported with as little as 20 mL of air. On the other hand, embolization of as little as 2 or 3 mL of air into the arterial circulation can be fatal.

Paradoxical air embolization into the arterial circulation can occur through direct passage of air into the arterial system via anomalous structures such as an atrial or ventricular septal defect, a patent foramen ovale, or pulmonary arterial-venous malformations. Direct arterial air embolism is caused by the introduction of air into the LA via the transeptal sheath, as well as via long vascular sheaths occasionally used for catheter stabilization during transaortic mapping and ablation in the LV.

With the patient in the supine position, large volumes of air rapidly entering the venous circulation typically lodge in the RVOT or pulmonary artery, and can cause RVOT obstruction, marked reduction of cardiac output, and potentially hemodynamic collapse. Also, air embolization can lead to serious inflammatory changes in the pulmonary vessels, including direct endothelial damage and accumulation of platelets and fibrin. Air in the systemic circulation can induce ischemia by various mechanisms, such as obstruction of the blood flow, vasospasm, and thrombus formation because of platelet activation.

Clinical Presentation

Most cases of venous air embolism are subclinical and do not result in untoward outcomes, and even when symptomatic, they go unrecognized because of the nonspecific nature of clinical presentation that can mimic other cardiac, pulmonary, and neurological dysfunctions. Therefore, a high index of suspicion is necessary to establish the diagnosis.

The outcome of venous air embolism is directly related to the amount of air and the rate at which it enters the vein. Spontaneously breathing patients can experience more serious consequences than those under controlled positive-pressure ventilation because they generate negative intrathoracic pressure during the respiratory cycle, facilitating air entrainment. Awake patients typically manifest shortness of breath, continuous coughing, chest pain, and a sense of “impending doom.” Jugular venous distention, hypotension, tachycardia, and electrocardiogram (ECG) signs of right heart strain (ST-T wave abnormalities) can be observed. Severe cases are characterized by cardiovascular collapse.

Arterial air emboli can distribute to almost any organ and can have devastating clinical sequelae. Direct cerebral air embolism can be associated with altered mental status, seizures, and focal neurological signs. A common presentation of air embolism during LA mapping and ablation is acute inferior ischemia, heart block, or both (eFig. 32.2). This reflects preferential downstream migration of air emboli into the right

coronary artery (ostium of the right coronary artery is located more superiorly than that of the left coronary artery in the supine patient). Importantly, atrial-esophageal fistula should be ruled out if air embolism is documented days or weeks after the ablation procedure.

Detection

Routine diagnostic modalities to identify air embolism in the terminal arterial circulations lack sensitivity, and diagnosis is typically based on the appropriate clinical scenario, with possible air identified in cardiac chambers. Air in the RV or pulmonary artery can be visualized on fluoroscopy as well as transthoracic echocardiography. TEE is currently the most sensitive monitoring device for venous air embolism. Prompt CT or MRI obtained before the intravascular air is absorbed can show multiple serpiginous hypodensities representing air in the cerebral vasculature, with or without acute infarction, but imaging later in the course of the disease shows diffuse acute infarcts (eFig. 32.3).

Prevention

The optimal management of air embolism is prevention. Careful sheath management, including constant infusion of heparinized saline and air filters, should be observed. Although air can be introduced through the infusion line, it can also occur with suction when catheters are removed. Therefore whenever catheters are removed, they need to be withdrawn slowly to minimize suction effects, and the fluid column within the sheath should be aspirated simultaneously. The sheath should then be aspirated and irrigated to ascertain that neither air nor blood has collected in the sheath. Importantly, the entire volume of the sheath should be aspirated after initial deployment as well as after each time a catheter is removed and reinserted, to ensure that a continuous column of fluid is present in the sheath and disallowing the possibility of trapped air that could otherwise be introduced when a catheter is advanced through the sheath. Testing to ascertain the sheath's capacity prior to insertion is a good practice. This is especially important when inserting and removing balloon catheters through large sheaths.

Management

Initially it is essential to take all measures necessary to prevent further air embolization. For venous air embolism, placing the patient in the left lateral decubitus and Trendelenburg position helps air remain in the RA, where it will not contribute to an “air lock” in the RVOT. In addition, direct extraction of air from the venous circulation if localized in the RA or RV can be attempted by aspiration from a central venous or pulmonary artery catheter. Air aspiration should be performed with the patient supine or in a Trendelenburg position while holding his or her breath at the end of inspiration or during a Valsalva maneuver.

Administration of intravenous (IV) fluids and vasopressors may be necessary for hemodynamic support. Supplemental 100% oxygen therapy can reduce the size of the air embolus by increasing the rate of nitrogen absorption from air bubbles. Because gas bubbles are not buoyant enough to counteract arterial blood flow, these measures are more suitable for treating venous and RV air emboli. Supportive care usually results in complete resolution of symptoms and signs within minutes. Suspected coronary arterial air embolism should be investigated with coronary arteriography, especially if ST segments changes persist beyond 2 to 3 min, to exclude spasm or true thrombus.

When cerebral air embolism is suspected, it is important to maximize cerebral perfusion by administration of fluids and supplemental oxygen. Hyperbaric oxygen therapy is regarded as the treatment of choice in patients with cerebral air embolism, and prompt transfer to a hyperbaric oxygen therapy center should be considered. When started within a few hours, hyperbaric oxygen therapy can potentially compress the existing bubbles, speed resolution of bubbles by establishing a high

eFig. 32.2 Coronary Air Embolism. Leads II and V₁ are shown from a patient with a left-sided bypass tract who suffered air embolism during transseptal catheterization and catheter advancement into the left atrium. Snapshots of electrocardiograms taken at the designated times show the baseline (10:33) normal findings, dramatic ST elevation immediately following transseptal catheterization (10:46), and progressive resolution over the next 25 minutes. Time scale and 10-mV calibration marks are shown.

eFig. 32.3 Cerebral Air Embolism. A transverse section of a magnetic resonance image of the brain in a patient who sustained cerebral air embolism during ablation of atrial fibrillation, showing many areas of diffusion restriction scattered throughout both hemispheres, representing acute infarcts.

diffusion gradient, improve oxygenation of ischemic tissues, and reduce endothelial thrombo-inflammatory injury.

CORONARY ARTERY INJURIES

The incidence of coronary artery injuries during ablation procedures is extremely low (0.06% to 0.1%), despite the close proximity of coronary arteries to common sites of ablation. The low incidence is likely due, at least in part, to the protective effect of convective cooling conferred by the high-velocity blood flow within the epicardial coronary arteries.^{14,15}

The potential for acute coronary artery occlusion is a significant risk consideration with catheter ablation within the aortic sinuses of Valsalva. Damage to the coronary arteries can result from catheter manipulation and ablation in the aortic root, secondary to RF energy delivery in close proximity to the ostium of the right or left coronary artery, as well as inadvertent catheter engagement of the left main coronary artery when ablating in the left sinuses of Valsalva.

It is also important to recognize the potential risk of coronary artery damage when ablating in the RVOT and pulmonary artery. The right coronary artery is typically 4 to 5 mm away from the proximal part of the RVOT near its rightward free wall, and is separated by a variable amount of fat. In addition, the cephalocaudal separation of the pulmonic and aortic valves results in close proximity of the pulmonic valve to the origin of the right coronary artery, and the left main coronary artery lies in immediate posterior proximity to the subvalvular RVOT near the pulmonic valve as well as the supra-ventricular pulmonary artery.

Because of the proximity of the right coronary artery to the cavotricuspid isthmus (CTI) and the left circumflex artery to the lateral mitral annulus, coronary artery injury can potentially occur during ablation at mitral or tricuspid annuli. Transient inferior ST segment elevation and acute occlusion of the right coronary artery have been reported following ablation of the CTI, and left circumflex artery injury has been reported following ablation of left-sided AV BTs. Also, late stenosis of the right coronary artery has been observed in children with Ebstein anomaly of the tricuspid valve who undergo ablation of a right-sided AV BT, and coronary injury or infarction has occurred during ablation of posterior septal BTs ablated within the CS or middle cardiac vein.

Percutaneous epicardial ablation probably poses a greater risk of coronary artery injury (laceration, intimal hyperplasia, intravascular thrombus formation, or vasospasm), especially in the anterior and posterior septal and the basal ventricular areas, where coronary arteries and veins are known to traverse. The CS and its branches are also in close relation to the distal circumflex and the posterolateral branches of the right coronary artery, and ablation within the coronary venous system (for AV BTs, lateral mitral isthmus, and VT) can cause coronary injuries.

Mechanism

RF ablation-induced acute coronary artery injury can be mediated by vasospasm, intravascular thrombus formation, or direct vessel trauma. Transient thermal irritability resulting in coronary spasm appears to be the most common mechanism. Acute or subacute thrombosis can result from RF-induced functional and morphological damage to the coronary artery media and endothelium. Thermally induced denaturation of collagen fibers can develop in the vessel wall, leading to intimal hyperplasia and subsequent vessel narrowing. In addition, an inflammatory mechanism can result in delayed medial necrosis and intimal hyperplasia causing late stenosis. During epicardial ablation, coronary injury can result from direct disruption of the arterial wall or coronary laceration.¹⁴

In general, the susceptibility of coronary arteries to thermal damage is inversely proportional to the electrode-to-artery distance. Arterial injury is inversely proportional to vessel diameter; there is little evidence of injury when vessel diameter exceeds 0.5 to 1.0 mm. High RF power delivery in small hearts, such as in pediatric patients, or in direct contact with the vessel can increase the risk of coronary arterial injury.¹⁴

The high-velocity blood flow within the epicardial coronary arteries confer a protective effect against RF-induced thermal injury by allowing these vessels to act as a heat sink. Substantive heating of vascular endothelium is prevented by heat dissipation in the coronary blood flow (convective cooling), even when the catheter is positioned close to the vessel. Convective cooling likely accounts for the low incidence of coronary artery complications following RF ablation. The protection conferred by convective cooling during RF ablation, however, can be limited by reduction in coronary blood flow, as can be seen in small caliber vessels and in arteries with preexisting stenosis.

Clinical Presentation

Acute occlusion of a coronary artery (by spasm or thrombosis) can manifest as chest discomfort (in nonanesthetized patients) or acute ST-T segment changes on the surface ECG. A high index of suspicion is warranted, since the clinical presentation of acute coronary injury (e.g., chest discomfort and elevation in cardiac troponin levels) can easily be misdiagnosed as pericardial irritation or myocardial injury secondary to RF ablation. Monitoring surface ECG leads for ST changes during an ablation at high-risk sites is imperative to detect acute coronary injury. Also, obtaining a 12-lead ECG immediately after ablation is a critical step that can diagnose ST changes while still treatable and possibly prevent dramatic complications.^{15,16}

Importantly, RF ablation frequently (in 25% to 100% of cases) causes significant elevations in cardiac troponin levels that are not related to coronary arterial injury, with mean peak levels of 0.13 to 6 ng/mL for troponin I, and 0.20 to 2.41 ng/mL for troponin T. In contrast to acute coronary syndromes, troponin elevations observed following RF ablation typically peak early (2 to 8 hours vs. 18 to 24 hours) and normalize early. The levels of troponin elevation correlate with the number of RF lesions applied, the site of lesions (ventricular more than atrial more than annular), and the approach to the left side (transaortic more than transseptal). Ablation of focal lesions (atrioventricular nodal reentrant tachycardia [AVNRT], atrioventricular reentrant tachycardia) causes less frequent (in 25% to 88% of cases) elevation of troponin levels as compared with linear lesion ablation (atrial flutter, AF, and VT), where all patients are expected to have an increase in troponin levels. The prognostic significance of asymptomatic elevations of troponin I remains unclear.¹⁷

Prevention

Several precautions are important to avoid injury to coronary arteries during percutaneous epicardial ablation, ablation via the coronary venous system, and ablation in the aortic sinuses of Valsalva. Prior to ablation, direct visualization of the relation between the ablation site and adjacent coronary arteries must be obtained, usually by coronary angiography (or ICE imaging) performed with the ablation catheter positioned at the target site. Although an absolute safe distance between the ablation site and epicardial artery has not been defined, a distance of at least 5 mm between the ablation catheter and an epicardial artery is commonly accepted. It is also important to ensure that the catheter is not touching the vessel at any point of the cardiac cycle during angiography.^{8,16,18–22}

When ablation in the aortic sinus of Valsalva is planned, aortic root angiography may be considered to visualize the aortic root and the ostia of the right and left coronary arteries. Also, when selective

angiography of the coronary arteries is performed, a 5 Fr coronary angiography catheter may be left at the ostium of the coronary artery to serve as a marker and for protection of the artery in case of ablation catheter dislodgment during RF application. Alternatively, a combination of electroanatomic mapping and ICE imaging can be used to confirm anatomic location, catheter tip position and contact, and distance to coronary vasculature, and to monitor RF delivery.

In addition, RF energy output should be minimized during ablation in close proximity to coronary arteries, especially in the presence of small-caliber or diseased vessels. RF application should also be stopped as soon as it is evident that the ablation lesion is not successful in achieving the desired EP effect. Furthermore, ablation is often performed during continuous fluoroscopy to observe for catheter dislodgment, and energy delivery should be discontinued when even minimal dislodgment from the site showing the best mapping findings. Coronary angiography is often performed immediately after the ablation procedure to exclude coronary artery spasm, dissection, or thrombus.²³

Of note, experimental studies suggest a potential benefit of intracoronary irrigation with chilled saline for coronary protection from heat-induced damage during epicardial RF ablation. The safety and efficacy of this technique in clinical practice, however, have not been evaluated. Also, cryoablation appears to have less risk of coronary injury in animal models, but can still create occlusion and intimal damage when in close proximity, particularly to small vessels.¹⁴

IATROGENIC CARDIAC ARRHYTHMIAS

Atrioventricular Block

AV block is the most important complication of AVNRT ablation, occurring in about 0.2% to 0.8% of slow pathway ablation. AV block generally occurs during RF delivery or within the first 24 hours postablation, and is almost always preceded by junctional ectopy with VA block. The level of block is usually in the atrioventricular node (AVN). Predictors of AV block include proximity of the anatomical ablation site to the compact AVN, occurrence of fast junctional tachycardia (cycle length [CL] <350 milliseconds) during RF application, occurrence of junctional rhythm with VA block, the number of RF applications (related to the amount of tissue damage), and significant worsening of anterograde AV conduction during the ablation procedure. The anterior approach for AVNRT ablation is associated with a higher risk of inadvertent complete AV block (approximately 10%, but ranging from 2% to 20%). During ablation of AVNRT, careful monitoring of AV conduction during RF application and prompt discontinuation of energy delivery on evidence of AV block are the keys to minimize the incidence of AV block. RF delivery should be immediately discontinued when the following occur: (1) the impedance rises suddenly (>10 Ω); (2) the PR interval (during NSR or atrial pacing) prolongs; (3) AV block develops; (4) retrograde conduction block is observed during junctional ectopy; or (5) fast junctional tachycardia (tachycardia cycle length <350 milliseconds) occurs, which can herald imminent heart block.

AV block can also occur when ablating along the interventricular septum in the close vicinity of the compact AVN or His bundle (HB), including ablation of superoparaseptal and midseptal AV BTs or ATs, as well as para-Hisian VTs. In addition, because the penetrating HB lies at the membranous septum formed in part by the commissure between the right coronary and noncoronary sinuses of Valsalva, ablation of VTs originating in this region can potentially damage the HB (Fig. 32.3).

When a His potential is detectable at the ablation catheter location, titrated RF energy output and RF application for a short duration should be used, coupled with overdrive atrial pacing to monitor AV

conduction in case accelerated junctional rhythm occurs. Alternatively, cryoablation can be used in this region, with its slightly better safety margin for AV conduction.

In some patients, mechanical trauma from the catheter induces temporary AV block. Also, catheter manipulation in the RV or LV can cause mechanical bundle branch block (often transient), which can potentially cause complete AV block in patients with preexisting block in the contralateral bundle branch. Furthermore, ablation of the right bundle branch in patients with bundle branch reentrant VT is commonly followed by complete AV block (in up to 30%) because of preexisting severe disease in the left bundle branch.

Macroreentrant Atrial Tachycardias

Whereas the occurrence of new arrhythmias following focal RF ablation has not been a clinical problem, linear ablation lesions, if incomplete, can promote reentry propagating through the gaps in the ablation lines. Even when conduction block across the ablation lines is verified, the ablation lines commonly performed in the LA for ablation of AF can still facilitate reentry by providing conduction obstacles and protected isthmuses with adjacent anatomical structures in the atrium. In fact, LA macroreentry is a relatively common complication of catheter ablation of AF, occurring in up to 50% of cases. The incidence of ATs seems to be lower following segmental ostial pulmonary vein (PV) isolation (<5%) compared with circumferential PV isolation, and much higher following circumferential or linear LA ablation. Targeting complex fractionated atrial electrograms without linear lesions or PV isolation is associated with a moderate risk for postablation ATs. Following stepwise approaches of catheter ablation incorporating extensive lesions in the LA and RA to terminate persistent AF, ATs can be observed in more than 50% of patients. Although ATs can occur at variable time intervals after AF ablation procedures, the most common timing appears to be 1 to 2 months postablation.

Ventricular Arrhythmias

Malignant ventricular arrhythmias and sudden cardiac death (SCD) have been observed in the early phase following AV junction ablation. Polymorphic VTs are related to electrical instability caused by an initial prolongation and then slow adaptation of repolarization caused by changes in the heart rate and activation sequence. Most polymorphic VTs, ventricular fibrillation, and torsades de pointes that have been reported seem to be consistent with a pause or bradycardia-dependent mechanism. To reduce the risk of these arrhythmias, routine pacing at 80 beats/min has been recommended following AV junction ablation for some period of time. Patients with high-risk factors for arrhythmias, such as congestive heart failure or impaired LV function, may require pacing at higher rates (e.g., at 90 beats/min for 1 to 3 months), as well as in-hospital monitoring for at least 48 hours. Adjustment of the pacing rate, although rarely to less than 70 beats/min, is usually undertaken after 1 week in most patients, preferably after an ECG evaluation for repolarization abnormalities at the lower rate.²⁴

Abnormal Sinus Node Function

Inappropriate sinus tachycardia can occur in some patients after posteroseptal BT or AVN ablation, suggesting disruption of the parasympathetic input and/or sympathetic input into the sinus node and AVN. This typically resolves within 3 months following ablation. Some patients have severe sinus bradycardia or arrest after AF ablation; this may be due to sinus node remodeling after long periods of AF (months), but has also been observed in patients with normal sinus node function prior to ablation. In these cases, damage to the sinoatrial node artery can occur when it originates from the circumflex artery (and courses over the LA roof), and an LA roof ablation line interrupts the sinus

Fig. 32.3 Atrioventricular (AV) Block Complicating Catheter Ablation of Premature Ventricular Complexes (PVCs) Originating From the Para-Hisian Region. In A, note the presence of anterograde His potentials on the proximal and distal ablation electrodes (ABLp and ABLd, respectively) during sinus rhythm (blue arrows) and retrograde His potentials during PVCs (red arrows) at the site of earliest ventricular activation during PVCs. In B, radiofrequency energy delivery results in complete AV block secondary to injury to the His bundle.

node artery. This often resolves but may take over a week, and some patients have had permanent pacemaker implantation.

VALVULAR DAMAGE

The aortic valve can be damaged during retrograde crossing of the ablation catheter for retrograde ablation of LV VTs and left-sided BTs. To prevent leaflet damage or perforation, the straight catheter tip must never be used to cross the aortic valve; instead, a tight J curve is formed with the catheter tip before passage to the aortic root. Ablation of arrhythmias originating from the aortic cusp can also result in valvular damage, and limiting RF power output and duration is necessary. If standard methods of prolapsing the catheter into the LV are unsuccessful after several attempts, consideration should be given to introducing a long vascular sheath into the LV over a guidewire or a pigtail catheter (usually with easier valve crossing). Though somewhat cum-

bersome, this is preferable to struggling to cross the aortic valve with the ablation catheter by itself, only to have the catheter fall back into the aortic root and needing to re-cross the valve.

Damage to the mitral valve can result from entanglement of the ablation catheter within the mitral valve apparatus during transaortic or transseptal ablation procedures, but serious damage is unlikely. The risk of valvular damage (occasionally requiring thoracic surgery and valve replacement) is higher following entrapment of catheters with multiple splines or circular mapping catheters in the valvular apparatus (e.g., during AF ablation), which can be particularly difficult to free. Forcible traction of the catheter should be avoided, as it can potentially damage the valve and ultimately lead to mitral valve replacement. To prevent injury to the papillary muscles or chordae tendineae, prior to pulling on the catheter, one may consider instead advancing the catheter toward the LV apex. Advancing the sheath over the catheter and withdrawing the catheter into the sheath followed by withdrawal of the

whole assembly can facilitate the effort further. When gentle manipulation and moderate traction are unsuccessful, removing the catheter by thoracic surgery may be preferable; in this way the valve can potentially be spared significant damage.

PHRENIC NERVE INJURY

Phrenic nerve damage and consequent diaphragmatic paralysis have been a long-recognized complication during endocardial ablation in the RA or LA, as well as during percutaneous epicardial ablation procedures.

The right phrenic nerve descends between the parietal pericardium and parietal pleura along the lateral side of the RA between the right superior PV and SVC. This course renders the phrenic nerve vulnerable to injury from endocardial ablation during sinus node modification or ablation of ATs arising in the vicinity of the crista terminalis, SVC, or right superior PV. Right phrenic nerve injury has become more frequent with the increasing number of AF ablation procedures that involve electrical isolation of the SVC, as well as ablation around the right superior PV, especially when balloon ablation catheters are used. Right phrenic nerve injury is rare after isolation of the right-sided (mostly superior) PV (up to 0.48%) or isolation of the SVC (2.1%) using RF energy. The incidence of right phrenic nerve injury is significantly higher in the setting of cryoballoon PV isolation, occurring in more than 11% with first-generation cryoballoon. Using second-generation cryoballoon, transient (intraprocedural only) and persistent right phrenic nerve injury has been observed in 9.0% and 3.0% of patients, respectively. The epicardial approach to sinus node modification also carries the risk of right phrenic nerve damage.^{25–29}

The left phrenic nerve descends behind the left brachiocephalic vein and passes over the aortic arch, pulmonary trunk, and then with the pericardium over the LA appendage. From there it descends (between the fibrous pericardium and the mediastinal pleural layers) over the LV and frequently passes laterally over the obtuse margin of the LV, close to the lateral vein and the left marginal artery and, in only a small percentage of cases, close to the left main coronary artery and great cardiac vein. Left phrenic nerve injury can occur during endocardial ablation AF or AT in the region of the proximal roof of the LA appendage, during ablation of left posterolateral BTs, ablation within the distal CS or persistent left SVC, as well as during percutaneous epicardial VT ablation adjacent to the lateral LV wall.^{8,16,28,30}

The use of a non-RF source of energy is unlikely to prevent this complication because phrenic nerve injury has been reported with ultrasound, laser, and cryotherapy. Of note, diaphragmatic paralysis may develop 1 to 2 days after the procedure despite normal function at the end of the ablation protocol; this may reflect inflammation rather than direct injury to the phrenic nerve.

Clinical Presentation

Phrenic nerve injury can be asymptomatic in about a third of cases. The most frequent symptom is dyspnea. Other symptoms or clinical findings are cough or hiccup during ablation, and the development of postablation pneumonia or pleural effusion. In asymptomatic patients, the diagnosis is made on physical examination or a routine chest x-ray (Fig. 32.4) with hemidiaphragm paresis or paralysis (hemidiaphragm elevation with paradoxical movement on exhalation and inhalation x-ray). There is no active treatment known to aid phrenic nerve healing. Complete or partial recovery of diaphragmatic function can be observed in 66% and 17% of patients, respectively, sometimes not realized until several weeks or even months later.

Prevention

Several strategies are used to minimize the risk of phrenic nerve injury. The best strategy is to avoid ablation at sites close to the phrenic nerve. However, this is not always feasible. Therefore, careful monitoring of phrenic nerve function during ablation at high-risk sites is important to terminate energy delivery before the development of frank phrenic nerve palsy. Occasionally, displacement of the phrenic nerve from the ablation target site needs to be considered to facilitate the ablation procedure.³¹

Avoiding Ablation in Close Proximity to the Phrenic Nerve

In areas at high risk of phrenic nerve injury (RA free wall, posteroseptal part of the SVC, inferoanterior aspect of the right PV ostium, and proximal roof of the LA appendage, lateral LV epicardium) that require ablation, high-output (20 to 25 mA at 1.0 to 2.0 milliseconds) pacing should be performed before energy delivery. The ability to capture the phrenic nerve should prompt attempts to find a slightly different site or, if this is not possible, applying RF energy at low power and/or for short duration. This technique can be combined with electroanatomic mapping of the RA, SVC, LA, and right PVs to reconstruct the anatomical

Fig. 32.4 Hemidiaphragmatic Paralysis Secondary to Phrenic Nerve Injury. Chest x-rays (posteroanterior views) showing right hemidiaphragmatic paralysis (arrowheads) caused by right phrenic nerve injury (A), and left hemidiaphragmatic paralysis caused by left phrenic nerve injury (B) during catheter ablation of atrial fibrillation.

Fig. 32.5 Three-Dimensional (3-D) Computed Tomography (CT) Imaging and Mapping of the Phrenic Nerve (PN). A comparison of the right and left PN pace map generated by CARTO and the 3-D CT of the pericardio-phrenic bundles (PBs). Panel A shows a PN pace map. Point tags are superimposed on the CT of the left atrium (LA). Red tags show ablation sites. Green, black, and yellow dots indicate PN-capture sites by electrical pacing from the superior vena cava-right atrium, RSPV, and LAA, respectively. Panel B shows a clear image of the PBs reconstructed from CT data in the same patient as panel A. The running course of the right PN and the right PB are in close accordance. LAA, Left atrial appendage; LIPV, left inferior pulmonary vein; LSPV, left superior pulmonary vein; RIPV, right inferior pulmonary vein; RSPV, right superior pulmonary vein. (From Fukumoto K, Takatsuki S, Jinzaki M, et al. Three-dimensional imaging and mapping of the right and left phrenic nerves: relevance to interventional cardiovascular therapy. *Europace*. 2013;15:937–943.)

course of the right phrenic nerve. This approach provides a guide to phrenic nerve position relative to potential ablation targets (Fig. 32.5).³¹

Monitoring Phrenic Nerve Function During Ablation

When ablation is performed at high-risk sites, monitoring of phrenic nerve function is necessary to prevent permanent damage, even when the phrenic nerve cannot be captured by high-output pacing at the site targeted by ablation. This approach entails continuous pacing of the phrenic nerve (at a site superior to the ablation target site) during energy application with simultaneous monitoring ipsilateral diaphragmatic contractility. Studies have indicated that transient phrenic nerve injury occurs early and uniformly before permanent injury; thus early recognition of impending phrenic nerve injury during energy delivery allows immediate interruption of the energy delivery prior to the onset of permanent injury, which is associated with the rapid recovery of phrenic nerve function.³¹

It is important to recognize that detection by phrenic nerve capture is prevented by the use of paralytic agents during general anesthesia. Therefore when the procedure is performed under general anesthesia, it is important to avoid paralytic agents or use short-acting paralytic agents only at the time intubation and allow sufficient time for the paralytic effect to fade away before ablation or use a reversal agent (e.g., neostigmine).^{12,32,33}

For monitoring right phrenic nerve function, a diagnostic catheter is positioned at the anterolateral aspect of the SVC at a site above the level of ablation where the phrenic nerve can be consistently captured. Pacing output is adjusted at twice the nerve capture threshold; higher pacing outputs can potentially overcome early nerve injury and thus delay necessary interruption of energy application. In addition, it is important to achieve a stable catheter position and consistent phrenic nerve capture; loss of phrenic nerve capture due to catheter movement can mimic phrenic nerve injury and lead to unnecessary interruption of ablation.³¹

Successful phrenic nerve capture is confirmed when contraction of the right hemidiaphragm can be observed both under fluoroscopy or ICE and with manual palpation of the right subcostal region. Phrenic nerve capture can also be monitored by diaphragmatic electromyography. Diaphragmatic compound motor activation potential (CMAP) of the right diaphragm can be recorded using two chest wall standard surface ECG electrodes; one electrode is positioned 5 cm above the xiphoid process and the second electrode positioned 16 cm away along the right costal margin (Fig. 32.6). These electrodes are connected to the EP recording system, where bipolar electromyography signals are amplified and band-pass filtered between 1 and 50 Hz. SVC catheter positioning is optimized during right phrenic nerve pacing to obtain the highest amplitude diaphragmatic CMAP signals. Diaphragmatic CMAPs can also be recorded via a standard EP catheter placed in a subdiaphragmatic hepatic vein (see Fig. 32.6). Although the latter technique attenuates respiratory variations in CMAP amplitude observed with surface electrode CMAP recording, it necessitates an additional venous puncture and EP catheter. A decrease in diaphragmatic CMAP amplitude is the earliest sign of detectable injury to the phrenic nerve; studies showed that a 30% reduction in diaphragmatic CMAP amplitude presaged impending hemidiaphragmatic paralysis by approximately 30 seconds, making it a valuable method for monitoring phrenic nerve function.^{32,33}

Impending phrenic nerve injury can be indicated by diminishing diaphragmatic excursion (on palpation, fluoroscopy, or ICE), or a reduction of the maximal diaphragmatic CMAP amplitude by more than 30% (Table 32.1). Palpation of the strength of diaphragmatic excursion is a simple method, but tactile feedback is inadequate as the sole technique for monitoring phrenic nerve injury. Continuous or intermittent fluoroscopy is more accurate, but it increases radiation exposure to the patient and operator. ICE (with the transducer positioned at the level of the diaphragm and pointed at the liver) may also be used to continuously visualize hepatic movement from the diaphragmatic excursion.

Fig. 32.6 Diaphragmatic Compound Motor Action Potential (CMAP). *Left panel*, Configuration of surface electrodes for recording diaphragmatic CMAP on modified lead I. (A) The right arm (RA black oval) surface electrode is placed 5 cm above the xiphoid, the left arm (LA black oval) surface electrode is placed 16 cm from the xiphoid along the costal margin. In some instances, the leads must be modified because of the patient's body habitus (e.g., in an obese patient) by moving the leads to the right and more separated (white ovals) to obtain the optimal CMAP amplitude (lower recording). (B) Surface electrocardiogram (ECG) lead V₁ and a diaphragmatic CMAP tracing (arrows) obtained by modified lead I. *Right panel*, CMAP tracing obtained by a quadripolar catheter in the right hepatic vein. (C) Anteroposterior fluoroscopic view centered on the diaphragm showing catheter position for phrenic CMAP recording. A quadripolar catheter is positioned in a hepatic vein to record phrenic CMAP. A decapolar catheter is placed in the superior vena cava to pace the right phrenic nerve. (D) Surface ECG lead V₁ and a diaphragmatic CMAP tracing obtained by quadripolar catheter in the right hepatic vein. This technique attenuates respiratory variations in CMAP amplitude observed with surface electrode CMAP recording (modified lead I). (A, Modified from Kowalski M, Ellenbogen KA, Koneru JN. Prevention of phrenic nerve injury during interventional electrophysiologic procedures. *Heart Rhythm*. 2014;11:1839–1844.)

TABLE 32.1 Pros and Cons of Various Phrenic Nerve Monitoring Strategies

Method	Description	Advantages	Disadvantages
Fluoroscopy	Direct visualization of diaphragmatic motion	Sensitive method for monitoring diaphragmatic motion	Additional radiation exposure to patient and operator Does not predict PNI
Palpation	Palpation of diaphragmatic excursion	Reliable and practical method for monitoring diaphragmatic motion	Requires additional staff member Palpable strength of diaphragmatic excursion may vary with respiration
Electromyography	Recording of diaphragmatic CMAP by 2 standard surface electrodes positioned across the diaphragm or by advancing a quadripolar catheter in the right hepatic vein during PN pacing	Earliest detection of PNI Simple, reliable, and easily applicable Only technique that predicts PNI	CMAP signals might be susceptible to respiratory variations Baseline amplitude must be adequate Affected by paralytic agents
Auditory cardiocardiography	Decrescendo pitch on fetal heart monitor (placed across patient's chest that can detect diaphragmatic contractions)	Auditory cue to the operator May portend PNI before palsy	Extra equipment needed Difficult to record in obese patients
Intracardiac echocardiography	Direct visualization of diaphragmatic excursion	Minimal radiation exposure to patient and operator	Requires additional venous access and intracardiac ultrasound

CMAP, Compound motor action potential; PN, phrenic nerve; PNI, phrenic nerve injury.

Furthermore, auditory monitoring of diaphragmatic contraction can be provided by an external fetal heart Doppler monitor placed at the costal margin. A change in the pitch of the diaphragmatic contraction is used to indicate reduction of the strength of the diaphragmatic contraction.³¹

Percutaneous Displacement of the Phrenic Nerve

During percutaneous epicardial ablation, proximity to the phrenic nerve can be detected by high-output pacing (typically at >10 mA) to detect diaphragmatic stimulation on fluoroscopy, allowing its course to be marked on the electroanatomic map. The nerve can branch over the LV; thus simply noting sites at which phrenic nerve capture occurs does not necessarily delineate the course of all branches. Further, the pacing output that would indicate a safe distance for epicardial ablation is not known.

If proximity to the phrenic nerve prohibits ablation at desired endocardial sites, interposing a balloon, saline, or air in the pericardium between the ablation catheter and the phrenic nerve can allow safe RF ablation. Mechanical separation of the phrenic nerve from adjacent structures, using a large balloon, entails insertion of a wire through one of the existing pericardial sheaths to the vicinity of the ablation catheter positioned at the target epicardial site. A 25 mm × 40 mm peripheral vascular angioplasty balloon (or esophageal balloon) is advanced over the wire to these locations. The balloon is inflated using an insufflator and contrast until complete inflation is seen on fluoroscopy. This technique can be limited by the inability to steer the balloon catheter and position it in the desired epicardial location. Not infrequently, a deflectable sheath is required to direct the balloon to the appropriate location and provide additional support and stability.^{31,34,35}

Another method is to introduce a combination of saline and air into the pericardium to achieve a “controlled hydropneumopericardium” to increase the distance between the phrenic nerve and the ablation target area. This involves using a 20-mL syringe to introduce saline and air alternately in 20-mL increments under careful monitoring of arterial pressure and fluoroscopy. At each step, epicardial pacing is performed to assess phrenic nerve capture and diaphragmatic stimulation. Instillation of air and saline is performed slowly until phrenic nerve capture is lost or severe hypotension develops. Although cardiac tamponade can develop secondary to sudden accumulation of fluid or air in the pericardial space, controlled and progressive introduction of fluid and air with careful hemodynamic monitoring usually allows separation of

the phrenic nerve from the epicardial surface without causing clinically significant tamponade. The combination of air and saline appears to be more successful in preventing phrenic nerve injury during epicardial ablation than injecting air alone or fluid alone. The combination of air and fluid allows the injection of a higher volume in the pericardial space with a lower impact on blood pressure than using fluid alone. With air only, a significant resistance can be felt in most patients after injections of more than 300 mL despite stable blood pressure. Of note, air is a poor conductor of electricity, and its presence in the pericardial space can increase the defibrillation threshold, requiring evacuation if defibrillation is anticipated (e.g., before induction of ventricular arrhythmias). In addition, ablation catheter contact with the epicardial surface is more problematic with a volume of fluid and/or air in the space.^{8,26,27,31}

PULMONARY VEIN STENOSIS

Incidence

PV stenosis is one of the most serious complications of AF ablation. A wide range of incidence (0% to 40%) of postablation PV stenosis has been reported, depending on the ablation strategy employed, methodology used for estimating PV ostial size and location, and intensity of surveillance. Focal ablation inside the PV carries the highest risk for PV stenosis, with rates of up to 33% to 42%. With PV isolation techniques, the incidence of severe PV stenosis is approximately 1% to 5%, with the highest risk in patients undergoing ostial PV isolation. Circumferential antral LA ablation, with ablation limited to atrial tissue outside the PV orifice, has a significantly lower rate of PV stenosis.³⁶

The severity of PV stenosis is generally categorized as mild (<50% decrease in diameter), moderate (50% to 70%), or severe (>70%). Late progression of PV stenosis to severe stenosis or even complete occlusion has been observed (Figs. 32.7 and 32.8), particularly in the smaller PVs. Of note, stenosis seems to be more common in the left-sided PVs. In a recent report, mild, moderate, and severe PV stenosis was observed (on cardiac magnetic resonance [CMR] or CT) in 31%, 4%, and 1% of patients who underwent RF antral PV isolation, respectively. Symptomatic PV stenosis necessitating intervention occurred in only 1 patient (0.1%).³⁶ Similar rates of PV stenosis have been reported following cryoballoon PV isolation.^{37,38} Significant PV stenosis (>50% diameter decrease) appears to be exceedingly rare following laser balloon PV isolation; however, the experience with this technology is still limited.^{39,40}

Fig. 32.7 Pulmonary Vein (PV) Stenosis. (A) Computed tomography (CT) image of the left atrium and PVs at baseline before segmental ostial PV isolation. (B) CT image 3 months after the ablation procedure, showing moderate stenosis of the left superior PV (LSPV; arrows) and mild stenosis of the left inferior PV (LIPV). (C) Angiogram (left anterior oblique view) of the LSPV, showing a moderate degree of stenosis (arrows). RIPV, Right inferior PV; RSPV, right superior PV.

Fig. 32.8 Pulmonary Vein (PV) Occlusion. *Upper panels,* Computed tomography (CT) image of the left atrium (LA) and PVs at baseline before segmental PV isolation (A) and 5 months after ablation (B). Following ablation complete occlusion of both superior PVs is observed. *Middle panels,* Fluoroscopic (antero-posterior) views during angiography of the right superior PV (RSPV) (C) and left superior PV (LSPV) (D), showing severe stenosis-occlusion of both PVs at the ostia. PV angiography was performed with contrast injection via a catheter positioned in the pulmonary artery (arrowheads). *Lower panels,* Fluoroscopic (antero-posterior) views during stenting of the LSPV: (E) Angioplasty balloon is inflated for stent deployment in the LSPV; (F) angiogram of the left superior PV following stenting. LIPV, Left inferior PV; RIPV, right inferior PV.

Mechanism

The mechanism of the development of PV stenosis remains unclear. Several mechanisms have been implicated, including reversible edema, endothelial disruption with platelet activation and later neointimal proliferation, and thermally induced collagen denaturation and shrinkage, leading to tissue contracture. The occurrence and degree of PV stenosis correlate with the amount of energy delivered and the proportion of the PV circumference ablated.

Cryothermal ablation is distinguished from hyperthermic injury by the lesser degree of endothelial disruption and collagen denaturation

or contracture, which helps preserve tissue ultrastructural integrity, and matrix architecture tensile strength. These characteristics were expected to translate into a reduction in PV stenosis as compared with RF ablation; nonetheless, cryoballoon ablation for PV isolation still can lead to PV stenosis. The true mechanism of the PV narrowing following cryoballoon PV isolation remains uncertain.³⁷

Severe stenosis or occlusion of a PV (especially when it develops suddenly) can potentially result in gradual decline and then cessation of the arterial flow to the affected lung segment, caused by a decline in the arteriovenous gradient as well as compression by the developing tissue edema. The resulting alveolar ischemia and surrounding edema

lead to atelectasis, infarction, or susceptibility to infections. Furthermore, with the resulting alterations in pulmonary hemodynamics, redistribution of blood flow occurs with the opening of vascular channels or neovascularization in which tissue hypoxia is known to play a role. Hence the venous drainage of the affected segment becomes mainly dependent on the ipsilateral veins draining the healthy lobes. If the ipsilateral vein(s) is also stenosed, the impedance to the pulmonary flow increases, adding to the hemodynamic burden. Symptoms attributable to PV stenosis are typically not seen unless the perfusion of the affected lobe falls below 20% or the perfusion of the entire lung on the affected side falls below 25%.

Clinical Presentation

PV stenosis after ablation is frequently asymptomatic, especially when a mild or moderate degree of PV stenosis is present or a single vein is involved. The severity of symptoms is related not only to the degree of stenosis, but also to the number of affected PVs. Severe PV stenosis can be associated with various respiratory symptoms that frequently mimic more common lung diseases, such as asthma, pneumonia, lung cancer, and pulmonary embolism. Therefore, a high degree of suspicion is necessary to avoid performing misleading diagnostic procedures and to allow proper and prompt management. The onset of symptoms is usually several months following ablation. The initial manifestation is generally dyspnea on exertion, which typically evolves over the course of 1 to 3 months. Persistent cough is a common symptom. Pleuritic chest pain and hemoptysis occur infrequently, and are likely related to complete vessel or branch occlusion.

Symptoms can potentially improve spontaneously over time in a significant percentage of patients. In one report, this improvement occurred in 50% of patients and was always related to improvement in the radiological abnormalities previously detected, although other hemodynamic compensatory mechanisms (e.g., development of collaterals) can also play a role.

Detection

Several imaging modalities have been used for detecting PV stenosis, including CT imaging, MRI, perfusion scans, TEE, and pulmonary venography. To date, it remains unclear which is the best and most cost-effective noninvasive modality for detecting PV stenosis after ablation, and no single imaging modality has been able to assess all relevant aspects of PV stenosis. Therefore complementary methods such as TEE and CT scanning are most commonly used (see Fig. 32.7). Although many investigators recommend routine follow-up CT or MR imaging for detection of asymptomatic PV stenosis 3 to 4 months after AF ablation, it is unknown whether early diagnosis and treatment of asymptomatic PV stenosis provide any long-term benefit to the patient. Nevertheless, it is recommended that follow-up PV imaging be performed to screen for PV stenosis during the initial experience with a new AF ablation technique for quality control purposes.

CT and CMR imaging of the PVs are readily available and are the most widely used for initial evaluation for PV stenosis. Although both imaging modalities can identify the location and extent of PV stenosis (see Fig. 32.7), their sensitivity and specificity need further evaluation. Also, the diagnosis of PV occlusion cannot be made reliably using CT or MR imaging, and pulmonary artery wedge angiography is the only method for confirming the diagnosis.

TEE provides adequate visualization of the superior PVs, but imaging of the right and left inferior PVs is inconsistent. Hence TEE is not typically used as a first-line imaging study for routine screening. Nonetheless, TEE provides additional functional data regarding the significance of PV stenosis. On TEE, PV stenosis is usually indicated by an increased maximal PV Doppler flow velocity, or by the presence of turbulence

and deformity of the flow signal, as defined by a minimal flow between systolic and diastolic peak flow of 60% of the mean of both peaks. ICE allows straightforward imaging of all PVs and provides a good view into the first 1 to 3 cm of the vein. Color flow contrast imaging is also useful for identifying the location of the orifice of the most tightly stenotic vessels.

Blood gas assessment and pulmonary function testing do not seem to be useful as screening measures for early PV stenosis. Radiographic findings in PV stenosis are nonspecific. Chest radiography often reveals parenchymal consolidation, pleural effusion, or both. Ventilation/perfusion scanning can characterize the functional significance of the stenosis; in the presence of significant PV stenosis, perfusion abnormalities are usually marked and appear similar to the changes seen in pulmonary embolism.

Prevention

The best strategy to manage PV stenosis is to avoid it. Limiting RF ablation to the extraostial portion of the PV or PV antrum and using electroanatomic mapping and ICE to accurately define the PV orifice and guide the positioning of the ablation catheter are important measures to achieve this goal.

With cryoablation, it is imperative to avoid mismatch between the cryoballoon size and the PV ostial dimensions. In addition, several measures can be undertaken to avoid distal positioning of the cryoballoon within the PV. Further, very low balloon temperatures (below -55°C to -60°C) can potentially indicate a distal balloon position, and should prompt interruption of the freezing cycle.

Management

PV intervention is recommended in symptomatic patients. PV stenting appears to be associated with a lower restenosis rate compared with angioplasty. For asymptomatic patients with severe PV stenosis, some investigators have also suggested interventional therapy, because lesions can progress and eventually lead to total occlusion, precluding dilation and potentially resulting in hemodynamic compromise (see Fig. 32.8). Others have proposed regular clinical follow-up, with intervention considered only when symptoms develop. However, it is important to understand that patients can become symptomatic only after the long-term sequelae of PV occlusion become manifest, at which time intervention may not be technically feasible or, even when successful, may not be associated with significant improvement in perfusion of the affected lung segments. It is also important to consider the age, functional capacity, and associated comorbidities, as well as anatomical and technical factors pertaining to the stenotic vein when deciding about interventional treatment in asymptomatic patients.

TEE or ICE can facilitate accurate stent placement by reliably identifying the orifice of the tightly stenotic vein. Unfortunately, both in-stent and in-segment restenosis can recur in up to 60% of patients, and repeat intervention is warranted in symptomatic patients. Stenosis within the body of the stent is likely caused by neointimal hyperplasia and fibrosis. Out-of-stent restenosis is usually observed at bifurcation points beyond the stent into the vessel, also suggesting the progression of PV pathology, despite stent placement. There is no experience to date with the use of drug-eluting stents in this setting, but such a high restenosis rate makes a strong case for the investigation of those devices and larger diameter stents.

ESOPHAGEAL INJURY

Incidence

The development of esophagus-related collateral damage, such as esophageal injury and periesophageal vagal nerve injury, remains a rare but

important complication of AF ablation procedures, regardless of the energy source.⁴¹

Esophageal mucosal changes consistent with thermal injury have been reported in up to 48% of the patients following AF RF ablation, and clinically silent esophageal ulcerations confirmed by esophagogastroscopy or capsule endoscopy can be observed in 14% to 18%.⁴²

Esophageal perforation can develop with or without fistula formation. Fistulas can develop connecting the esophageal lumen to either the LA or pericardium. In a recent survey, about a quarter of patients with esophageal perforation presented without fistula or with pericardial-esophageal fistula, and the prognosis of these patients was significantly better than that of patients presenting with atrioesophageal fistula.⁴¹

The true incidence of atrioesophageal fistula after RF catheter ablation is unknown, but has been estimated to be between 0.01% and 0.25%, although underreporting is likely. Despite its rarity, atrioesophageal fistula remains a devastating complication associated with high mortality (more than 60%), and accounts for 16% of cases with fatal outcome (the second leading cause of death post AF ablation, following cardiac tamponade).

Cryoballoon ablation commonly causes significant decreases in esophageal temperature, especially during cryoablation of the inferior PVs, resulting in esophageal injury. Esophageal ulcerations have been observed following cryoballoon ablation at rates similar to those seen with RF ablation. In a recent study, esophageal thermal lesions with the second-generation cryoballoon were detected by endoscopy in 20% of patients at a mean of 1.5 days after ablation. Nevertheless, the occurrence of atrioesophageal fistula following cryoballoon ablation of AF is very rare (0.009% to 0.014%), and the risk seems less than that following RF ablation.⁴³

Excessive esophageal heating, esophageal ulcerations, and atrioesophageal fistula formation have been observed post PV isolation using high-intensity focused ultrasound (HIFU). In one report, elevated esophageal temperature prompting cessation of HIFU energy delivery occurred in 9% of PVs. Despite use of the safety algorithm, the occurrence of esophageal thermal damage and lethal atrioesophageal fistula could not be prevented, occurring in 1 of 28 patients. This safety concern led to a halt of the clinical use of HIFU for PV isolation.⁴⁴

Mechanism

The precise mechanism of atrioesophageal fistula formation has not yet been determined. The most likely mechanism involves direct thermal injury of the esophageal wall in immediate proximity to the posterior LA wall. A second proposed mechanism is ablation-related injury to the esophageal vasculature with late esophageal wall ischemia and necrosis. The latter mechanism likely explain the deferred development of atrioesophageal fistula.^{42,45,46}

The esophagus is located at the center of the posterior mediastinum and runs in close proximity to the posterior LA wall for about 5 cm of its course. In that region, the esophagus is separated from the LA only by the pericardial sac (the oblique sinus), which insinuates itself between the openings of the right and left PVs, and in some patients a thin fat pad. The LA posterior wall thickness is approximately 2 to 4 mm, and the thickness of the esophageal wall is 2 to 3 mm in cross section at the LA-esophageal area of contact.

The esophagus does not have a serosal layer, and it is fixed primarily in the pharynx and gastroesophageal junction. In the mediastinum, the esophageal position is dynamic because of peristalsis. In fact, the esophagus often shifts sideways by 2 cm or more in most patients undergoing catheter ablation for AF under conscious sedation. In addition, the position of the esophagus in relation to the LA and PV demonstrates high variability. In many cases, the esophagus is very close to the ostia of the PVs and lies only a short distance from the LA wall.

In most subjects (90%), the esophagus courses down beside the ostia of the left PVs with a mean distance of 10 mm to the left superior PV and 3 mm to the left inferior PV. Therefore anatomical localization of the esophagus can be critical before or during AF ablation to prevent atrioesophageal fistula, especially as there is a need for transmural atrial lesions.

During RF catheter ablation, the risk of esophageal injury likely is enhanced by increasing the magnitude and duration of local tissue heating (i.e., the total ablation energy delivered to cardiac tissue near the esophagus), which is related to catheter tip size, contact pressure, catheter orientation, and power output and duration. In fact, all reported cases of atrioesophageal fistulas have in common attempts to perform deep RF lesions on the LA posterior wall. In addition, ablation strategies incorporating extensive ablation in the LA posterior wall and the type of AF (persistent more than paroxysmal AF, possibly due to the additional linear ablation lesions) have been associated with an increased rate of esophageal ulcerations. A short LA-to-esophagus distance, the use of nasogastric tubes, and general anesthesia are other potential risk factors for esophageal injury during RF ablation.⁴⁷

The potential mechanisms of esophageal injury during cryoablation are similar to those with RF ablation: direct effect of thermal ablation on esophageal tissue or thermal-related injury to esophageal vasculature with subsequent esophageal wall ischemic necrosis. Factors associated with ulcerations include the mean nadir and the cumulative decrease of luminal esophageal temperature. During cryoballoon PV isolation, extracardiac damage can result from deeper positioning of the balloon within the PV, which reduces exposure of the balloon surface area to the convective warming effects by the circulating blood in the atria and, as a result, leads to an increased freezing area and greater ice formation. If the esophagus is in contact with the pericardium at the site of the ice formation, the freezing area will extend into esophageal tissues. A distal position of the cryoballoon within a PV can be indicated by a rapid decline in balloon temperatures to less than -40°C within 30 seconds of ablation or nadir temperatures of -60°C or lower during ablation. To date, all documented cases of cryoballoon-associated atrioesophageal fistulas have been in relation to the left PVs—particularly the left inferior PV. The esophagus appears more vulnerable to injury during cryoballoon ablation of the left inferior PV; the ostium of the left inferior PV has the closest relationship to the esophagus, and inflation of the cryoballoon in this vein, especially when positioned deep into the vein and forward pressure is applied on the balloon for stability, exerts posteriorly directed forces that brings the balloon closer to the esophagus. There is some evidence that gastric acid refluxing into the esophagus is a component of the injury process as well.^{46,48}

Clinical Presentation

Mild esophageal injury, manifesting as mucosal changes or ulceration, is predominantly asymptomatic, but can cause epigastric or retrosternal pain or discomfort and dysphagia.

The leading symptom of esophageal perforation is high fever or severe chest or epigastric pain. Esophago-pericardial fistulas are characterized by chest or epigastric pain resulting from pericardial effusion and pericarditis accompanied by signs of infection (fever and leukocytosis).⁴⁹

Patients with atrioesophageal fistulas can also present with hematemesis, odynophagia, sepsis, and stroke (secondary to air embolization). Furthermore, hematemesis or hemorrhagic shock can occur secondary to bleeding in the esophagus. The clinical course of atrioesophageal fistula formation varies in the mode and timing of presentation, and mostly is manifest after patient discharge from the hospital. In a recent report, the mean interval between the procedure and presentation of 20 ± 12 days (range, 2 to 60 days).^{41,49}

Detection

Leukocytosis is the earliest and most sensitive laboratory marker in patients with atrioesophageal fistulas. Thoracic CT or CMR imaging is the most valuable diagnostic examination (Figs. 32.9 and 32.10). The dramatic neurological complications occur with a delay of at least a few hours after the first symptoms.

The sensitivity of barium swallow studies for detection of a fistula is limited. Endoscopy is a diagnostic modality that should be avoided because insufflation of the esophagus with air can force air from the esophagus into the LA and result in a devastating cerebrovascular accident and death secondary to a large air embolus. The use of CO₂ instead of air for insufflation appears to present a lower risk.

Management

Although the prevalence of atrioesophageal fistula post-AF ablation is low, the fatality rate is high, reported between 67% and 100%, and traditionally it has been attributed to the lack of recognition and late presentation of this complication. The prognosis of patients who survive to obtain an accurate diagnosis and receive corrective surgical intervention is unknown, but the morbidity and mortality associated remain high despite surgical repair.

The window from symptom onset to neurological injury is often short; therefore a high index of suspicion is crucial to establish the diagnosis and implement immediate intervention. Delayed diagnosis (after the onset of neurological symptoms because of air embolism and sepsis) dramatically worsens prognosis, and delayed treatment is unlikely to prevent permanent disability or death. Because fistula tracts develop over the first 2 to 4 weeks after the procedure, when the patient is already home and recovering in other regards, it is important that patients be aware of and report symptoms of dysphagia, fever, stroke-like symptoms, new chest discomfort, or gastrointestinal bleeding. Early diagnosis of atrioesophageal fistula is critical to give the best chance for survival and recovery.

Immediate surgical repair of atrioesophageal fistula (within a few hours after the first symptoms) can potentially prevent neurological complications and possibly improve survival rate. Esophageal stenting can be sufficient in patients with esophageal perforation without fistula formation. Esophageal stenting in conjunction with pericardial drainage has also been described for the treatment of esophageal-pericardial fistulas once esophageal-atrial communication is excluded. However, it is important to recognize that although esophageal stenting can quickly establish a barrier that minimizes air and solid material embolism without the risks of esophageal surgery, this approach can be detrimental when an undiagnosed atrioesophageal fistula is also present. Fatal complications can result from air insufflation during upper gastrointestinal endoscopy or stent dislocation. Therefore an early surgical approach to esophageal perforation should be strongly considered, even when the formation of atrioesophageal fistula has not been established.^{41,49}

Prevention

Various strategies may be used to try to avoid the development of an atrioesophageal fistula. However, because of the rarity of this complication,

Fig. 32.9 Atrioesophageal Fistula Postablation of Atrial Fibrillation. Multiple transverse sections of a chest computed tomography scan, revealing air bubbles (blue arrows) in the superior aspect of the left atrium (A–C) and at the level of the mitral valve (D). Note that air appears to originate from the anterior esophageal wall (B and C). Nasogastric tube is visualized in the esophagus (yellow arrow).

Fig. 32.10 Esophageal-Pericardial Fistula. A 62-year-old patient presented with chest pain 21 days following ablation of atrial fibrillation, and was diagnosed with esophageal-pericardial fistula. (A) Chest x-ray (left lateral projection) obtained in supine position showing air accumulation (arrow) anterior to the cardiac silhouette. (B) Computed tomographic scan showing pneumopericardium (arrowheads). The free air wraps around the anterior right ventricle (RV) extending across the apex of the left ventricle (LV). No air is observed within the cardiac chambers. (C) Gastrografin esophagogram showing focal out-pouching from the esophageal wall (arrow) at the junctions of the middle and distal thirds of the esophagus representing local ulceration or sinus tract. LA, Left atrium; RA, right atrium.

it remains unproven whether the use of these approaches lowers or eliminates the risk of esophageal perforation or fistula formation, and the optimal technique has not yet been determined. Therefore it appears prudent to apply a combination of these preventive techniques during AF ablation.

Avoiding Ablation in the Vicinity of the Esophagus

The most effective measure to prevent atrioesophageal fistula formation is to avoid ablation in the LA posterior wall at sites close to the esophagus. However, effective treatment of AF and PV isolation typically require ablation at those sites, and complete avoidance of the LA posterior wall usually is not feasible. Nonetheless, inclusion of a linear lesion connecting the PV encirclements in the posterior LA wall is no longer advised. If such a connection is thought to be clinically necessary, it should be performed superiorly in the dome of the LA instead of the posterior wall.

Assessment of Esophageal Location

The precise understanding of the real-time esophageal location and anatomical characteristics is critical for the prevention of ablation-induced esophageal injury. Newer imaging techniques have been used to visualize the anatomical relationship between the esophagus and the LA during AF catheter ablation. Esophageal imaging is not part of the usual CT or CMR of the LA and PVs. Visualization of the esophagus can be achieved during the CT angiography using barium sulfate or Gastrografin (with swallowing instructions to help the contrast substance to lodge in the middle and distal esophagus, rather than in the stomach (Fig. 32.11)). Visualization of the esophagus during CMR can be achieved by combining the barium sulfate paste with gadolinium diglutamate. The barium cream helps the gadolinium lodge in the esophagus. However, these approaches have several limitations. The esophagus is a mobile structure, and CT and CMR scans of the esophagus are static and not real-time images, acquired on a previous session; therefore these images

may be an unreliable guide to the position of the esophagus during the ablation procedure. This may be particularly true for procedures performed while the patient is under conscious sedation, when esophageal peristalsis is likely to occur. Furthermore, the image of the esophagus is obtained with a barium sulfate paste, and the real dimensions of the esophagus depend on the volume of contrast media injected. During ablation, the esophagus is empty, and the real dimension and probably the exact location can be misinterpreted.

The use of 3-D mapping systems that allow the integration of pre-acquired 3-D CT scans or CMR of the LA, PVs, and esophagus provides a visualization tool that permits a rapid understanding of complex cardiac anatomical relationships. In addition, 3-D rendering of the esophagus can be generated during the procedure using an electroanatomic mapping system; esophageal location can be marked by advancing a diagnostic EP catheter into the esophagus and tagging its location (see Fig. 32.11). It is important to recognize, however, that the catheter used for tagging can be positioned eccentrically in the esophageal lumen, thus providing potentially misleading information.

Phased-array ICE can provide rapid real-time identification of esophageal location in relation to the posterior LA wall. The location of the esophagus determined by ICE during the ablation procedure was found to correlate well with the location determined by CMR before the procedure. This technique has the advantage of providing real-time information on the location of the esophagus, especially when movement occurs.

Another strategy to limit the risk of esophageal injury is real-time imaging of the anatomical course of the esophagus during the ablation procedure by placement of a radiopaque esophageal monitoring probe or use of a viscous radiopaque contrast paste. Orally administered barium provides a simple, inexpensive, and safe way to keep track of the esophagus accurately during an ablation procedure (see Fig. 32.11). In most patients, barium paste coats the wall of the esophagus, and residual barium often allows visualization of the esophagus for 1 to 2 hours

Fig. 32.11 Assessment of Esophageal Location During Catheter Ablation of Atrial Fibrillation. (A and B) Anteroposterior and posteroanterior (PA) views of a computed tomography (CT) image of the left atrium (LA), pulmonary veins (PVs) and esophagus. The esophagus is visualized during CT scanning by the use of Gastrografin (contrast medium). Note that the real dimensions of the mid-segment are not very clear because of peristaltic movements and inadequate filling of the esophagus. (C) Electroanatomic (CARTO) map of the LA and PVs (PA view) incorporating reconstruction of the esophagus (*arrows*). The esophageal mapping catheter can also be visualized. (D) Electroanatomic (CARTO) map of the LA and PVs (left posterior oblique view). Intracardiac echocardiography is used to visualize the esophagus (*arrows*) and incorporate its location in the electroanatomic map (CARTO-Sound). (E and F) Fluoroscopic (right anterior oblique [RAO] and left anterior oblique [LAO]) views of the esophagus during catheter ablation of atrial fibrillation. Barium paste was given to the patient just before initiation of sedation for real-time visualization of the esophagus (*arrowheads*) during the ablation procedure. The ring (*Lasso*) and ablation (*Abl*) catheters are positioned at the ostium of the left superior PV. CS, Coronary sinus.

after the initial barium swallow. However, to avoid the risk of aspiration, patients should receive little or no sedation before swallowing the barium. The ablation procedure can also be performed with the patient under general anesthesia with orotracheal intubation and esophagography during the procedure. General anesthesia guarantees enough esophageal immobilization because the swallow reflex is abolished. Placement of an orogastric tube to allow esophageal localization is carried out before anticoagulation to avoid any risk of trauma and bleeding. At the end of the procedure, the contrast is totally removed. This technique allows visualization of the esophagus position in real time. However, the use of nasogastric tubes can potentially increase the risk of esophageal injury by pressing the anterior esophageal wall against the LA posterior wall.

Mechanical Displacement of the Esophagus

When ablation cannot be performed in certain LA regions because of proximity of the ablation site to the esophagus, mechanical displacement of the esophagus to the contralateral side from the ablation catheter by an endoscope has been suggested to facilitate safe energy delivery. However, the risk of esophageal perforation by the endoscope should be recognized, and the safety of this strategy needs to be determined before implementation into general clinical practice. Furthermore, apparent displacement of the esophagus with an endoscope can potentially represent mere distortion rather than anatomical displacement. In addition, the presence of the endoscope probe can increase the diameter of the esophagus and increase its contact with the posterior LA wall, rendering it more vulnerable to injury.

Luminal Esophageal Temperature Monitoring

Thermal monitoring of the esophagus during ablation is the most widely applied method for prevention of esophageal injury. Measurement of esophageal temperature involves the placement of a monotherm temperature probe, which is advanced under fluoroscopy guidance to the lower third of the esophagus directly posterior to the LA. This technique requires general anesthesia to allow tolerability of the esophageal probe. Adjustment of the position of the temperature probe during ablation to keep the probe in close vicinity to the ablation catheter tip is crucial to obtain reliable information on the real current esophageal temperature. The use of a multithermocouple temperature probe requires less manipulation since it can monitor a broader area of the esophagus simultaneously.

The role of esophageal temperature monitoring remains controversial. Discrepancies between the temperatures of the external and internal esophagus and thermal latency in heat transfer from the atrium to the esophagus can limit the utility of esophageal temperature monitoring. In addition, if the temperature sensor is not in contact with the esophageal wall, temperature changes may not be accurately detected. Also, because the esophagus is broad, a lateral position of the temperature probe may not align with the ablation electrode. The possibility of heating of the esophageal wall without recording a change in central luminal esophageal temperature can be harmful by providing a false sense of safety. In fact, atrioesophageal fistula formation occurred in the absence of changes in luminal esophageal temperature in the majority of patients in which temperature monitoring was reported. This can be confounded by the possibility that esophageal injury may be precipitated by injury to the esophageal vasculature with consequent remote esophageal necrosis, rather than direct thermal injury, which may not be heralded by monitoring of the luminal esophageal temperature.^{45,47}

Although studies demonstrated the absence of esophageal lesions in patients with a maximal esophageal luminal temperature lower than 41.8°C, the safety zone of temperature rise from baseline has not been

validated. It is also important to note that esophageal temperature can continue to increase for several seconds after discontinuation of RF delivery; thus energy application must be stopped as soon as there is any increase in esophageal temperature.

Despite monitoring of esophageal temperatures, esophageal lesions can occur in 10% to 30% of cases. It is worth noting that esophageal temperature monitoring of some form was performed in the vast majority of published cases of esophageal perforation, suggesting that the use of esophageal monitoring alone is insufficient for prevention of this complication.^{41,49}

Even more alarming, some studies have suggested that luminal esophageal temperature monitoring by itself might contribute to thermal injury of the esophagus during RF ablation. The metal thermistor electrodes of the esophageal temperature probes can potentially interact with the RF current and act as secondary antennas during RF energy delivery, so that inductive heating of stainless steel thermocouples of the esophageal probe itself can result in thermal injury to esophageal tissue.⁴²

Luminal esophageal temperature monitoring has also been utilized during cryoballoon PV isolation. In animal studies, evidence of esophageal injury was seen only below 10°C. Several studies showed that interrupting cryoapplication if the intraesophageal temperature falls to less than 12°C to 15°C was associated with the lowest incidence of esophageal injury, given that the esophageal temperature probe is positioned as close as possible to the inflated cryoballoon. In addition, rapid decline in luminal temperature when the esophagus is located in immediate proximity to the left inferior PV probably should prompt the termination of cryoenergy delivery. However, it is important to know that thermal esophageal injury, including atrioesophageal fistula formation, has been observed despite luminal esophageal temperatures higher than 20°C. Therefore a clear cutoff for a luminal esophageal temperature beyond which thermal damage can be prevented remains uncertain. Furthermore, some reports found that the use of esophageal temperature probes was associated with increased the risk of subclinical esophageal lesions on routine endoscopy following cryoballoon ablation.^{43,48,50}

Limiting Ablation Energy

Modifying RF application parameters at sites close to the esophagus is the most widely used strategy to avoid atrioesophageal fistula formation. Limiting the power and duration of RF applications, particularly in the posterior LA, even if a significant reduction in bipolar electrogram amplitude is not recorded, can be the most important safety consideration for avoidance of fistula formation. Although no data exist on which to make specific recommendations, there is widespread agreement that prolonged RF applications in the posterior LA are to be avoided, and that low power settings should be used. When standard RF energy is to be applied close to the esophagus, the RF power is typically reduced to 20 to 30 W and 55°C for no more than 20 seconds. When using open-irrigated RF ablation, lower energy outputs (15 W compared with 25 W) were found to be associated with a decreased rate of esophageal ulcerations. Also, direct perpendicular orientation of the ablating electrode and forward pressure against the posterior LA wall are better avoided, particularly if an 8-mm or irrigated electrode is used. It is preferable to maintain frequent movements of the ablation catheter when RF energy is applied at the posterior LA wall in the vicinity of the esophagus. The impact of using contact force-sensing ablation catheters is not known, but it is worth noting that the number of reported atrioesophageal fistula cases has increased since the introduction of contact force technology. The optimal contact force setting and energy output in the posterior wall of the LA to help maximize safety while enhancing long-term efficacy of AF ablation procedures is yet to be determined.⁴⁷

The value of limiting the duration of RF application without energy output reduction for prevention of ulcerations remains to be evaluated. Although many investigators recommend using lower power settings for longer periods of time (25 W for 20 to 30 seconds), some investigators suggest that short RF applications (for 2 to 5 seconds) at a higher power (50 W, irrigation rate 30 mL/min, maximum temperature 43°C) result in momentarily higher LA tissue temperatures and allow the tip to be set at a high power to injure the superficial tissue while minimizing time-dependent deep heating through excessive heat transfer. The latter approach can compromise lesion efficacy because the time-dependent variable of “total heat transferred” is decreased. Typically the ablation catheter is dragged continuously in small increments every 2 to 5 seconds during continuous RF delivery, and ablation is repeated at each site, if required, for many times throughout the procedure until the local atrial electrogram is completely eliminated. It is probably reasonable to allow at least 2-minute time intervals before returning to ablate a previously ablated site to allow for heat dissipation and complete cooling of potential esophageal heating.

Of note, using light conscious sedation during the procedure can allow the use of pain as an indicator for potential esophageal injury; RF application should be interrupted promptly and the catheter moved to a different site on the development of significant or sharp pain during energy delivery.

During cryoballoon ablation, it is recommended to terminate cryoapplication if excessive freezing is observed, as indicated by rapid descent to less than -40°C within 30 seconds of freezing or nadir temperatures less than -55°C during ablation. Limiting the maximal cryoapplication time to 180 seconds may also help reduce the risk of esophageal injury.

Prophylactic Proton Pump Inhibitors

The value of routine prophylactic administration of proton pump inhibitors after AF ablation to reduce the risk of fistula formation is unknown. However, this therapy is commonly offered to patients in whom esophageal lesions are detected by endoscopy or capsule endoscopy following the procedure.

RADIATION EXPOSURE

Ionizing radiation (such as x-ray) is radiation that has enough energy to remove electrons from atoms or molecules when it passes through matter. The loss of an electron causes the atom (or molecule) to become positively charged (ionized). In contrast, the energy of microwave, infrared, and ultraviolet radiation is not enough to remove electrons and, thus, those types radiation are considered nonionizing.

Biological Effects of Ionizing Radiation

The biological effects of ionizing radiation can be described in terms of *deterministic* (tissue damage) and *stochastic* effects (genetic changes and resultant carcinogenesis).

The *stochastic* effects are effects for which the probability of occurring is proportional to the dose of radiation exposure but there is no identifiable threshold for producing the effect, and its severity is independent of the dose (i.e., nonthreshold function of the dose; eFig. 32.4). Radiation-related malignancy is a stochastic risk, and can occur even with minimum dose of radiation, but likelihood of occurring increases with increasing radiation dose. The stochastic mechanism represents an unpredictable, unrepaired radiation damage to the DNA of a limited, potentially single, number of viable cells.

The *deterministic* effect is a dose-dependent direct biological effect of radiation, typically associated with a threshold dose above which tissue damage occurs and the severity increases with increasing dose (see eFig. 32.4). Below the threshold radiation exposure, the probability

of causing harm is zero. The deterministic effect occurs when a significant, predictable number of existing cells are sufficiently damaged to cause a directly observable injury. Radiation-induced skin injury (threshold, 2 to 3 Gy) is a deterministic effect.^{51,52}

Nomenclature of Radiation Quantities and Units

Modern radiographic imaging systems provide several measurements of the amount of radiation exposure during procedures. The radiation dose is related to the damage inflicted on the body and is usually described in terms of the following parameters: the absorbed dose, the equivalent dose, the effective dose, or the collective dose.

Fluoroscopy Time

Fluoroscopy time (in minutes) is the time during a procedure that fluoroscopy is used, but does not include cine acquisition imaging. In addition, patient body habitus has a dramatic effect on actual dose (see below) despite similar values of simple fluoroscopy time. Therefore fluoroscopy time alone is not a useful descriptor of patient radiation dose.

Air Kerma

Air kerma represents the “kinetic energy released per unit mass” when an x-ray beam is traveling through air at a specific point, and it is how the intensity (strength) of the x-ray beam is characterized. Air kerma is expressed in grays (Gy). The total air kerma is the procedural cumulative air kerma, and is used to monitor patient dose burden as it is associated with threshold-dependent deterministic skin effects. Air kerma does not address the extent (area) of the x-ray beam.

The “kerma area product” (KAP), also known as the “dose area product” (DAP), is reported in $\text{Gy}\cdot\text{cm}^2$, as the average air kerma (in Gy) multiplied by the corresponding x-ray beam cross-sectional area (in cm^2). The KAP can be used to estimate organ doses, effective doses, and the total energy deposited in the patient and is therefore directly related to the total patient stochastic risk. Converting KAP into accurate patient dose estimates requires explicit information on the x-ray beam quality, the size and age of the exposed patient, and data on the body region exposed and exposure geometry (projections and field sizes).

Peak Skin Dose

Peak skin dose (in Gy) is the maximum radiation dose received by any local patient skin area. Both the probability and severity of skin effects increases as peak skin dose increases. Peak skin dose is highly dependent upon instantaneous dose rate, and the duration that the x-ray is directed at a specific body area. There is no currently available method to measure peak skin dose, but it can be estimated (by a physicist) when the air kerma and x-ray geometry details are known.

Absorbed Dose

The absorbed dose is the radiation energy absorbed per unit mass of an organ or tissue. The absorbed dose describes the intensity of the energy deposited in any small amount of tissue located anywhere in the body, and is used to assess the potential for damage to a particular organ or tissue. The unit is joule per kilogram (J/kg), which is assigned the special name “Gray” (Gy), thus replacing the units of “rad” (short for “radiation absorbed dose”). One hundred rad equals 1 joule/kilogram (J/kg), which also equals 1 Gy.

The absorbed dose is a measure of the actual energy deposited in the irradiated tissue and can be used to compare against deterministic effects, but it is not satisfactory for comparing the stochastic radiological risk. To estimate the stochastic risk, the type of radiation and the sensitivity of the irradiated tissues must be considered. The dose quantities *equivalent dose* and *effective dose* were devised to calculate the biological effect of an absorbed dose.

eFig. 32.4 Risk of Deterministic and Stochastic Effects of Ionizing Radiation.

Equivalent Dose

The equivalent dose addresses the impact that the type of radiation has on that tissue, and is defined as the absorbed radiation dose in an organ or tissue corrected by a radiation weighting factor. The equivalent dose takes into account the different probability of effects that occur when the same amount of absorbed dose is delivered by different types of radiation (alpha particles, electrons, and photons). This correction factor is numerically 1 for x-rays, and the unit is J/kg and is given the special name “Sievert” (Sv), which replaced the units of “rem” (short for “roentgen equivalent in man”; 1 Sv = 100 rem).

The equivalent dose is used to assess how much biological damage is expected from the absorbed dose of certain type of radiation. Because all radiation used in diagnostic medicine has the same low-harm potential, the equivalent dose in Sv is numerically equal to the absorbed dose in Gy.

Effective Dose

The effective dose takes three factors into account: (1) the absorbed dose to all organs or tissues of the body; (2) the relative harm level of the radiation; and (3) the radiosensitivity of each organ or tissue. As different organs or tissues exhibit different sensitivities to radiation, the equivalent dose is multiplied by the appropriate tissue weighting factors (i.e., the sensitivity factors assigned to specified tissues and organs). The tissue weighting factors summate to 1.0, so that if an entire body is radiated with uniformly penetrating external radiation, the effective dose for the entire body is equal to the equivalent dose for the entire body. When only part of the body is irradiated, then only those regions are used to calculate the effective dose. The sum of effective doses to all organs and tissues of the body represents the effective dose for the whole body.

The *effective dose* is used to assess patient stochastic risk (i.e., the long-term risk of radiation-induced cancer and genetic effects). The effective dose is not intended as a measure of *deterministic* health effects, which is measured by the quantity *absorbed dose*. Further, the effective dose is not intended to apply to a specific patient; rather, it relates to the overall long-term risk to a person from a procedure and is useful for comparing risks from different procedures. This unit is widely used to estimate the ionizing radiation exposure to patients and staff during procedures. The unit is the joule per kilogram (J/kg) and is given the special name sievert (Sv).⁵³

Exposure to Ionizing Radiation During Electrophysiology Procedures

Ionizing radiation exposure related to natural sources is relatively minimal, whereas nowadays, medicine-related exposure is considered a major exposure source. Fluoroscopic guidance remains the standard tool for catheter visualization in interventional cardiac and EP procedures, and cardiologists are among the leading users of medical radiation. In fact, interventional cardiology accounts for almost 40% of the entire cumulative radiation dose to the US population from all medical sources, excluding radiotherapy. Moreover, data suggest that the occupational radiation exposure to interventional cardiologists and cardiac electrophysiologists is the greatest registered by any medical staff exposed to x-rays.⁵¹

Radiation exposures during the different cardiac interventional procedures are highly variable. In general, the average radiation exposure to patients is estimated at 2.5 mSv for diagnostic cardiac catheterization, 6.4 mSv for percutaneous coronary interventions, 3.2 mSv for diagnostic EP study, and 4.4 mSv for SVT ablation. Catheter ablation of complex cardiac arrhythmias, including AF, macroreentrant ATs, and reentrant VTs, can be associated with markedly prolonged fluoroscopy durations and radiation exposure (Table 32.2). In addition, the same patient often

TABLE 32.2 Exposure to Ionizing Radiation During Electrophysiology Procedures

Type of Electrophysiology Procedure	Exposure to Patient in mSv: Median (Range)
Diagnostic electrophysiology study	3.2 (1.3–23.9)
Supraventricular tachycardia (AVNRT, AVRT, AT) ablation procedure	4.4 (1.6–25)
Atrial fibrillation ablation	16.6 (6.6–59.6)
Ventricular tachycardia ablation	12.5 (3 to >45)
CIED pacemaker or ICD implant	4 (1.4–17)
CRT-CIED implant	7 (2.0–16)

AT, Atrial tachycardia; AVNRT, atrioventricular nodal reentrant tachycardia; AVRT, atrioventricular reentrant tachycardia; CIED, cardiac implantable electronic device; CRT, cardiac resynchronization therapy; ICD, implantable cardioverter defibrillator.

Radiation safety and ergonomics in the electrophysiology laboratory: update on recent advances. *Curr Opin Cardiol*. 2016;31:11–22.

requires different or repeated procedures, increasing the radiation exposure and risk. The use of CT scanning before and after AF ablation procedures further increases patient exposure to radiation. Typical effective dose estimates are 7.0 mSv for a standard chest CT, 16 mSv for cardiac CT, and 0.1 mSv for a chest x-ray.

Compared with patients, operators and laboratory staff get exposed to much smaller amounts of radiation during each procedure, but are exposed repeatedly, resulting in potentially substantial lifetime occupational radiation doses. In fact, the occupational radiation exposure to interventional cardiologists is estimated at 5 mSv (which is equivalent to 250 chest x-rays), which is two to three times higher than that of diagnostic radiologists. Operator exposure is expressed as equivalent dose for organ-specific exposure and effective dose for whole-body exposure. The effective dose represents the sum of equivalent doses from different tissues, adjusted to the radiation sensitivity of each tissue.^{51,54}

Clinical Presentation

Exposure to ionizing radiation can adversely impact both the patient and the medical personnel and expose them to an increased risk of radiation-related injuries. Even low doses appear to be potentially harmful, particularly in women, children, and young adults.

Radiation-Induced Skin Injury

In EP procedures, the patient tissue receiving the greatest radiation dose is the skin area of the back at the entrance point of the x-ray beam, and skin injuries are well-recognized complications for catheter ablation procedures.

The response of the skin to radiation is dose related. The thresholds for dose or time of appearance of radiation-induced skin changes are variable, depending on the individual patient's radiosensitivity. Several conditions can increase radiation sensitivity, including autoimmune and connective tissue disorders, obesity, hyperthyroidism, diabetes, ataxia telangiectasia, and a number of drugs (e.g., doxorubicin, 5-fluorouracil, and methotrexate).⁵³

For most patients, the lowest dose that may produce a noticeable skin changes is 2 Gy, which can manifest transient skin erythema and epilation, which usually occurs within hours of exposure and fades after 24 hours. When the absorbed skin dose exceeds 6 Gy, a second

Fig. 32.12 Acute Radiation-Induced Skin Injury (Erythema) 2 to 3 Weeks Following Radiofrequency Ablation of Atrial Fibrillation Using Biplane Fluoroscopy. The affected areas have well-defined borders congruent with the entrance of the x-ray beam.

hyperemic phase (main erythema) can develop after several days and fade away over a period of weeks. This usually manifests as erythematous and edematous skin, with burning, tenderness, and itching (Fig. 32.12). At higher doses, progressively more severe dose-dependent skin damage can manifest as hyperpigmentation, dry desquamation, skin blisters, and ischemic dermal necrosis. Chronic radiation injury manifests months to years after exposure and presents clinically as permanent erythema, dermal atrophy, and ulceration. Of note, skin cancer directly related to radiation from an interventional procedure has not been reported.

The diagnosis of radiation-induced skin injury is often delayed. Acute radiation-induced skin injury (characterized by erythema with vesiculation, erosion, and pain) can be misdiagnosed as contact dermatitis, viral or bacterial infection, or insect bite, and the history of fluoroscopy often is overlooked or considered irrelevant. Therefore a high index of suspicion is required. Characteristically, fluoroscopy-induced skin injuries affect an area congruent to the entrance of the x-ray beam that typically has well-defined borders (see Fig. 32.12), which occur when the beam is not moved or resized during prolonged fluoroscopy over one site. It is important to alert patients who have undergone prolonged procedures, or are known to have received a high skin radiation dose, to examine themselves about 2 to 3 weeks after the procedure to look for skin changes, contacting the physician if any are observed.

Skin biopsy usually is not necessary and not recommended, especially given the potential risk of a nonhealing ulcer at the site of biopsy in the radiation-damaged skin area. Furthermore, the findings on skin biopsy generally are not specific for radiation injury.

Radiation-Induced Cataract

The lens is a highly radiosensitive tissue, and an association between cataracts and radiation exposure has been well established and has been demonstrated among staff involved in interventional procedures using x-rays.

Ionizing radiation typically causes posterior subcapsular cataract formation. This type of cataract is uncommon but can also develop secondary to diabetes or systemic corticosteroids. Age-related cataracts, in contrast, are cortical or nuclear. Cataracts cause impairment of visual acuity, sensitivity to glare, and slow light-dark adaptation.

Radiation-induced cataractogenesis has traditionally been considered a deterministic tissue reaction and thus requires a threshold radiation dose (0.5 Gy) and damage to multiple cells. However, recent evidence suggests that cataracts may form stochastically, without a threshold dose.^{55,56}

Radiation-Induced Cardiovascular Disease

Cardiovascular radiation effects include focal myocardial degeneration and fibrosis and accelerated arterial atherosclerosis, which can lead to ischemic heart disease and cardiomyopathy. Although uncertainty remains, cardiovascular radiation effects have been reported to occur at doses greater than 0.5 Gy.⁵⁵

Radiation-Induced Carcinogenesis

The absolute risk of fatal cancer increases by 0.05% for every 10 mSv of exposure over and above the background fatal cancer risk of 20%. An effective dose of 15 mSv is associated with an excess cancer risk of 1 per 750 men older than 50 years, with half the cancers being fatal. The risk of stochastic effects is not a great concern for older patients because of the latency period (10 years or more) for the development of most cancers. The risk, however, is fourfold higher in children, who have longer life expectancies.⁵⁷

Ionizing radiation is one of the few established causes of brain tumors. Increased risk of skin cancer, breast cancer, and leukemias had been linked to high occupational doses before 1950, when knowledge of the effects of radiation exposure was still developing and before modern radiation safety practices were common.^{55,58}

Prevention

Reduction of Radiation Exposure

Radiation safety is the responsibility of all health care professionals working in an x-ray producing environment. Understanding adverse effects of radiation exposure and formal education and training on radiation safety and management are essential for minimizing the adverse impact of radiation exposure on patients as well as medical personnel. A policy to reduce exposure to ionizing radiation to a level that is “as low as reasonably achievable” (ALARA) for medical necessity has recently been adopted by occupational health groups. No amount of radiation can be considered safe; thus there should not be any exposure to ionizing radiation without the expectation of an overall benefit from the activity causing the exposure.^{51,58,59}

An important step to reduce fluoroscopy exposure is to optimize setting of the fluoroscopy system, such as x-ray beam collimation, frame rate, protocol setting, and system angulation, detector sensitivity and distance, and signal filtering. In addition, optimizing permanent and temporary shielding, correct use of personal protective equipment, optimal positioning of both the patient and the operator, and operator behavior modification during the procedure are essential for reducing exposure to ionizing radiation. Several strategies have been recommended to optimize patient radiation dose and to minimize occupational injury to staff in the EP laboratory (Boxes 32.1 and 32.2).^{54,57}

Recent technologies, such as low-exposure radiographic imaging, improved radiographic imaging protection systems, nonfluoroscopic navigation and mapping systems, contact force-sensing catheters, and remote navigation systems have allowed for a marked reduction in ionizing radiation exposure in the EP laboratory. With the assistance of novel technologies, strategies to perform EP procedures zero or near-zero fluoroscopy are being increasingly adopted.^{51,60–62}

Radiation Dosimetry

Personal dosimetry for all staff employed is required for radiation surveillance in an area utilizing ionizing radiation, including the EP

BOX 32.1 Practical Advice to Reduce Patient Radiation Exposure

- Use a low-dose-rate fluoroscopy mode when possible.
- Use a low-pulse-rate fluoroscopy mode when possible.
- Remove the grid when performing procedures on small children.
- Use the lowest-dose mode for image (cine) acquisition that is compatible with the required image quality.
- Minimize fluoroscopy time: use fluoroscopy only to guide devices and observe motion.
- Use the last-image-hold image for review when possible, instead of using fluoroscopy.
- When possible, store a fluoroscopy loop instead of performing a cine run.
- If available, use a stored fluoroscopy loop for review instead of using fluoroscopy.
- Minimize the number of cine series.
- Minimize the number of frames per cine series.
- Never use cine as a substitute for fluoroscopy.
- Collimate the radiation beam to the area of interest.
- Use virtual collimation if it is available.
- Use wedge filters when they are appropriate.
- Keep the image detector (image intensifier or flat detector) as close as possible to the patient.
- Keep the patient as far as possible from the x-ray tube.
- Try to avoid steeply angulated projections (especially left anterior oblique cranial).
- Try to vary the C-arm angulation slightly to avoid concentrating the radiation dose at a single site on the patient's skin.
- Use magnification only when necessary.
- Remember that for large patients, and also for steeply angulated projections, the dose to the patient increases substantially.
- Pay attention to the patient radiation dose display in the procedure room.
- If the patient has had previous similar procedures, try to obtain information about the previous radiation doses to optimize subsequent procedures.

laboratory. The International Commission on Radiological Protection (ICRP) recommendations suggest two personal dosimeters: one worn under the personal protective lead garment at the level of the waist and the second worn at the thyroid collar outside the protective garment that provides information regarding radiation exposure to the brain and eye.⁵⁴

Periodic audits and feedback to operators, along with review of EP laboratory radiation protection equipment, are mandated. The World Health Organization recommends investigation of high occupational dose whenever the effective operator dose exceeds 0.5 mSv/month, the lens equivalent dose exceeds 5 mSv/month, or the extremity equivalent dose exceeds 15 mSv/month. ICRP has established a 100 mSv 5-year limit of whole-body effective dose and a 50 mSv limit in any single year. Dose equivalents should not exceed 20 mSv per year for the lens (averaged over 5 consecutive years) and 500 mSv per year for skin, hands, and feet.⁵⁴

A clear dose limit for exposure has not been applied to patients undergoing procedures. In general, the radiation dose for an individual patient should not be a reason to terminate a procedure. However, high values of patient doses (DAP >500 Gy·cm², total air kerma >5 Gy, or fluoroscopy time >60 minutes) should prompt surveillance for skin injuries. Appropriate actions should be taken to inform the patient and provide him with follow-up instructions to notify the operator or a

BOX 32.2 Practical Advice to Reduce Staff Radiation Exposure

- Increase your distance from the patient (the source of scatter radiation) whenever possible. This is obviously only possible when angiographic runs are not performed by hand. Scatter radiation levels decrease drastically with increased distance from the irradiated volume of the patient.
- Try to position yourself in a low scatter area. Scattered radiation is higher at the x-ray-tube side of the gantry and lower on the side of the image receptor.
- Use a ceiling-suspended shield, a table-suspended screen, and other protective shielding (e.g., a lead apron, thyroid collar, and leaded glasses with side shields) whenever possible.
- The ceiling-suspended shield should be placed as close to the patient as possible.
- If biplane systems are used, proper use of lateral shields is very important for eye protection.
- When appropriate, use a dose reduction pad or drape at the catheter entrance site to reduce your hand dose.
- Minimize the use of fluoroscopy and use low-dose fluoroscopy modes (e.g., low-dose-rate pulsed fluoroscopy) when possible.
- Minimize the number of cine series and the number of frames in each cine series.
- Use magnification as little as possible.
- Collimate the x-ray beam as tightly as possible.
- Avoid direct exposure of the hands to primary radiation.
- Obtain appropriate training in radiation management and radiation protection.
- Wear your dosimeters and know your own dose.
- In addition, a final general concept: reduce the patient's radiation dose and you will also reduce your own dose.

From Cousins C, Miller DL, Bernardi G, et al. ICRP publication 120: radiological protection in cardiology. *Ann ICRP*. 2013;42:1–125.

medical physicist if deterministic effects to the irradiated skin area are noted during self-examination.⁵⁴

Video 32.1 Pericardiocentesis: Guided by Fluoroscopy. Sequence of events in a patient who developed a large pericardial effusion during ablation of atrial fibrillation. Fluoroscopy at baseline (left anterior oblique [LAO] projection) demonstrates normal cardiac silhouette motion in the absence of pericardial effusion. Normal excursion of the lateral cardiac border is also visualized immediately after atrial septal puncture. Decreased excursion of the lateral cardiac border becomes evident later in the procedure secondary to development of a large pericardial effusion. Pericardiocentesis is performed under fluoroscopy guidance. The pericardial needle is advanced in the subxiphoid region toward the inferior cardiac border in the LAO fluoroscopic projection. Injection of contrast through the needle confirms the location of the tip in the pericardial space, as evident with layering of the contrast within the pericardial effusion. A pigtail catheter is inserted in the pericardial space. Contrast injection via this catheter demonstrates the size of the pericardial effusion. Note that cardiac border movement is now evident within the standstill silhouette of the pericardial effusion.

Video 32.3 Intrapericardial Thrombus: Fluoroscopy and Echocardiography. Pericardiocentesis via the subxiphoid approach is performed in a patient with cardiac perforation during catheter ablation, resulting in large pericardial effusion and cardiac tamponade. Contrast pericardiography is performed via the pericardial drain, demonstrating a large pericardial effusion and a large thrombus. Transthoracic echocardiography revealed a large intrapericardial thrombus overlying the left ventricle (LV).

Video 32.2 Pericardiocentesis: Guided by Echocardiography. Transthoracic echocardiography is utilized to guide pericardiocentesis in a patient who developed a large pericardial effusion (PE) during ablation of atrial fibrillation. A moderately large PE is visualized on the four-chamber apical and long-axis echocardiographic view. The pericardiocentesis needle (not visualized) is advanced from the precordial region under the guidance of transthoracic echocardiography. Access to the pericardial space is confirmed by injection of agitated saline through the needle, which is visualized on echocardiography as a dense shower of bubbles. After pericardiocentesis, only a trivial pericardial effusion is observed.

INDEX

A

Aberrancy, supraventricular tachycardia with, 779
versus in bundle branch reentrant ventricular tachycardia, 903

Aberration, 286. *see also* Bundle branch block
 acceleration-dependent, 290*f*
 persistence of, 292–293, 292*f*
 alternation during atrial bigeminy, 293, 288.e1*f*
 due to Ashman phenomenon, 287–289, 288*f*
 due to concealed conduction, 292–293
 due to concealed transseptal conduction, 291–293
 due to heart rate acceleration, 289
 due to premature excitation, 287, 287*f*
 phase 3, 286
 phase 4, 289
 premature ventricular complexes, 289.e1*f*
 in supraventricular tachycardia, persistence of, 291, 292*f*
 during tachyarrhythmias, perpetuation of, 291, 292*f*
 tachycardia-dependent, 289*f*

Ablation
 of atrial flutter, 359–372
 anticoagulation for, 359–361
 catheter positioning for, 361–362, 362*f*
 complications of, 371
 cryoablation, 364
 difficult cavotricuspid isthmus in, 363–364
 endpoints for, 364–365
 maximum voltage-guided technique, 363
 outcome of, 371–372
 radiofrequency, 360*f*, 362
 role of electroanatomic mapping systems, 363
 target of, 359, 361*f*
 technique for, 359–364
 of atrial tachycardia macroreentrant, 397–404
 of anterior mitral isthmus, 402, 405*f*
 atrial fibrillation after, 399
 endpoints for, 400
 left atrial macroreentry, 399
 of mitral isthmus, 399.e1*f*
 of mitral isthmus block, 402–404, 403*f*–404*f*, 402.e1*f*
 outcome of, 404
 overdrive suppression, 388
 perimitral left atrial macroreentry, 399
 perimitral macroreentrant, 401–404, 399.e1*f*
 of posterior mitral isthmus, 401–402
 right atrial macroreentry and, 398–399
 target of, 397–399
 technique of, 399–400
 termination of, 388
 transformation to different loop/tachycardia in, 388
 of atrioventricular nodal reentrant tachycardia, 591–597
 anatomical approach in, 591–593, 592*f*
 atrioventricular block after, 596

Ablation(Continued)

electroanatomic approach in, 591, 593, 593*f*, 593.e1*f*
 endpoints of, 595
 junctional rhythm after, 594–595, 594*f*–595*f*
 palpitations, 596
 radiofrequency energy delivery in, 593–594
 slow pathway, 596–597
 target of, 591
 technique of, 591–595
 of bypass tract, 660–674
 anterosseptal (superoparaseptal), 667–670
 electrophysiological criteria of, 663*b*
 endpoints of, 662–663
 epicardial, 672–673
 failed, causes of, 673–674, 673.e1*f*, 674.e1*f*
 left free-wall, 663–666
 midseptal, 667–670
 outcome of, 674
 posteroseptal (inferoparaseptal), 670–672
 right free-wall, 666–667
 target of, 660–661
 technique for, 661–662, 664*f*
 catheter. *see also* Catheter ablation
 of focal atrial tachycardia, 333
 of focal atypical tachycardia, 310–311
 for idiopathic focal ventricular tachycardia, 827
 of congenital heart disease, 973–974, 973*f*
 energy sources for, 206–237
 of focal atrial tachycardia, 333–337
 endpoints for, 335–337
 outcome of, 337
 of para-Hisian atrial tachycardias, 333–335, 335*f*
 target of, 333
 technique of, 333, 334*f*
 in idiopathic focal ventricular tachycardia, 843–854

- QRS complex in, 395
- right atrial, 381–382
 - in absence of previous surgery, 378
 - incisional, 378, 381–382
 - intra-isthmus reentry, 382
 - isthmus-dependent, 377–378, 377f
 - noncavotricuspid isthmus-dependent, 378
 - upper loop reentry, 378

Atrial tachycardia (AT) (*Continued*)

- tachycardia
 - atrial extrastimulation, 383
 - atrial pacing during, 384–388
 - diagnostic maneuvers during, 383–388
 - documentation of line of block, 400
 - features of, 382–383, 383f–384f
 - induction of, 382, 383b
 - noninducibility of, 400
 - termination, 400
 - upper loop reentry, 378, 382
- macroreentrant, classification of, 306t
- microreentrant, 321–322
- multifocal, 308–309, 308f
- P wave morphology in, 348
- paroxysmal, 309
- pulmonary vein, 308
- triggered-activity, 322

Atrial-His bundle

- interval, 109
- interval jump, 572, 572.e1f
- intervals during normal sinus rhythm, 572–573

Atrial-His bundle (AH) interval, in paroxysmal

- supraventricular tachycardia
- atrial overdrive pacing in, 714
- atrial pacing at tachycardia cycle length, 722–723

Atrial-ventricular relationship

- in antidromic atrioventricular reentrant tachycardia, 640
- in atrioventricular nodal reentrant tachycardia, 578–579
- in orthodromic atrioventricular reentrant tachycardia, 637–638, 638f
- in paroxysmal supraventricular tachycardia, 703, 710–711
- in permanent junctional reciprocating tachycardia, 640

Atriosophageal fistula, after atrial fibrillation

- ablation, 523

Atriofascicular bypass tracts, 677–688, 680f

- ablation in, 687f, 688
- endpoints of, 688
- outcome of, 688
- target of, 688
- technique in, 688
- arrhythmias associated with, 678
- comparison of atrioventricular pathway to, 682f
- differential diagnosis of, 684, 684f, 685b–686b
- electrocardiographic features of, 678–679
- electrophysiologic testing in, 679–684
 - baseline observations during sinus rhythm, 679
 - diagnostic maneuvers during tachycardia, 683–684
 - features of tachycardia, 682–683
 - induction of tachycardia, 679–681
- long decrementally conducting, 677–678
- mapping in, 684–688
 - of atrial insertion site, 685–686
 - of bypass tract potential, 686
 - of sites of mechanically induced loss of preexcitation, 686–688
 - of ventricular insertion sites, 686

Atrio-Hisian bypass tracts, 599, 692–695

- electrophysiologic testing for, 695
- programmed atrial stimulation, 695
- programmed ventricular stimulation, 695
- response to pharmacologic maneuvers, 695

- Atrio-Hisian bypass tracts (*Continued*)
 general considerations in, 692–695, 694f, 694t
 supraventricular tachycardias in, 695
 with enhanced atrioventricular node conduction, 695
- Atrionodal bypass tracts, 599
- Atrionodal cells, 257
- Atrionodal region, 561
- Atrioventricular block
 after ablation, of atrioventricular nodal reentrant tachycardia, 596
 in ablation, 337
 acquired, 258–261
 in athletes, 260
 atrial fibrillation with slow ventricular rate and, 276–277, 277f
 atrial tachyarrhythmias and, 276
 atrioventricular dissociation and, 275–276, 276f
 bundle branch block and, 299.e1f
 causes of, 261
 concealed junctional ectopy and, 274–275, 275.e1f
 congenital, 257–258, 263
 diagnosed in utero, 264
 permanent pacing for, 279, 279b
 defined, 257
 echo beats and, 276
 first-degree
 permanent pacing for, 277–278
 site of, 273
 hereditary cardiac conduction disease and, 258
 high-grade, 270, 270f
 iatrogenic, 260–261
 permanent pacing for, 278–279
 in iatrogenic cardiac arrhythmias, 1049, 1050f
 nonconducted premature atrial complexes and, 274, 274f–275f
 pacemaker device and mode selection for, 280–281, 281b
 paroxysmal, 261–262
 differential diagnosis of, 262t
 idiopathic, 262, 263f
 intrinsic, 261–262, 261f
 vagally mediated, 261
 permanent pacing for, 279, 280f
 in paroxysmal supraventricular tachycardia, 711, 711f
 pathophysiology of, 257–262
 pseudoblock, 113, 113f
 second-degree, 265–270
 Mobitz type 1 (Wenckebach), 113, 265–267
 atypical, 113
 site of block in, 267
 in ventricular pacing, 117
 Mobitz type 2, 267–268, 268f, 267.e1f
 permanent pacing for, 277
 sinus node dysfunction, 242
 site of, localization of, 272–274
 third-degree, 270, 271f
 permanent pacing for, 277
 ventriculophasic sinus arrhythmia and, 277
- Atrioventricular bypass tracts (AV BTs), 599–677.
